The known methods of constructing block designs are of two main types, direct and recursive. Recursive methods are a way of constructing designs from smaller ones. Direct methods yield easier constructions, but are applicable only for special values of the parameters. A direct method of constructing a BIBD designates the treatments and blocks, respectively, as the points and subspaces of the \dagger projective space and the \dagger affine space over a \dagger finite field. To explain another method of constructing a BIBD, we let G be an \dagger additive group of order n and $x_1^{(i)}, \dots, x_m^{(i)}$ be m treatments corresponding to each element $x^{(i)}$ of the group ($i=1, 2, \dots, n$). The treatment $x_\alpha^{(i)}$ is said to belong to the α th class ($\alpha=1, 2, \dots, m$), and a pair $(x_\alpha^{(i)}, x_\beta^{(j)})$ of treatments is called a **difference** of type $(\alpha, \beta, x^{(p)})$ if $x^{(i)} - x^{(j)} = x^{(p)} (\neq 0)$. We can form t blocks of size k

$$B_1 = \{x_{\alpha_1}^{(i_1)}, \dots, x_{\alpha_k}^{(i_k)}\}, \quad \dots, \\ B_t = \{x_{\beta_1}^{(j_1)}, \dots, x_{\beta_k}^{(j_k)}\},$$

such that each block B_i contains exactly r treatments belonging to the α th class ($\alpha=1, \dots, m$) and among all pairs of treatments in the same block there are λ differences of each type $(\alpha, \beta, x^{(p)})$. Such a set of t blocks is called a **difference set**. The t blocks in a difference set are called **initial blocks**. Given such a difference set, we can obtain nt blocks by joining elements of G to the elements of each B_s ($s=1, 2, \dots, t$). These nt blocks form a BIBD($v=mn, b=nt, r, k=rm/t, \lambda$) ($\rightarrow 66$ Combinatorics).

As a generalization of Fisher's inequality, for an unequal-replicated block design with unequal block sizes, $b \geq v - \delta$ holds, where δ is

the multiplicity of the maximum eigenvalue 1 of the matrix $D_r^{-1/2} C D_r^{-1/2}$. The equality sign holds if and only if the projection operator corresponding to zero eigenvalue of $D_r^{-1/2} C D_r^{-1/2}$ is a zero matrix.

F. Estimation in a Mixed Model

Consider a block design (4), where every block has the same size k and every treatment has the same number r of replications. Let ξ be a fixed effect and η a random effect denoted by \mathbf{H} , and assume that \mathbf{W} satisfies conditions (a) and (b) of Section A and that \mathbf{H} satisfies conditions (d), (e), and (f) (where the \mathcal{E}_j are replaced by the coordinates H_j of \mathbf{H}). If $E(H_j) = \gamma$, $j=1, \dots, b$, then, changing the notation $\mathbf{H} - E_{v1}\gamma$ to \mathbf{H} , we can rewrite (4) as

$$\mathbf{Y} = \Gamma\gamma + \Phi\xi + \Psi\mathbf{H} + \mathbf{W}, \quad (8)$$

with $E(\mathbf{H}) = \mathbf{0}$. The normal equation that gives the least square estimate of ξ is

$$(C + \sigma^2(\sigma^2 + k\sigma_1^2)^{-1}C_1)\hat{\xi} \\ = \mathbf{Q} + \sigma^2(\sigma^2 + k\sigma_1^2)^{-1}\mathbf{Q}_1, \quad (9)$$

where C and \mathbf{Q} are the same as in (6) and $C_1 = ND_k^{-1}N' - rv^{-1}E_{vv}$, $\mathbf{Q}_1 = (ND_k^{-1}\Psi' - v^{-1}E_{v1}\Gamma')\mathbf{Y}$. Equation (9) cannot be solved unless the ratio $\sigma^2:\sigma_1^2$ is given. When $\sigma^2:\sigma_1^2$ is not known, substituting in $\sigma^2 + k\sigma_1^2$ its \dagger unbiased estimate given by analysis of variance, one obtains a solution of (9) which tends to a \dagger consistent estimate of ξ as the number of blocks tends to infinity.

G. Estimation in a Random-Effects Model

Let ξ (denoted by Ξ) and \mathbf{H} in the model (8) be random effects. Suppose that Ξ , \mathbf{H} , and \mathbf{W} are mutually independent, and that the distributions of Ξ , \mathbf{H} , and \mathbf{W} are $N(\mathbf{0}, \sigma_\xi^2 I_v)$, $N(\mathbf{0}, \sigma_1^2 I_b)$, and $N(\mathbf{0}, \sigma^2 I_n)$, respectively. The distribution of \mathbf{Y} in (8) contains four parameters $\gamma, \sigma^2, \sigma_1^2, \sigma_\xi^2$. When $k_j < v$, the \dagger minimal sufficient statistic is generally incomplete, and therefore the optimal estimate of $\gamma, \sigma^2, \sigma_1^2$, and σ_ξ^2 cannot be determined. As an example, the minimal sufficient statistic for the random-effects model of a BIBD(v, b, r, k, λ) is

$$(\sum_i Y_i, \mathbf{Y}' P_{21} \mathbf{Y}, \mathbf{Y}' P_{22} \mathbf{Y}, \mathbf{Y}' P_3 \mathbf{Y}, \mathbf{Y}' P_4 \mathbf{Y}, \mathbf{Y}' P_5 \mathbf{Y}),$$

where

$$P_{21} = k^{-1}(r-\lambda)^{-1}BTB - kr(r-\lambda)^{-1}n^{-1}E_{nn},$$

$$P_{22} = k((k-1)r + \lambda)^{-1}r^{-1}$$

$$\times (T - k^{-1}BT)(T - k^{-1}TB),$$

$$P_3 = k^{-1}B - k^{-1}(r-\lambda)^{-1}BTB$$

$$+ v\lambda(r-\lambda)^{-1}n^{-1}E_{nn},$$

$$P_4 = I_n - k^{-1}B - P_{22}, \quad P_5 = r^{-1}T - n^{-1}E_{nn},$$

with $T = \Phi\Phi'$ and $B = \Psi\Psi'$. In this case, $E(Y'P_4Y) = (n - v - b + 1)\sigma^2$, $E(Y'P_3Y) = (b - v)(\sigma^2 + k\sigma_1^2)$. From these equations unbiased estimates of σ^2 and σ_1^2 can be derived, but their optimality is not guaranteed (\rightarrow 396 Statistic).

H. Factorial Experiments

Suppose that there are h factors F_1, \dots, F_h which affect Y , and each factor F_i has s_i levels ($i = 1, \dots, h$). It is assumed that $v = s_1 \times s_2 \times \dots \times s_h$ treatment combinations are derived by all the combinations of the levels of h factors, and that v treatment effects are represented by the sum of subeffects called **main effects** and **interactions**, or **factorial effects** covering both. Such an experiment is called a **factorial experiment** or **factorial design**; it allows us to examine the effects of two or more factors, each factor being applied at two or more levels, by testing all possible treatment combinations formed from the factors under study. Specifically, suppose that we have the case $h = 2$, called a **two-way layout**. Let main effects be denoted by $\xi^1 = (\xi_1^1, \dots, \xi_{s_1}^1)$, $\xi^2 = (\xi_1^2, \dots, \xi_{s_2}^2)$, and interaction by $\xi^{12} = (\xi_{11}^{12}, \xi_{12}^{12}, \dots, \xi_{s_1 s_2}^{12})$, where $\sum_i \xi_i^1 = 0$, $\sum_j \xi_j^2 = 0$, $\sum_i \xi_i^{12} = \sum_j \xi_j^{12} = 0$. When there is no restriction on the number of observations, each of $v = s_1 \times s_2$ treatment combinations is replicated t times. Components Y_{ijk} of the observation vector Y are represented by a linear model

$$Y_{ijk} = \gamma + \xi_i^1 + \xi_j^2 + \xi_{ij}^{12} + W_{ijk},$$
$$i = 1, \dots, s_1; \quad j = 1, \dots, s_2; \quad k = 1, \dots, t,$$

or, in vector notation,

$$Y = \Gamma\gamma + X_1\xi^1 + X_2\xi^2 + X_{12}\xi^{12} + W.$$

The analysis of variance in this case is given by

$$Y'Y = \sum_i Y'P_iY,$$

where P_i is the projection operator matrix on the subspace derived by a direct sum decomposition

$$R^n = L(\Gamma) + L_\Gamma^\perp(X_1) + L_\Gamma^\perp(X_2) + L_{X_1, X_2}^\perp(X_{12}) + L_{X_{12}}^\perp,$$

where $n = s_1 s_2 t$. Denoting by $\bar{Y}_{ij\cdot}$ the arithmetic mean of Y_{ijk} over the subscript k and using similar notation $\bar{Y}_{i\cdot\cdot}$, $\bar{Y}_{\cdot j\cdot}$, and $\bar{Y}_{\cdot\cdot\cdot}$, we have $Y'P_1Y = n\bar{Y}_{\cdot\cdot\cdot}^2$, $Y'P_2Y = s_2 t \sum (\bar{Y}_{i\cdot\cdot} - \bar{Y}_{\cdot\cdot\cdot})^2$, $Y'P_3Y = s_1 t \sum (\bar{Y}_{\cdot j\cdot} - \bar{Y}_{\cdot\cdot\cdot})^2$, $Y'P_4Y = t \sum (\bar{Y}_{ij\cdot} + \bar{Y}_{\cdot\cdot\cdot} - \bar{Y}_{i\cdot\cdot} - \bar{Y}_{\cdot j\cdot})^2$, $Y'P_5Y = \sum (Y_{ijk} - Y_{ij\cdot})^2$. The analysis of variance table is given in Table 1. For $h \geq 3$ similar models can also be considered for dealing with interactions up to h -factor. The factorial experiment is said to be **symmetric** if $s_1 = s_2 = \dots = s_h = s$ and is called the s^h **factorial experiment**. Otherwise it is

Table 1 Analysis of Variance

Source	Sum of Squares	Degrees of Freedom
F_1 main effects	$Y'P_2Y$	$s_1 - 1$
F_2 main effects	$Y'P_3Y$	$s_2 - 1$
$F_1 F_2$ interactions	$Y'P_4Y$	$(s_1 - 1)(s_2 - 1)$
Error	$Y'P_5Y$	$s_1 s_2 (t - 1)$

said to be **asymmetric** and is called the $s_1 \times s_2 \times \dots \times s_h$ **factorial experiment**.

I. Fractional Factorial Designs

Factorial designs require at least an experiment for all the combinations of levels of factors under consideration. When there are a large number of treatment combinations resulting from a large number of factors to be tested, it will often be beyond the resources of the investigator to experiment with all of them. For such cases Finney (*Ann. Eugen.*, 12 (1945)) proposed a method in which only a fraction of the treatment combinations are experimented with. A design of this type is called a **fractional factorial design**. One reason for the usefulness of fractional factorial designs in preference to factorial designs is that they involve a smaller number of treatment combinations, since, in most scientific experiments, it is usually found that a large number of the higher-order interactions are negligible. The crucial part of the specification of fractional factorial designs is the suitable choice of the defining or identity relationship. Equating the nonestimable factorial effects for the selected fraction of treatment combinations with I gives the **identity relation**. Each factorial effect is not estimable after selecting a fraction of treatment combinations, and any contrast of the selected treatment combinations represents more than one factorial effect. All factorial effects represented by the same treatment combinations are called **aliases**. In aliases, by assuming that other interactions are negligible when compared to the one of interest, estimation can be made by means of the corresponding contrast of the selected treatment combinations. When all factorial effects of order higher than l are assumed to be zero, a fractional factorial design is said to be of **resolution $2l + 1$** if it satisfies the condition that under the usual model all factorial effects up to order l are estimable, whereas a fractional factorial design is said to be of **resolution $2l$** if it satisfies the condition that under the usual model all factorial effects up to order $l - 1$ are estimable.

In the beginning, the theory was developed

for an **orthogonal fractional factorial design** in which the estimates of various effects of interest are all uncorrelated. However, these are available only for special values of the number n of treatment combinations and are in general uneconomical in the sense that they require a large value of n in comparison with the number of unknown effects. As a generalization of orthogonal fractional factorial designs, I. M. Chakravarti (*Sankhyā*, 17 (1956)) introduced the concept of **balanced fractional factorial designs**. In these designs, the estimates of effects are not always uncorrelated. However, the \dagger covariance matrix of the estimates is invariant under any permutation of factors. Balanced fractional factorial designs are flexible in the number of treatment combinations, with the result that more experimental situations can be handled. These two kinds of fractional factorial designs can be constructed by using orthogonal arrays and balanced arrays, defined in Section L. All alias relations can be derived from the identity relation in orthogonal designs.

In the model (1) for a design, the variance of the estimates of estimable linear functions of ξ depends on the matrix $X'X$ which is called the **information matrix**. For eigenvalues of $X'X$, the D -, E -, and A -optimalities of fractional factorial designs can be defined similarly to (I), (II), and (III) given in Section E. An orthogonal fractional 2^h factorial design is D -, E - and A -optimal. A fractional factorial design is said to be **saturated** if the number of treatment combinations is equal to that of parameters in the model to be estimated. However, since saturated designs do not provide an estimate of experimental error, their use should, in general, be confined to those situations in which a prior estimate of experimental error is available. The existence of a symmetric BIBD($4t-1, 4t-1, 2t-1, 2t-1, t-1$) implies that of an orthogonal saturated fractional 2^{4t-1} factorial design of resolution III.

J. Application of Algebras

In the theory of design of experiments, the ideas of association algebra and relationship algebra play an important role. Let A_i be a $v \times v$ symmetric matrix with entries 0 or 1 ($i = 0, 1, \dots, m$). If a set $\{A_i | i = 0, 1, \dots, m\}$ satisfies the conditions

$$A_0 = I_v, \quad \sum_{i=0}^m A_i = E_{vv},$$

and there is a nonnegative integer p_{jk}^i for every i, j, k such that

$$A_j A_k = \sum_{i=0}^m p_{jk}^i A_i,$$

then the A_i are called **association matrices**. In this case, there exists a natural number n_i for every i such that $A_i E_{vv} = n_i E_{vv}$ holds. If an (α, β) component $a_{\alpha\beta}^i$ of A_i is unity, then the treatments α and β are said to be the i th associates. The \dagger algebra \mathcal{A} over the real number field generated by the matrices A_0, A_1, \dots, A_m is called the **association algebra**. \mathcal{A} is commutative and \dagger completely reducible. $A_k \rightarrow \mathcal{P}_k = (p_{jk}^i)$ is the \dagger regular representation of \mathcal{A} . There is a nonsingular matrix $U = (u_{ij})$ that transforms all \mathcal{P}_i into diagonal matrices simultaneously:

$$U \mathcal{P}_i U^{-1} = \text{diag}(z_{0i}, \dots, z_{mi}), \quad i = 0, 1, \dots, m.$$

$$A_i^\# = \left(\sum_{f=0}^m u_{if} z_{if} \right)^{-1} \sum_{j=0}^m u_{ij} A_j, \quad i = 0, 1, \dots, m,$$

are mutually orthogonal idempotent elements of \mathcal{A} . For example, consider the case where $A_0 = I_{s_1} \otimes I_{s_2}$, $A_1 = (E_{s_1 s_1} - I_{s_1}) \otimes I_{s_2}$, $A_2 = I_{s_1} \otimes (E_{s_2 s_2} - I_{s_2})$, $A_3 = (E_{s_1 s_1} - I_{s_1}) \otimes (E_{s_2 s_2} - I_{s_2})$ with $m = 3$, where \otimes means the \dagger Kronecker product. The algebra \mathcal{A} generated by A_0, A_1, A_2, A_3 is called an F_2 type association algebra. The association matrices A_0, A_1, A_2 , and A_3 correspond to the relationships between the treatments in a two-way layout. The mutually orthogonal idempotent elements in this case are $A_0^\# = s_1^{-1} E_{s_1 s_1} \otimes s_2^{-1} E_{s_2 s_2}$, $A_1^\# = (I_{s_1} - s_1^{-1} E_{s_1 s_1}) \otimes s_2^{-1} E_{s_2 s_2}$, $A_2^\# = s_1^{-1} E_{s_1 s_1} \otimes (I_{s_2} - s_2^{-1} E_{s_2 s_2})$, and $A_3^\# = (I_{s_1} - s_1^{-1} E_{s_1 s_1}) \otimes (I_{s_2} - s_2^{-1} E_{s_2 s_2})$. For the factorial experiment with h factors ($h \geq 3$), association matrices can be constructed in a similar way. If $h = 3$, the number m of association matrices is 7. Many types of association schemes are known, and some of them for $m = 2$ are classified as group divisible, triangular, Latin square, cyclic type, and so on. For a group divisible type of $v = s_1 s_2$, $A_0 = I_v$, $A_1 = I_{s_1} \otimes E_{s_2 s_2} - A_0$, $A_2 = E_{vv} - A_0 - A_1$; $A_0^\# = v^{-1} E_{vv}$, $A_1^\# = v^{-1} \{(s_1 - 1)(A_0 + A_1) - A_2\}$, $A_2^\# = s_2^{-1} \{(s_2 - 1)A_0 - A_1\}$.

An experimental design consists of a set of n experimental units called plots. Define a relationship R between the plots as a set of ordered pairs (i, j) of plots. A relationship R among a set of n plots can be expressed as a symmetric $n \times n$ matrix (r_{ij}) of 0's and 1's:

$$r_{ij} = \begin{cases} 1 & \text{if the } i\text{th plot is related to the } j\text{th} \\ & \text{plot by the relationship } R, \\ 0 & \text{otherwise,} \end{cases}$$

and this matrix is also denoted by R . If there are k types of relationships R_1, \dots, R_k among n plots, the algebra \mathcal{R} over the real number field generated by the matrices R_1, \dots, R_k is called the **relationship algebra** of the design. \mathcal{R} is a \dagger semisimple algebra.

Example (1). The relationship algebra \mathcal{R} of the factorial experiment with $h = 2$ and t replications is generated by the following matrices

over the real number field: $B_1 = A_0 \otimes I_t$, $B_2 = A_0 \otimes (E_{tt} - I_t)$, $B_3 = A_1 \otimes E_{tt}$, $B_4 = A_2 \otimes E_{tt}$, $B_5 = A_3 \otimes E_{tt}$, where A_i , $i = 0, 1, 2, 3$, are the association matrices of F_2 type. The mutually orthogonal idempotents that correspond to the two-sided ideal decomposition of \mathcal{R} are $B_1^\# = A_0^\# \otimes t^{-1}E_{tt}$, $B_2^\# = A_1^\# \otimes t^{-1}E_{tt}$, $B_3^\# = A_2^\# \otimes t^{-1}E_{tt}$, $B_4^\# = A_3^\# \otimes t^{-1}E_{tt}$, and $B_5^\# = A_0 \otimes (I_t - t^{-1}E_{tt})$. These are the same as the projection P_i in the two-way layout design given in Section H.

Example (2). Consider a block design with v treatments, each having the same number r of replications, and with b blocks, each having the same size k ($< v$). Suppose that association matrices A_i , $i = 0, 1, \dots, m$, are given, by which the associations among the treatments are defined. Let $\lambda_{\alpha\beta}^i$ be the number of blocks to which the i th associate treatments α and β are applied. The design is called the **partially balanced incomplete block design (PBIBD)** if $\lambda_{\alpha\beta}^i = \lambda_i \geq 0$ independently of α and β . When $m = 1$, the design is a BIBD. Let the observation vector be represented by (4). The relationship algebra \mathcal{R} of a PBIBD is generated by $n \times n$ matrices I_n , E_{nn} , $B = \Psi\Psi'$, $T_i = \Phi A_i \Phi'$, $i = 1, 2, \dots, m$, where $NN' = \sum_{i=0}^m \lambda_i A_i = \sum_{i=0}^m \rho_i A_i^\#$, $\rho_i = \sum_{j=0}^m \lambda_j z_{ij}$ ($0 \leq \rho_i \leq rk$; $i = 0, 1, \dots, m$), and $\rho_0 = rk = \sum_{i=0}^m n_i \lambda_i$. Write $T_i^\# = \Phi A_i^\# \Phi'$. According as $\rho_i = rk$, $0 < \rho_i < rk$, or $\rho_i = 0$, $L(T_i^\#)$ is said to be **confounded** with the blocks, **partially confounded** with the blocks, or **orthogonal** to the blocks. \mathcal{R} is noncommutative, completely reducible, and isomorphic to the algebra of matrices of the type shown in Fig. 1.

Fig. 1

The analysis of variance of a PBIBD is given by a decomposition of I_n into mutually orthogonal idempotent elements of \mathcal{R} . For a PBIBD, the matrix C in (6) is of the form $C = \sum_i \tau_i A_i^\#$, where $\tau_i = r - k^{-1} \rho_i$. For a connected PBIBD, all $A_i^\# \xi$, $i = 1, 2, \dots, m$, are estimable. If there exists a group divisible PBIBD ($m = 2$) with $\lambda_2 = \lambda_1 + 1$, then it is E - and A -optimal.

K. Design for Two-Way Elimination of Heterogeneity

Consider a design with v treatments in a $u \times w$ rectangular block. The row effect and the column effect of this block are denoted by η and ν , respectively. Thus the observation vector \mathbf{Y} is of the form

$$\mathbf{Y} = \Gamma\gamma + \Phi\xi + \Psi\eta + \Pi\nu + \mathbf{W}, \quad (10)$$

where the definitions of Γ , Φ , Ψ and Π are similar to those for block designs. Set $L = \Phi'\Pi$, $M = \Phi'\Psi$, $D_r = \Phi'\Phi$, $F = D_r - w^{-1}LL' - u^{-1}MM' + (uw)^{-1}LE_{uu}L'$. The matrix F plays a role similar to that of the matrix C in (6). When the rank of F equals $v - 1$, the design is said to be **connected**. If

$$F = \tau(I_v - v^{-1}E_{vv}), \quad (11)$$

then the design satisfies the optimum criteria (I), (II), and (III) given in Section E. When $u = w = v$ and (11) holds, the design is called the **Latin square**. When $u = v$ and (11) holds, the design is called the **Youden square**. When $u > v$ and (11) holds, the design is called the **Shrikhande square**. In a **Youden square design** treatments are grouped into replications in two different ways, i.e., rows and columns, where rows constitute a BIBD, whereas columns are complete blocks. The existence of a Youden square design is equivalent to that of a symmetric BIBD.

If the associations among v treatments are defined in terms of association matrices, the partially balanced design for **two-way elimination of heterogeneity** can be defined in a way similar to the PBIBD. In this case, the equation $F = \sum_i \tau_i A_i^\#$ holds, and if $\mathcal{A} = \{I_v, E_{vv} - I_v\}$, then (11) holds, hence the optimum criteria are fulfilled. The definition of the relationship algebra \mathcal{R} of a partially balanced design for two-way elimination of heterogeneity is similar to that used for the PBIBD. \mathcal{R} is isomorphic to the algebra of matrices shown in Fig. 2.

Fig. 2

The analysis of variance of this design is given by a decomposition of I_n into mutually orthogonal idempotent elements of \mathcal{R} .

L. Balanced Array and Orthogonal Array

Suppose that T is an $n \times h$ matrix with entries from a set A of s (≥ 2) distinct elements. Consider the $s^t \times t$ matrices $X = (x_1, x_2, \dots, x_t)$ that can be formed by giving different values to the x_i ($\in A$), $i = 1, 2, \dots, t$. Suppose that associated with each $1 \times t$ matrix X there is a non-negative integer $\lambda(x_1, x_2, \dots, x_t)$ which is invariant under any permutation of a given set $\{x_1, x_2, \dots, x_t\}$. If, for every t -columned submatrix of T , the $s^t \times t$ matrices X occur as

rows $\lambda(x_1, x_2, \dots, x_t)$ times, then the matrix T is called the **balanced array (BA)** of size n , h constraints, s levels, and strength t having the index set $\{\lambda(x_1, \dots, x_t)\}$. Such an array is denoted by $BA(n, h, s, t)$; n is also called the **number of treatment combinations**. In particular, when $\lambda(x_1, \dots, x_t) = \lambda$ for every x_1, \dots, x_t , such an array is called an **orthogonal array (OA)** of size n , h constraints, s levels, strength t , and index λ , which is denoted by $OA(n, h, s, t)$. We have $n = \lambda s^t$. Balanced arrays have the advantage that they can be constructed with fewer treatment combinations than the orthogonal arrays for given h, s, t parameters. The transpose of the incidence matrix of a BIBD(v, b, r, k, λ) is, for $A = \{0, 1\}$, a BA($b, v, 2, 2$) with $\lambda(0, 0) = b - 2r + \lambda$, $\lambda(1, 0) = \lambda(0, 1) = r - \lambda$, and $\lambda(1, 1) = \lambda$. There is a close relation between the existence of an OA and that of a BIBD. For example, the existence of an $OA(s^2, h, s, 2)$ is equivalent to that of $h - 2$ mutually orthogonal Latin squares of order s that is for $h = s + 1$ equivalent to the existence of a BIBD($s^2, s(s + 1), s + 1, s, 1$). The existence of an $OA(4t, 4t - 1, 2, 2)$ is equivalent to that of a symmetric BIBD($4t - 1, 4t - 1, 2t - 1, 2t - 1, t - 1$) which is also equivalent to the existence of an $OA(8t, 4t, 2, 3)$.

Balanced arrays and orthogonal arrays play a vital role in the construction of symmetric and asymmetric confounded factorial experiments and fractional factorial designs. In an $OA(n, h, s, t)$, regarding columns and entries as h factors and levels of a factor of the column, respectively, each row corresponds to a treatment combination. In this case, this orthogonal array gives an orthogonal fractional s^t factorial design of resolution $t + 1$ with n treatment combinations. A necessary and sufficient condition for a fractional s^h factorial design of resolution $2l + 1$ to be orthogonal (resp. balanced) is that the design be an orthogonal (resp. balanced) array of strength $2l$, provided that the information matrix of the design is nonsingular.

M. Response Surface

If all the factors represent quantitative variables, such as time, temperature, amount of ingredients, etc., it is natural to think of the yield or response Y of the experimental results as a continuous function of the levels of these factors. We can write a functional relationship

$$Y_\alpha = f(x_{1\alpha}, x_{2\alpha}, \dots, x_{h\alpha}) + W_\alpha, \quad \alpha = 1, 2, \dots, n,$$

where Y_α represents the α th observation in the designed experiment and $x_{i\alpha}$ represents the level of the i th factor in the α th observation. The function f or the surface defined in $(h + 1)$ -

dimensional Euclidean space by f is called the **response surface**. The residual W_α measures the experimental error of the α th observation. A knowledge of the function f gives a complete summary of experimental results and also enables us to predict the response for values of the $x_{i\alpha}$ that were not tested in the experiment, or to determine such combinations of the values of variables $x_{i\alpha}$ that give the maximum (or minimum) value of f . When the mathematical form of f is not known, the function can sometimes be approximated satisfactorily within the experimental region, which is relatively small, by flexible graduating functions, such as polynomials of degrees 1 and 2 in the variables $x_{i\alpha}$:

$$Y_\alpha = \beta_0 + \sum_{i=1}^h \beta_i x_{i\alpha} + W_\alpha,$$

$$Y_\alpha = \beta_0 + \sum_{i=1}^h \beta_i x_{i\alpha} + \sum_{i=1}^h \beta_{ii} x_{i\alpha}^2 + \sum_{i < j} \beta_{ij} x_{i\alpha} x_{j\alpha} + W_\alpha.$$

The coefficients β_0, β_1, \dots are parameters to be estimated from the data. Thus, (i) when the form of the true f is assumed known, the object is to estimate the parameters; (ii) when the form of the true f is unknown, the object is to approximate the f by some graduating function. Designs appropriate for (i) and (ii) are called **designs for estimating parameters** and **designs for exploring a response surface**, respectively. Some experimental designs that have been developed for fitting polynomials of the first and second degrees are called **first-order designs** and **second-order designs**, respectively. The problem here is to increase the precision of fitting response surfaces by appropriately choosing n points in a given experimental region S of variable x . That is, how do we find the experimental region that interests us in the sense of finding optimum conditions and, having found it, how do we design experiments to map f over the region? As optimum criteria of allocations, corresponding to (I) and (II) given in Section E, consider the following: (IV) the generalized variance of the estimates of coefficients is minimal; (V) the supremum of the variance of estimates of the expectation $E(Y)$ of response Y is minimal for all variables $x \in S$. For example, when an observation Y is given by a polynomial regression of a variable x as $Y_\alpha = \beta_0 + \beta_1 x_\alpha + \beta_2 x_\alpha^2 + \dots + \beta_h x_\alpha^h + W_\alpha$, if for the Legendre polynomial $P_h(x)$ we allocate an experiment replicated at $x = \pm 1$ and $h - 1$ roots of $P_h(x) = 0$ the same number of times, then it is an optimum design in the sense of (IV) and (V).

As a design for fitting first-order response planes, we can use a 2^h factorial design (or its fraction) of resolution III, since it is sufficient to consider only linear effects for each of h

factors. In comparing first-order designs, we take as an optimum criterion the minimum of the average variance of the estimates of the coefficients, corresponding to (III) of Section E. For a design for fitting second-order response surfaces, we need at least three levels of each factor for estimating all effects up to quadratic ones; then we can use a 3^h factorial design (or its fraction) of resolution V for estimating the linear \times linear component of interactions of two factors. In this case, treatment combinations are too large in number, so we can adopt **central composite designs**, which are constructed by adding further treatment combinations to those obtained from a 2^h factorial design (or its fraction). If the coded levels of each factor are -1 and $+1$ in the 2^h factorial design, the $(2h+1)$ additional combinations are $(0, 0, \dots, 0)$, $(\pm d, 0, \dots, 0)$, $(0, \pm d, 0, \dots, 0)$, \dots , $(0, \dots, 0, \pm d)$. The total number of treatment combinations to be tested is $2^h + 2h + 1$ ($< 3^h$ for $h \geq 3$). The value of d can be chosen to make the coefficients in the quadratic polynomials as orthogonal as possible to each other or to minimize the bias that is created if the true form of the response surface is not quadratic or to give the design with the property of being rotatable. If \hat{Y}_0 is the estimated response at $(x_{10}, x_{20}, \dots, x_{h0}) \in S$, the response surface design is said to be **rotatable** if and only if the variance of \hat{Y}_0 is a function only of the distance $\rho = (x_{10}^2 + x_{20}^2 + \dots + x_{h0}^2)^{1/2}$ of $(x_{10}, x_{20}, \dots, x_{h0})$ from the origin, so that the variance contours in the experimental region of the variables are circles, spheres, or hyperspheres centered at the origin. Now, when $Y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{11} x_1^2 + \beta_{22} x_2^2 + 2\beta_{12} x_1 x_2 + W$ with $|x_i| \leq 1$ for $i = 1, 2$, an optimum experiment in the sense of (V) is given by allocating 0.0960 at the origin, 0.0802 at experimental points $(1, 0)$, $(-1, 0)$, $(0, 1)$, $(0, -1)$, and 0.1458 at experimental points $(1, 1)$, $(1, -1)$, $(-1, 1)$, $(-1, -1)$, respectively. However, this design is not rotatable. Instead of an optimum criterion (V), we can consider a region \tilde{S} which is not always equal to the original experimental region S and a criterion: (V') The supremum of the variance of estimates of the expectation $E(Y)$ of response Y is minimal for all variables $x \in \tilde{S}$. Within $x_1^2 + x_2^2 \leq c^2$, an optimum allocation depends on the value of c , and it is shown that a rotatable design is obtained only if c is in a certain range.

There are many topics in the theory of experimental design besides the ones mentioned in this article (\rightarrow [4] for multiple comparison, [9] for confounding designs that are factorial experiments in which the block size is reduced and in which for each block a fractional of all the treatment combinations are tested, [10] for split-plot designs in which certain main effects

are confounded with blocks, [15] for weighing designs).

103 (III.3) Determinants

A. Definition

The **determinant** of an $n \times n$ matrix $A = (a_{ik})$ in a \dagger commutative ring R is defined to be the following element of R :

$$\sum (\text{sgn } P) a_{1p_1} a_{2p_2} \dots a_{np_n},$$

where

$$P = \begin{pmatrix} 1 & 2 & \dots & n \\ p_1 & p_2 & \dots & p_n \end{pmatrix}$$

is a permutation of the numbers $1, 2, \dots, n$,

$\text{sgn } P$ denotes the **sign** of the permutation P (that is, $\text{sgn } P = 1$ if P is an even permutation and $\text{sgn } P = -1$ if P is an odd permutation), and the summation extends over all $n!$ permutations of $1, 2, \dots, n$. The determinant of A is denoted by

$$\begin{vmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{vmatrix}.$$

It is written $|a_{ik}|$ or $|A|$ and is also denoted by $\det A$. Usually we suppose that R is the field \mathbf{R} of real numbers or the field \mathbf{C} of complex numbers, but the following theorems are also valid for cases in which R is any commutative ring, unless otherwise stated.

B. Relation to Exterior Algebras

Consider an r -exterior algebra (r -Grassmann algebra) of a linear space (r -free module) of dimension n over R with a basis (e_1, e_2, \dots, e_n) . Set

$$e'_i = a_{i1}e_1 + a_{i2}e_2 + \cdots + a_{in}e_n,$$

where $a_{ij} \in R$. Then we have $e'_1 \wedge e'_2 \wedge \cdots \wedge e'_n = |a_{ik}| e_1 \wedge e_2 \wedge \cdots \wedge e_n$. Conversely, we can define the determinant $|a_{ik}|$ by this relation. The properties of determinants can be easily deduced from those of exterior algebras.

C. Fundamental Properties of Determinants

(1) The determinant of the r -transposed matrix tA of a matrix A is equal to the determinant of A . Hence the theorems stated for rows are also valid for columns.

(2) If the elements of one row (column) of a matrix are multiplied by a factor c , the determinant of the matrix is also multiplied by c . If the elements of one row (column) of a matrix are zero, its determinant is equal to zero.

(3) If from a matrix $A = (a_{ik})$, we obtain two matrices A' and A'' by replacing one row, for instance the i th row, by a'_{i1}, \dots, a'_{in} and by $a_{i1} + a'_{i1}, \dots, a_{in} + a'_{in}$, respectively, then $|A''| = |A| + |A'|$. This relation is equally valid for a column.

(4) If we obtain A_Q by a permutation Q on the rows of a matrix A , then $|A_Q| = (\text{sgn } Q)|A|$. In particular, if two rows (columns) of a matrix are interchanged, then the determinant changes sign.

(5) The determinant of a matrix is zero if two rows (or columns) are identical.

(6) The determinant of a matrix is not changed if the elements of any row (column), each multiplied by the same factor, are added

to the corresponding elements of another row (column).

(7) Suppose that R has unity element. Let x_{ik} ($i, k = 1, \dots, n$) be n^2 variables in R , and denote a function (having its values in R) of these variables by $\varphi(X)$, $X = (x_{ik})$. Assume that $\varphi(X)$ has the following properties: (i) if the elements of one row of X are multiplied by a factor λ , the value of φ is also multiplied by λ ; (ii) if we obtain two matrices X' and X'' by replacing one row of X , for instance the i th row, by x'_{i1}, \dots, x'_{in} and by $x_{i1} + x'_{i1}, \dots, x_{in} + x'_{in}$, respectively, then $\varphi(X'') = \varphi(X) + \varphi(X')$; and (iii) if two rows of X are equal, $\varphi(X) = 0$. Then $\varphi(X) = c|X|$ for some constant c (in R).

(8) Suppose now that R is a field K . Assume that a function $\varphi(X)$ (in K) has the following properties: (i) if the elements of one row in X are multiplied by λ , the value of φ is also multiplied by λ ; and (ii) the value of φ is not changed if the elements of any row are added to the corresponding elements of another row. Then $\varphi(X) = c|X|$ for some constant c (in K).

D. The Laplace Expansion Theorem

Let $A = (a_{ik})$ be an $n \times n$ matrix. Take r -tuples (i_1, \dots, i_r) and (k_1, \dots, k_r) , where i_a and k_b belong to $\{1, \dots, n\}$ and $i_1 < \dots < i_r$, $k_1 < \dots < k_r$. Let (i_{r+1}, \dots, i_n) and (k_{r+1}, \dots, k_n) be $(n-r)$ -tuples such that $i_{r+1} < \dots < i_n$, $k_{r+1} < \dots < k_n$ and $\{i_1, \dots, i_r, i_{r+1}, \dots, i_n\} = \{k_1, \dots, k_r, k_{r+1}, \dots, k_n\} = \{1, \dots, n\}$. Let $a_{(i_1, \dots, i_r)(k_1, \dots, k_r)}$ be the determinant of an $r \times r$ matrix whose (p, q) -component is the (i_p, k_q) -component of A for each p and q . We call this determinant a **minor** of degree r of the matrix A . (The corresponding submatrix of A is sometimes also called a minor of A .) In particular, if $(i_1, \dots, i_r) = (k_1, \dots, k_r)$, then it is called a **principal minor**. Furthermore, we define the **cofactor** of the minor $a_{(i_1, \dots, i_r)(k_1, \dots, k_r)}$ of A to be

$$\tilde{a}_{(i_1, \dots, i_r)(k_1, \dots, k_r)} = (-1)^{\lambda + \mu} a_{(i_{r+1}, \dots, i_n)(k_{r+1}, \dots, k_n)},$$

where $\lambda = i_1 + \dots + i_r$ and $\mu = k_1 + \dots + k_r$. In the particular case $r = 1$, the cofactor of a_{ik} is $\tilde{a}_{ik} = (-1)^{i+k} \Delta_{ik}$, where Δ_{ik} is the determinant of the $(n-1) \times (n-1)$ matrix obtained from A by eliminating its i th row and k th column. For simplicity, we abbreviate (i_1, \dots, i_r) , (k_1, \dots, k_r) , and (j_1, \dots, j_r) as (i) , (k) , and (j) , respectively. Then we have

$$\sum_{(j)} a_{(i)(j)} \tilde{a}_{(k)(j)} = \begin{cases} |A| & \text{if } (i) = (k), \\ 0 & \text{if } (i) \neq (k), \end{cases}$$

$$\sum_{(j)} a_{(j)(k)} \tilde{a}_{(j)(i)} = \begin{cases} |A| & \text{if } (i) = (k), \\ 0 & \text{if } (i) \neq (k), \end{cases}$$

where $\sum_{(j)}$ means that the sum is taken over all combinations (j) . This is called the **Laplace expansion theorem**. If a matrix A has the form

$$A = \begin{pmatrix} B & 0 \\ * & C \end{pmatrix} \quad \text{or} \quad A = \begin{pmatrix} B & * \\ 0 & C \end{pmatrix},$$

and B and C are square matrices, then by this theorem we have $|A| = |B||C|$. If we number the combinations $(i) = (i_1, \dots, i_r)$ and $(k) = (k_1, \dots, k_r)$ appropriately (for instance, in lexicographical order) and regard the numbers assigned to them as row numbers and column numbers, respectively, to form a matrix $(a_{(i)(k)})$, then the Laplace theorem can be expressed as

$$(a_{(i)(k)}) (\tilde{a}_{(k)(i)}) = (\tilde{a}_{(k)(i)}) (a_{(i)(k)}) \\ = \begin{pmatrix} |A| & & 0 \\ & \ddots & \\ 0 & & |A| \end{pmatrix}.$$

In the particular case $r = 1$, we have

$$\sum_{j=1}^n a_{ij} \tilde{a}_{kj} = \begin{cases} |A| & \text{if } i = k, \\ 0 & \text{if } i \neq k, \end{cases}$$

$$\sum_{j=1}^n a_{jk} \tilde{a}_{ji} = \begin{cases} |A| & \text{if } i = k, \\ 0 & \text{if } i \neq k. \end{cases}$$

E. Product of Determinants

Let $A = (a_{ik})$ and $B = (b_{ik})$ be two $n \times n$ matrices. For the product $AB = C = (c_{ik})$, where $c_{ik} = \sum_{j=1}^n a_{ij} b_{jk}$ ($i, k = 1, \dots, n$), we have $|AB| = |A||B|$. The \dagger inverse matrix A^{-1} exists for an $n \times n$ matrix $A = (a_{ik})$ if and only if $|A| \neq 0$, and then $A^{-1} = (b_{ik})$ with elements $b_{ik} = \tilde{a}_{ki}/|A|$. Moreover, we have $|A^{-1}| = |A|^{-1}$. (In the case where the elements a_{ik} are in the commutative ring R with unity element, A^{-1} exists if and only if $|A|$ is a \dagger regular element of R .)

F. Theorems on Determinants

(1) Let \tilde{a}_{ik} be the cofactor of a_{ik} in the determinant of an $n \times n$ matrix $A = (a_{ik})$. Then the determinant $|\tilde{a}_{ik}|$ is equal to $|A|^{n-1}$. In general,

$$|a_{(i_1, \dots, i_r)(k_1, \dots, k_r)}| = |A|^{\binom{n-1}{r-1}}, \\ |\tilde{a}_{(i_1, \dots, i_r)(k_1, \dots, k_r)}| = |A|^{\binom{n-1}{r}}.$$

(2) The determinant of a submatrix of the matrix (\tilde{a}_{ik}) , composed of the i_1 th, \dots , i_r th rows and k_1 th, \dots , k_r th columns of (\tilde{a}_{ik}) is equal to

$$|A|^{r-1} \tilde{a}_{(i_1, \dots, i_r)(k_1, \dots, k_r)}.$$

(3) Let $\Delta \begin{pmatrix} i_1, \dots, i_r \\ k_1, \dots, k_r \end{pmatrix}$ be the determinant

of the $(n-r) \times (n-r)$ matrix obtained from an $n \times n$ matrix A by eliminating its i_1 th, \dots , i_r th rows and k_1 th, \dots , k_r th columns. Then

$$|A| \Delta \begin{pmatrix} i & j \\ k & l \end{pmatrix} = \Delta \begin{pmatrix} i \\ k \end{pmatrix} \Delta \begin{pmatrix} j \\ l \end{pmatrix} - \Delta \begin{pmatrix} i \\ l \end{pmatrix} \Delta \begin{pmatrix} j \\ k \end{pmatrix}, \\ i < j, \quad k < l.$$

(4) **Sylvester's theorem.** Let b_{ik} ($i, k = 1, \dots, n-r$) denote the minor $a_{(1, \dots, r, r+i)(1, \dots, r, r+k)}$ of an $n \times n$ matrix $A = (a_{ij})$. Then

$$|b_{ik}| = |A| \begin{vmatrix} a_{11} & \dots & a_{1r} \\ \vdots & \ddots & \vdots \\ a_{r1} & \dots & a_{rr} \end{vmatrix}^{n-r-1}.$$

(5) Let A be an $n \times m$ matrix and B an $m \times n$ matrix. Then AB is an $n \times n$ matrix. If $n > m$, then $|AB| = 0$. If $n \leq m$, let $(i) = (i_1, \dots, i_n)$ ($i_1 < \dots < i_n$) be a combination of $1, 2, \dots, m$, taken n at a time. Let $A_{(i)}$ be the $n \times n$ matrix composed of the i_1 th, \dots , i_n th columns of A , and $B_{(i)}$ the $n \times n$ matrix composed of the i_1 th, \dots , i_n th rows of B . Then $|AB| = \sum_{(i)} |A_{(i)}| |B_{(i)}|$, where the summation extends over all possible combinations (i) .

(6) **Determinant of a \dagger Kronecker product.** If A is an $m \times m$ matrix and B is an $n \times n$ matrix, then $|A \otimes B| = |A|^n |B|^m$.

(7) Let H be an $n \times n$ \dagger Hermitian matrix, and let H_k denote the matrix composed of its first k rows and columns. Then H is positive definite if and only if $|H_k| > 0$ for all $k = 1, \dots, n$.

G. Special Determinants

(1) A determinant of the form

$$\begin{vmatrix} 1 & 1 & \dots & 1 \\ x_1 & x_2 & \dots & x_n \\ x_1^2 & x_2^2 & \dots & x_n^2 \\ \vdots & \vdots & \ddots & \vdots \\ x_1^{n-1} & x_2^{n-1} & \dots & x_n^{n-1} \end{vmatrix}$$

is called a **Vandermonde determinant**. It is equal to the \dagger simplest alternating function $\prod_{i>k} (x_i - x_k)$.

(2) A **cyclic determinant** is one of the form

$$\begin{vmatrix} x_0 & x_1 & x_2 & \dots & x_{n-1} \\ x_{n-1} & x_0 & x_1 & \dots & x_{n-2} \\ & & & \ddots & \\ x_1 & x_2 & x_3 & \dots & x_0 \end{vmatrix} \\ = \prod_{i=0}^{n-1} (x_0 + \zeta^i x_1 + \zeta^{2i} x_2 + \dots + \zeta^{(n-1)i} x_{n-1}),$$

where ζ is a \dagger primitive n th root of unity.

(3) Consider the vectors $\alpha_i = (a_{i1}, a_{i2}, \dots, a_{in})$ ($i = 1, 2, \dots, n$), and let (α_i, α_j) denote the \dagger inner product of α_i and α_j . Then the following determinant is called the **Gramian** of these vectors:

$$\begin{vmatrix} (\alpha_1, \alpha_1) & (\alpha_1, \alpha_2) & \dots & (\alpha_1, \alpha_n) \\ (\alpha_2, \alpha_1) & (\alpha_2, \alpha_2) & \dots & (\alpha_2, \alpha_n) \\ \vdots & \vdots & \ddots & \vdots \\ (\alpha_n, \alpha_1) & (\alpha_n, \alpha_2) & \dots & (\alpha_n, \alpha_n) \end{vmatrix} \\ = \begin{vmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & \dots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \dots & a_{nn} \end{vmatrix}^2.$$

(4) For an alternating matrix (namely, a square matrix X such that $X = -X^T$), we have the identity

$$\begin{vmatrix} 0 & x_{12} & x_{13} & \cdots & x_{1n} \\ -x_{12} & 0 & x_{23} & \cdots & x_{2n} \\ -x_{13} & -x_{23} & 0 & \cdots & x_{3n} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ -x_{1n} & -x_{2n} & -x_{3n} & \cdots & 0 \end{vmatrix} = \begin{cases} P_n(\dots, x_{ij}, \dots)^2 & \text{if } n \text{ is even,} \\ 0 & \text{if } n \text{ is odd,} \end{cases}$$

where $P_n(\dots, x_{ij}, \dots)$ is a polynomial of variables x_{ij} , which (equipped with appropriate sign) is called the **Pfaffian** of these variables.

104 (XIII.15) Difference Equations

A. General Remarks

Let y be a function of a real variable x defined on an interval I and let Δx be a fixed quantity. When two points x and $x + \Delta x$ are in I , we define the **difference** $\Delta y(x)$ of y at x by $\Delta y(x) = y(x + \Delta x) - y(x)$ and the difference quotient by $\Delta y(x)/\Delta x$; Δx is called the difference of x . Without loss of generality, we can take $\Delta x = 1$, for otherwise there is a constant b such that $\Delta x' = 1$ for the new independent variable $bx = x'$. If $\Delta x = 1$, the **second difference** $\Delta^2 y(x) = \Delta(\Delta y(x))$ is given by

$$\begin{aligned} \Delta^2 y(x) &= \Delta y(x+1) - \Delta y(x) \\ &= y(x+2) - 2y(x+1) + y(x). \end{aligned}$$

Similarly, the **difference of the n th order** is defined by $\Delta^n y(x) = \Delta(\Delta^{n-1} y(x))$, and

$$\Delta^n y(x) = \sum_{k=0}^n (-1)^{n-k} \binom{n}{k} y(x+k).$$

Conversely, $y(x+n)$ is expressed by differences as

$$y(x+n) = \sum_{k=0}^n \binom{n}{k} \Delta^k y(x)$$

(\rightarrow 223 Interpolation).

B. Summation

Given a function $g(x)$ and Δx , a function $y(x)$ that satisfies $\Delta y(x)/\Delta x = g(x)$ is called a **sum** of $g(x)$. **Summation** of $g(x)$ is to find a sum of $g(x)$. Given a sum $y(x)$ of $g(x)$, an **indefinite sum** of $g(x)$, written as $Sg(x)\Delta x$, is given by $Sg(x)\Delta x = y(x) + c(x)$, where $c(x)$ is an arbitrary periodic function of period Δx . In many cases, $c(x)$, which corresponds to an arbitrary constant in an indefinite integral, is omitted. For example, a sum of $g(x) = nx^{n-1}$ for $\Delta x = 1$ is the n th-order \dagger Bernoulli polynomial $B_n(x)$ for $n \neq 0$; a sum of x^{-1} is $\psi(x)$, given by $\psi(x) = d \log \Gamma(x)/dx$ (\rightarrow 174 Gamma Function).

When the series $-\Delta x \sum_{k=0}^{\infty} g(x+k\Delta x)$ or $\Delta x \sum_{k=-1}^{\infty} g(x-k\Delta x)$ converges, both can be sums of $g(x)$. Since the requirement of convergence for these series was found to be too strict, the following requirement was given by N. E. Nörlund instead: Let x be a real variable and $g(x)$ be continuous for $x \geq b$. Define $\lambda(x)$ by $\lambda(x) = x^p (\log x)^q$ ($p \geq 1, q \geq 0$). Then if for a positive η

$$\begin{aligned} F(x, \Delta x, \eta) &= \int_a^{\infty} g(z) e^{-\eta \lambda(z)} dz \\ &\quad - \Delta x \sum_{k=0}^{\infty} g(x+k\Delta x) e^{-\eta \lambda(x+k\Delta x)} \end{aligned}$$

is convergent for $a > b$, F satisfies $\Delta F(x, \Delta x, \eta)/\Delta x = g(x) \exp(-\eta \lambda(x))$. Accordingly, if $F(x, \Delta x, \eta)$ approaches a limit $F(x)$ as $\eta \rightarrow 0$, $F(x)$ is a solution of $\Delta F(x)/\Delta x = g(x)$. $F(x)$ is called the **principal solution** of $\Delta F(x)/\Delta x = g(x)$.

C. Difference Equations

Let $\Delta x = 1$. An equation $F(x, y(x), \Delta y(x), \dots, \Delta^n y(x)) = 0$ in x and differences of an unknown function $y(x)$ is called a **difference equation**. If the substitution $y = \varphi(x)$ satisfies the equation for x in some interval, $\varphi(x)$ is a **solution** of the equation. Because of the relation between $y(x), y(x+1), \dots, y(x+n)$ and the differences of y at x , we can transform the given difference equation in the form $G(x, y(x), y(x+1), \dots, y(x+n)) = 0$. This form appears more often in applications and is called the **standard form** of a difference equation.

If the equation is linear in $y(x)$, $y(x+1)$, \dots , $y(x+n)$, namely, if it is given by

$$\sum_{i=0}^n p_i(x)y(x+i)=q(x),$$

the difference equation is said to be **linear**.

When $q(x) \equiv 0$, it is **homogeneous**; otherwise, it is **inhomogeneous** (or **nonhomogeneous**).

D. Linear Difference Equations

Assume that $p_0(x), \dots, p_n(x)$ are single-valued analytic functions without poles and common zeros in some domain. Consider the linear difference equation

$$\sum_{i=0}^n p_i(x)y(x+i)=0. \quad (1)$$

If $\varphi_1(x), \varphi_2(x), \dots, \varphi_m(x)$ are solutions of (1), then a linear combination $a_1(x)\varphi_1(x) + a_2(x)\varphi_2(x) + \dots + a_m(x)\varphi_m(x)$ with arbitrary periodic functions $a_1(x), a_2(x), \dots, a_m(x)$ of period 1 is also a solution of (1).

Let β_1, β_2, \dots be singular points of $p_1(x), p_2(x), \dots, p_n(x)$, $\alpha_1, \alpha_2, \dots$ be the zeros of $p_0(x)$, and $\gamma_1, \gamma_2, \dots$ be the zeros of $p_n(x+n)$. Then the set of **singular points** of the linear difference equation (1) is the set $\{\alpha_i, \beta_i, \gamma_i\}$.

A function $\varphi_m(x)$ is said to be **linearly dependent** on the functions $\varphi_1(x), \varphi_2(x), \dots, \varphi_{m-1}(x)$ with respect to the difference equation (1) if $\varphi_m(x) = a_1(x)\varphi_1(x) + a_2(x)\varphi_2(x) + \dots + a_{m-1}(x)\varphi_{m-1}(x)$, where $a_1(x), a_2(x), \dots, a_{m-1}(x)$ are functions of period 1, every one of which takes a nonzero finite value at least at one point not congruent (mod \mathbf{Z}) to any of the singular points, where \mathbf{Z} is the additive group of integers.

A set of m functions is called **linearly independent** if none of the functions is dependent on the other $m-1$ functions. When a set of n solutions of equation (1) is linearly independent, it is a **fundamental system** for (1). Any solution of (1) can be expressed as a linear combination of n solutions of a fundamental system.

The determinant

$$\begin{vmatrix} \varphi_1(x) & \varphi_2(x) & \dots & \varphi_n(x) \\ \varphi_1(x+1) & \varphi_2(x+1) & \dots & \varphi_n(x+1) \\ \dots & \dots & \dots & \dots \\ \varphi_1(x+n-1) & \varphi_2(x+n-1) & \dots & \varphi_n(x+n-1) \end{vmatrix}$$

formed from n functions $\varphi_1(x), \varphi_2(x), \dots, \varphi_n(x)$ is called **Casorati's determinant** and is denoted by $D(\varphi_1(x), \varphi_2(x), \dots, \varphi_n(x))$. A necessary and sufficient condition for a given set of n functions to be independent is that Casorati's determinant be nonzero at every point except those which are congruent to singular points of (1). Casorati's determinant is used to deter-

mine whether a given set of solutions is fundamental.

Let $\psi(x)$ be a solution of a nonhomogeneous linear difference equation

$$P_x(y) = \sum_{i=0}^n p_i(x)y(x+i) = q(x). \quad (2)$$

If $\varphi_1(x), \varphi_2(x), \dots, \varphi_n(x)$ are n linearly independent solutions of (1), then an arbitrary solution of (2) is given by

$$y = a_1(x)\varphi_1(x) + a_2(x)\varphi_2(x) + \dots + a_n(x)\varphi_n(x) + \psi(x),$$

where $a_1(x), \dots, a_n(x)$ are arbitrary periodic functions of period 1. Then the expression for y is called a **general solution** of (2). If we abbreviate Casorati's determinant of a fundamental system of solutions $\varphi_1(x), \varphi_2(x), \dots, \varphi_n(x)$ of (1) by $D(x)$ and write $\mu_i(x)$ as the quotient of the cofactor of $\varphi_i(x+n)$ of $D(x+1)$ by $D(x+1)$, we have

$$\psi(x) = \sum_{i=1}^n \varphi_i(x) S q(z) \mu_i(z) \Delta z,$$

assuming that the summation S on the right-hand side is known. This is the analog of Lagrange's method of variation of constants in the theory of linear ordinary differential equations.

E. Linear Difference Equations with Constant Coefficients

If all the coefficients in

$$\sum_{i=0}^n p_i y(x+i) = 0, \quad p_0 \neq 0, \quad p_n \neq 0, \quad (3)$$

are constants, n linearly independent solutions are obtained easily. Indeed, if λ is a root of the algebraic equation $\sum_{i=0}^n p_i \lambda^i = 0$, λ^x is a solution of (3). This algebraic equation is called the **characteristic equation** of (3). If it has n distinct roots $\lambda_1, \lambda_2, \dots, \lambda_n$, then $\lambda_1^x, \lambda_2^x, \dots, \lambda_n^x$ are n linearly independent solutions. In general, if λ is an m -tuple root of the characteristic equation, then $\lambda^x, x\lambda^x, \dots, x^{m-1}\lambda^x$ are solutions of (3). Accordingly, if λ_j is a root of multiplicity m_j ($\sum_{j=1}^s m_j = n, j = 1, 2, \dots, s$), then $\lambda_j^x, x\lambda_j^x, \dots, x^{m_j-1}\lambda_j^x$ ($j = 1, \dots, s$) constitute a set of n linearly independent solutions.

Even if all the p_i are real, the characteristic equation may have complex roots. In such a case real solutions are obtained as follows: When $\lambda = \mu + iv$ is a root of multiplicity m , $\bar{\lambda} = \mu - iv$ is also a root of the same multiplicity. If we write $\rho = \sqrt{\mu^2 + v^2}$, $\tan \varphi = v/\mu$, then $\rho^x \cos \varphi x, \rho^x \sin \varphi x, x\rho^x \cos \varphi x, x\rho^x \sin \varphi x, \dots, x^{m-1}\rho^x \cos \varphi x, x^{m-1}\rho^x \sin \varphi x$ are $2m$ independent real solutions.

Nonhomogeneous equations with con-

stant coefficients can be generally solved by Lagrange's method with these solutions. However, when the nonhomogeneous term has a special form such as

$$\sum_{i=0}^n p_i y(x+i) = p(x)\lambda^x,$$

where $p(x)$ is a polynomial in x and λ is a root of multiplicity m of the characteristic equation, we can use the method of undetermined coefficients. In this particular case, the substitution $(A_0 + A_1 x + \dots + A_k x^k)x^m \lambda^x$ with undetermined coefficients A_0, A_1, \dots, A_k gives solutions, k being the degree of $p(x)$.

F. Difference and Differential Equations

The differential operator d/dx acts on the family of functions $\{x^m | m=0, \pm 1, \dots\}$ according to $dx^m/dx = mx^{m-1}$, just as the difference operator Δ acts on the family $\{x^{(m)} = \Gamma(x+1)/\Gamma(x-m+1) | m=0, \pm 1, \dots\}$ according to $\Delta x^{(m)} = mx^{(m-1)}$. Hence by using the **factorial series** $\sum a_m x^{(m)}$ and its similarity to the power series $\sum a_m x^m$, we may obtain some analogies with the theory of differential equations. For example, the \dagger Frobenius method in the theory of \dagger regular singular points can be applied to the system of difference equations

$$(z-1)\Delta_{-1} w_k(z) = \sum_{j=1}^n a_{jk}(z)w_j(z),$$

$$k=1, 2, \dots, n.$$

However, there are certain essential differences between functions defined as solutions of differential and difference equations. For example, **Hölder's theorem** states that no solution of the simple difference equation $y(x+1) - y(x) = x^{-1}$ satisfies any \dagger algebraic differential equation. Consequently, the gamma function, which is related to a solution of the equation $\psi(x) = d \log \Gamma(x)/dx$, cannot be a solution of any algebraic differential equation. For the numerical solution of ordinary differential equations by difference equation approximation — 303 Numerical Solution of Ordinary Differential Equations.

G. Geometric Difference Equations

For an arbitrary complex number q , an equation of the form $y(qx) = f(x, y(x))$ is called a **geometric difference equation**. For example, the ordinary difference equation (1) can be transformed into

$$\sum_{k=0}^n p_k(z)U(zq^k) = B(z) \quad (1')$$

by the change of variable $z = q^x$. Although it is

possible to transform an equation of the type (1') into that of the type (1), there are theories developed specifically for the type (1'), since the coefficients of the equation may become more complicated by such a transformation.

105 (VII.2) Differentiable Manifolds

A. General Remarks

The rudimentary concept of n -dimensional manifolds can already be seen in J. Lagrange's dynamics. In the middle of the 19th century n -dimensional \dagger Euclidean space was known as a continuum of n real parameters (A. Cayley; H. Grassmann, 1844, 1861; L. Schläfli, 1852). The notion of general n -dimensional manifolds was introduced by B. Riemann as a result of his differential geometric observations (1854). He considered an n -dimensional manifold to be a set formed by a 1-parameter family of $(n-1)$ -dimensional manifolds, just as a surface is formed by the motion of a curve. Analytical studies of topological structures of manifolds and their local properties were initiated and developed by Riemann, E. Betti, H. Poincaré, and others. To avoid the difficulties and disadvantages of analytical methods, Poincaré restricted his consideration to those topological spaces X that are \dagger connected, \dagger triangulable, and such that each point of X

has a neighborhood homeomorphic to an n -dimensional Euclidean space. We often refer to such spaces as **Poincaré manifolds**; Poincaré called them n -dimensional manifolds. In 1936, H. Whitney published a monumental paper [14] on differentiable manifolds in which the various fundamental concepts on differentiable manifolds were established. This and subsequent papers written by Whitney during nearly twenty years greatly influenced the rapid advance of the theory of differentiable manifolds since 1950.

B. Topological Manifolds

An n -dimensional **topological manifold** M is by definition a Hausdorff space in which each point p has a neighborhood $U(p)$ homeomorphic to an open set of \mathbf{R}^n .

Let M' be a Hausdorff space in which each point p of M' has a neighborhood $U(p)$ homeomorphic to an open set of H^n , where H^n is the half-space $\{(x_1, x_2, \dots, x_n) \in \mathbf{R}^n | x_n \geq 0\}$. Let $\partial M'$ denote the set consisting of points p of M' such that p corresponds to a point of $H_0^n = \{(x_1, \dots, x_n) \in H^n | x_n = 0\} \subset H^n$ under the homeomorphism from $U(p)$ to an open set of H^n . M' is called an n -dimensional **topological manifold with boundary** if $\partial M' \neq \emptyset$, and $\partial M'$ is called the **boundary** of M' . On the other hand, M defined as above or M' with $\partial M' = \emptyset$ is called an n -dimensional **topological manifold without boundary**. The **interior** of M' is the complement $M'_0 = M' - \partial M'$ of the boundary. The boundary of an n -dimensional topological manifold is an $(n-1)$ -dimensional topological manifold. A topological manifold without boundary is called **closed** or **open** according as it is compact or has no connected component which is compact. There exist connected topological manifolds that are not \dagger paracompact; among them, the 1-dimensional ones are called **long lines**. A connected paracompact topological manifold M has a \dagger countable open base and is \dagger metrizable.

C. Local Coordinates

Let M be an n -dimensional topological manifold. A pair (U, ψ) consisting of an open set U of M and a homeomorphism ψ of U onto an open set of \mathbf{R}^n is called a **coordinate neighborhood** of M . If we denote by $(x^1(p), \dots, x^n(p))$ ($p \in U$) the coordinates of the point $\psi(p)$ of \mathbf{R}^n , then x^1, x^2, \dots, x^n are real-valued continuous functions defined on U . We call these n functions the **local coordinate system** in the coordinate neighborhood (U, ψ) and the n real numbers $x^1(p), \dots, x^n(p)$ the **local coordinates** of the point $p \in U$ (with respect to (U, ψ)).

A set $S = \{(U_\alpha, \psi_\alpha)\}_{\alpha \in A}$ of coordinate neighborhoods is called an **atlas** of M if $\{U_\alpha\}_{\alpha \in A}$ forms an \dagger open covering of M .

D. Differentiable Manifolds

Let $S = \{(U_\alpha, \psi_\alpha)\}_{\alpha \in A}$ be an atlas of an n -dimensional topological manifold M . For each pair of coordinate neighborhoods (U_α, ψ_α) and (U_β, ψ_β) in S such that $U_\alpha \cap U_\beta \neq \emptyset$, $\psi_\beta \circ \psi_\alpha^{-1}$ is a homeomorphism of the open set $\psi_\alpha(U_\alpha \cap U_\beta)$ of \mathbf{R}^n onto the open set $\psi_\beta(U_\alpha \cap U_\beta)$ of \mathbf{R}^n . Let $x = (x^1, \dots, x^n) \in \psi_\alpha(U_\alpha \cap U_\beta)$. Then we can write $(\psi_\beta \circ \psi_\alpha^{-1})(x) = (f_{\beta\alpha}^1(x), \dots, f_{\beta\alpha}^n(x))$. If the n real-valued functions $f_{\beta\alpha}^1, \dots, f_{\beta\alpha}^n$ defined in $\psi_\alpha(U_\alpha \cap U_\beta)$ are of \dagger class C^r ($1 \leq r \leq \infty$) (resp. \dagger real analytic) for any α, β in A such that $U_\alpha \cap U_\beta \neq \emptyset$, then we call S an **atlas of class C^r** (resp. C^ω) of M . When an n -dimensional topological manifold M has an atlas S of class C^r ($1 \leq r \leq \omega$), we call the pair (M, S) an n -dimensional **differentiable manifold of class C^r** (or **C^r -manifold**). A C^ω -manifold is also called a **smooth manifold**, while a C^0 -manifold is called a **real analytic manifold**. We call M the **underlying topological space** of (M, S) , and we say that S defines a **differentiable structure of class C^r** (or **C^r -structure**) in M .

In particular, a C^ω -structure is called a **real analytic structure**. A C^r -manifold whose underlying topological space is compact (\dagger paracompact) is called a **compact (paracompact) C^r -manifold**. A coordinate neighborhood (U, ψ) of M is called a **coordinate neighborhood of class C^r** of (M, S) if the union $S \cup \{(U, \psi)\}$ is also an atlas of class C^r of M . In particular, each coordinate neighborhood of M belonging to S is of class C^r . The set \tilde{S} of all coordinate neighborhoods of class C^r of (M, S) is an atlas of M containing S , and we call \tilde{S} the maximal atlas containing S . Let S and S' be two atlases of class C^r of M . If $\tilde{S} = \tilde{S}'$, then we say that S and S' define the same differentiable structure of class C^r on M and that the differentiable manifolds (M, S) and (M, S') of class C^r are equivalent. In particular, (M, S) and (M, \tilde{S}) are equivalent C^r -manifolds. Let S and S' be atlases of class C^r and class C^s , respectively, where $1 \leq r < s \leq \omega$. Since $s > r$, we can consider S' an atlas of class C^r . If S and S' define the same C^r -structure in M , then we say that the C^s -structure defined by S' is **subordinate** to the C^r -structure defined by S . If M is paracompact, then there exists a C^ω -structure subordinate to a C^r -structure of M (Whitney [14]).

E. Differentiable Manifolds with Boundaries

Let U and U' be open sets in the half-space H^n , and let $\varphi: U \rightarrow U'$ be a continuous mapping. If

Differentiable Manifolds

there exist open sets W and W' in \mathbf{R}^n containing U and U' , respectively, and a mapping $\psi: W \rightarrow W'$ of class C^r that extends φ , we call φ a mapping of U into U' of class C^r . Let M be a Hausdorff topological space. A structure of a C^r -manifold on M is defined by a set $S = \{(U_\alpha, \psi_\alpha)\}_{\alpha \in A}$, where $\{U_\alpha\}_{\alpha \in A}$ is an open covering of M , and, for each α , ψ_α is a homeomorphism of U_α onto an open set of H^n such that for any $\alpha, \beta \in A$ with $U_\alpha \cap U_\beta \neq \emptyset$, $\psi_\beta \circ \psi_\alpha^{-1}$ is a mapping of class C^r from $\psi_\alpha(U_\alpha \cap U_\beta)$ onto $\psi_\beta(U_\alpha \cap U_\beta)$. Let ∂M denote the set consisting of points p of M such that $p \in U_\alpha$ and $\psi_\alpha(p) \in H_0^n = \{(x_1, \dots, x_n) \in H^n \mid x_n = 0\}$ for some $\alpha \in A$. If $\partial M \neq \emptyset$, the pair (M, S) is called an n -dimensional **differentiable manifold with boundary of class C^r** (or **C^r -manifold with boundary**), and ∂M is called the **boundary** of M . ∂M forms an $(n-1)$ -dimensional C^r -manifold. If we put $U'_\alpha = U_\alpha \cap \partial M$ and denote the restriction of ψ_α to U'_α by ψ'_α , then $S' = \{(U'_\alpha, \psi'_\alpha)\}_{\alpha \in A}$ is an atlas of class C^r of ∂M . If ∂M is empty, then (M, S) is a C^r -manifold. In this sense a C^r -manifold is sometimes called a **C^r -manifold without boundary**.

F. Orientation of a Manifold

Let $S = \{(U_\alpha, \psi_\alpha)\}_{\alpha \in A}$ be an atlas of class C^r in M , and for each α let $\{x_\alpha^1, \dots, x_\alpha^n\}$ be the local coordinate system in a coordinate neighborhood (U_α, ψ_α) . If U_α and U_β intersect, then there exist n real-valued functions F^i ($i = 1, \dots, n$) defined on $\psi_\alpha(U_\alpha \cap U_\beta)$ such that $x_\beta^i(p) = F^i(x_\alpha^1(p), \dots, x_\alpha^n(p))$ for $p \in U_\alpha \cap U_\beta$ and $i = 1, \dots, n$. The Jacobian $D_{\alpha\beta} = D(F^1, \dots, F^n)/D(x_\alpha^1, \dots, x_\alpha^n)$ is different from zero at each point $(x_\alpha^1, \dots, x_\alpha^n)$ of $\psi_\alpha(U_\alpha \cap U_\beta)$. If we can choose an atlas S of M so that, for any α, β such that $U_\alpha \cap U_\beta$ is nonempty, the Jacobian $D_{\alpha\beta}$ is always positive, then we say that the C^r -manifold M is **orientable**, and we call S an **oriented atlas**.

Let $S = \{(U_\alpha, \psi_\alpha)\}_{\alpha \in A}$ and $S' = \{(V_\lambda, \varphi_\lambda)\}_{\lambda \in \Lambda}$ be two oriented atlases of a connected C^r -manifold M . If M is connected, then the sign of the Jacobian $D_{\alpha\lambda}(p)$ of the transformation of local coordinates is independent of the choice of $\alpha \in A$, $\lambda \in \Lambda$, and $p \in U_\alpha \cap V_\lambda$. We say that S and S' define the **same (opposite) orientation** if $D_{\alpha\lambda}$ is always positive (negative). Hence if M is connected, the set of all oriented atlases of class C^r is composed of two subsets such that atlases belonging to one of them have the same orientation, while two atlases belonging to different ones have the opposite orientation. Each of these subsets is called an **orientation** of the connected C^r -manifold M . When we assign to M one of two possible orientations, M is called an **oriented manifold**; the assigned

orientation is called its **positive orientation** and the other its **negative orientation**. If $S = \{(U_\alpha, \psi_\alpha)\}_{\alpha \in A}$ belongs to the positive orientation, S and (U_α, ψ_α) are called an **atlas** and **local coordinate system**, respectively, compatible with the positive orientation.

G. Differentiable Functions

Let f be a real-valued function defined in a neighborhood of a point p of a C^∞ -manifold M . Let (U, ψ) be a coordinate neighborhood of class C^∞ such that $p \in U$. If the function $f \circ \psi^{-1}$ is of class C^r ($1 \leq r \leq \infty$) in a neighborhood of the point $\psi(p)$ in \mathbf{R}^n , then the function f is called a **function of class C^r at p** . This definition is independent of the choice of a coordinate neighborhood of class C^∞ . If we denote the local coordinate system in (U, ψ) by (x^1, \dots, x^n) , there exists a function $f(x^1, \dots, x^n)$ of n variables defined in a neighborhood of $\psi(p)$ in \mathbf{R}^n such that $f(q) = f(x^1(q), \dots, x^n(q))$ for each point q in the neighborhood of p . Here we use the same symbol f for the function f defined in a neighborhood of p in M and for the function $f \circ \psi^{-1}$ defined in the image of the neighborhood by ψ in \mathbf{R}^n . The function f is of class C^r at p if and only if $f(x^1, \dots, x^n)$ is of class C^r in a neighborhood of the point $(x^1(p), \dots, x^n(p))$ of \mathbf{R}^n . A **function of class C^r** (or **C^r -function**) **in M** is a real-valued function in M that is of class C^r at every point of M .

H. Tangent Vectors

Let M be a C^∞ -manifold, and let $\mathfrak{F}(M)$ be the real vector space consisting of all C^∞ -functions in M . (For the sake of simplicity, we denote a manifold (M, S) by M .) A **tangent vector L** at a point p of M is a linear mapping $L: \mathfrak{F}(M) \rightarrow \mathbf{R}$ such that $L(fg) = L(f)g(p) + f(p)L(g)$ for any f and g in $\mathfrak{F}(M)$. For any two tangent vectors L_1, L_2 and any pair of real numbers λ_1, λ_2 we define $\lambda_1 L_1 + \lambda_2 L_2$ by $(\lambda_1 L_1 + \lambda_2 L_2)(f) = \lambda_1 L_1(f) + \lambda_2 L_2(f)$, $f \in \mathfrak{F}(M)$.

Thus tangent vectors at p form a real vector space T_p , which we call the **tangent vector space** (or simply the **tangent space**) of M at the point p . The dimension of the tangent vector space T_p equals the dimension of M . The set of all tangent vectors of M forms a vector bundle over the base space M , called the **tangent vector bundle** (or **tangent bundle**) of M .

By a **tangent r -frame** ($r \leq n$) at p we mean an ordered set of r linearly independent tangent vectors at p . The set of all tangent r -frames also forms a fiber bundle over M called the **tangent r -frame bundle** (or **bundle of tangent r -frames**) (\rightarrow 147 Fiber Bundles F).

I. Differentials of Functions

For a C^∞ -function f in M and a point p of M we can define a linear mapping $df_p: T_p \rightarrow \mathbf{R}$ by $df_p(L) = L(f)$ for all $L \in T_p$, and we call df_p the **differential of f at p** . The totality of differentials at p of C^∞ -functions in M forms the dual vector space of the tangent vector space T_p .

J. Differentiable Mappings

Let φ be a continuous mapping of a C^∞ -manifold M into a C^∞ -manifold M' . We call φ a **differentiable mapping of class C^r** (or simply a **C^r -mapping**) ($1 \leq r \leq \infty$) if the function $f \circ \varphi$ is of class C^r for any C^r -function f on M' . If φ is a homeomorphism of M onto M' and φ and φ^{-1} are both of class C^r , then we call φ a **diffeomorphism of class C^r** . If there exists a diffeomorphism of class C^∞ of a C^∞ -manifold M onto a C^∞ -manifold M' , then M and M' are said to be **diffeomorphic**.

Let M and M' be C^∞ -manifolds and φ be a C^∞ -mapping of M into M' . For a tangent vector L of M at p , a tangent vector L' of M' at $\varphi(p)$ is defined by $L'(g) = L(g \circ \varphi)$, $g \in \mathfrak{F}(M')$. The mapping $L \rightarrow L'$ defines a linear mapping $(d\varphi)_p$ of the tangent vector space T_p of M at p into the tangent vector space $T_{\varphi(p)}$ of M' at $\varphi(p)$. The linear mapping $(d\varphi)_p$ is called the **differential of the differentiable mapping φ at p** . If $(d\varphi)_p$ is surjective, p is called a **regular point** of φ . A point on M which is not a regular point is called a **critical point** of φ . A point q on M' which is an image of a critical point is called a **critical value** of φ , and a point on M' which is not a critical value is called a **regular value**. In \mathbf{R}^n , the diffeomorphic image of a set of Lebesgue measure zero has Lebesgue measure zero. So the set of Lebesgue measure zero is well defined on a (paracompact) C^∞ -manifold. Then **Sard's theorem** states: Let $\varphi: M \rightarrow M'$ be a C^∞ -mapping; then the set of critical values of φ has Lebesgue measure zero in M' .

K. Immersions and Embeddings

Let M and M' be C^∞ -manifolds and φ be a C^∞ -mapping of M into M' . If $(d\varphi)_p$ is injective at every point p of M , then φ is called an **immersion** of M into M' . If φ is an immersion, then for some neighborhood U_p of any point p of M the restriction $\varphi|U_p$ gives rise to a homeomorphism from U_p into M' . If an immersion φ is injective, then φ is called an **embedding** (or an **imbedding**) of M into M' . An alternative definition is often used, which says that φ is an **embedding** if, in addition to the

above conditions, φ gives a homeomorphism from M onto $\varphi(M)$, where $\varphi(M)$ has the relative topology of M' . If the former definition is adopted as embedding, then a mapping φ satisfying the conditions of the alternative definition is sometimes referred to as a **regular embedding**. If M is compact, the two definitions coincide. In Sections L and M, embedding always means regular embeddings.

The theory of embeddings and immersions is mainly concerned with ways to embed and immerse a given manifold M into a manifold M' of a particular type with lowest possible dimension. M' is usually the Euclidean space \mathbf{R}^n , the projective space $P^n \mathbf{R}$ or a certain standard manifold. The theory was initiated by Whitney (1936). He proved by "general position" argument that an n -dimensional C^∞ -manifold M with countable basis can always be immersed in the $2n$ -dimensional Euclidean space and can always be embedded in the $(2n+1)$ -dimensional Euclidean space as a closed set (**Whitney's theorem**).

L. Submanifolds

A C^∞ -manifold M is said to be a **submanifold** of a C^∞ -manifold M' if M is a subset of M' and the identity mapping of M into M' is an immersion. If the identity mapping of M into M' is an embedding, then M is called a **regular submanifold** of M' . A regular submanifold M of M' is called a **closed submanifold** if M is a closed subset of M' .

Let φ be a C^∞ -mapping from M into M' and M'' be a submanifold of M' . Then for each $q \in M''$ the tangent space T_q'' of M'' at q is a linear subspace of the tangent space T_q' of M' at q . Denote by π_q the projection of quotient vector space onto T_q'/T_q'' . A C^∞ -mapping φ is called **transverse** to M'' if for each $p \in \varphi^{-1}(M'')$ the composite $\pi_{\varphi(p)} \circ d\varphi_p: T_p \rightarrow T_{\varphi(p)}'/T_{\varphi(p)}''$ is surjective. If φ is transverse to M'' then $\varphi^{-1}(M'')$ is a submanifold of M . For any C^∞ -mapping $\varphi: M \rightarrow M'$ and any submanifold $M'' \subset M'$, we can find a C^∞ -mapping $\varphi': M \rightarrow M'$ which is transverse to M'' and arbitrarily close to φ (**transversality theorem**). Let M_1 and M_2 be submanifolds of M' . Then we say M_1 **intersects transversely** to M_2 if the inclusion $M_1 \subset M'$ is transverse to M_2 .

A C^∞ -mapping is called a **submersion** if it has no critical point. Let φ be a submersion from M into M' . Then for each point $q \in M'$, $\varphi^{-1}(q)$ is a regular submanifold of M , and M is covered by a mutually disjoint family of submanifolds: $M = \bigcup_{q \in M'} \varphi^{-1}(q)$.

Let M be a submanifold of an n -dimensional Euclidean space \mathbf{R}^n . We can identify the tangent vector space T_p of M at p with the geom-

etric tangent space of M at p in the Euclidean space \mathbf{R}^m . A vector in \mathbf{R}^m that is orthogonal to the tangent vector space T_p of M at p is called a **normal vector** to M at p . The set of all vectors normal to M forms a vector bundle over M , which we call the **normal vector bundle** (or **normal bundle**) of M . If M is compact, then the totality of vectors normal to M whose length is $\leq \varepsilon$ (where ε is a sufficiently small positive real number) forms a neighborhood $N(M)$ of M in \mathbf{R}^m which we call a **tubular neighborhood** of M . $\text{Int } N(M)$ is called an **open tubular neighborhood**.

M. Vector Fields

Let N be a subset of a C^∞ -manifold M . By a **vector field** on N we mean a mapping X that assigns to each point p of N a tangent vector X_p of M at p . We can consider X as a cross section over N of the tangent vector bundle of M . Let X be a vector field in M , and let f be a C^∞ -function in M . Then we can define a function Xf in M by $(Xf)(p) = X_p f$. We call X a **vector field of class C^r** if the function Xf is of class C^r for any C^∞ -function f in M . Let (x^1, \dots, x^n) be the local coordinate system in a coordinate neighborhood (U, ψ) , and let $(\partial/\partial x^i)_p f = (\partial f/\partial x^i)(p)$ for $p \in U$ and $f \in \mathfrak{F}(M)$. Then $\partial/\partial x^i$ ($i = 1, \dots, n$) are vector fields in U , and the $(\partial/\partial x^i)_p$ form a basis of T_p at every point $p \in U$. A vector field X in U is written uniquely as $X_p = \sum_i \xi^i(p) (\partial/\partial x^i)_p$ at each point $p \in U$. Then ξ^1, \dots, ξ^n are real-valued functions defined in U , called the **components** of X with respect to the local coordinate system (x^1, \dots, x^n) . A vector field X in M is of class C^r if and only if its components ξ^i with respect to each coordinate system are functions of class C^r ($0 \leq r \leq \infty$). Let $(\bar{x}^1, \dots, \bar{x}^n)$ be another local coordinate system in a neighborhood U of p , and let $(\bar{\xi}^1, \dots, \bar{\xi}^n)$ be the components of X with respect to $(\bar{x}^1, \dots, \bar{x}^n)$. Then we have $\bar{\xi}^i(q) = \sum_j (\partial \bar{x}^i/\partial x^j)(q) \xi^j(q)$ at each point $q \in U$.

For the rest of this article we mean by a vector field in M a vector field of class C^∞ , and we denote by $\mathfrak{X}(M)$ the set of all vector fields in M . Then $\mathfrak{X}(M)$ is an $\mathfrak{F}(M)$ - $\mathfrak{X}(M)$ -module, where $\mathfrak{F}(M)$ denotes the algebra of all C^∞ -functions in M . In fact, for $f, g \in \mathfrak{F}(M)$ and $X, Y \in \mathfrak{X}(M)$, we can define a vector field $fX + gY$ by $(fX + gY)_p = f(p)X_p + g(p)Y_p$, and this defines an $\mathfrak{F}(M)$ -module structure in $\mathfrak{X}(M)$.

In a coordinate neighborhood (U, ψ) , we can write $X = \sum_i \xi^i (\partial/\partial x^i)$. The right-hand side of this equation is sometimes called the **symbol** of the vector field X . A vector field X can also be interpreted as a linear differential operator that acts on $\mathfrak{F}(M)$.

Let X and Y be vector fields in M . Then

there exists a unique vector field Z in M such that $Zf = X(Yf) - Y(Xf)$ for any C^∞ -function f in M . We denote Z by $[X, Y]$ and call it the **Poisson bracket** (or simply **bracket**) of X and Y . If ξ^i and η^i denote the components of X and Y , respectively, in a coordinate neighborhood (U, ψ) , then the components ζ^i of $[X, Y]$ are given by $\zeta^i = \sum_k \{ \xi^k (\partial \eta^i/\partial x^k) - \eta^k (\partial \xi^i/\partial x^k) \}$. The bracket of vector fields has the following properties: (i) $[X, Y]f = X(Yf) - Y(Xf)$, (ii) $[fX, gY] = fg[X, Y] + f(Xg)Y - g(Yf)X$, (iii) $[X + Y, Z] = [X, Z] + [Y, Z]$, (iv) $[X, Y] = -[Y, X]$, and (v) $[[X, Y], Z] + [[Y, Z], X] + [[Z, X], Y] = 0$ (**Jacobi identity**). These identities show that $\mathfrak{X}(M)$ is a Lie algebra (\rightarrow 248 Lie Algebras) over \mathbf{R} .

If φ is a diffeomorphism of M onto M' , then for any vector field X in M we can define a vector field $\varphi_* X$ in M' by the condition $(\varphi_* X)_p = d\varphi_q(X_q)$, $p = \varphi(q)$. Then φ_* is an isomorphism of the Lie algebra $\mathfrak{X}(M)$ onto the Lie algebra $\mathfrak{X}(M')$.

N. Vector Fields and One-Parameter Groups of Transformations

A **one-parameter group of transformations** of M is a family φ_t ($t \in \mathbf{R}$) of diffeomorphisms satisfying the following two conditions: (i) the mapping of $\mathbf{R} \times M$ into M defined by $(t, p) \rightarrow \varphi_t(p)$ is of class C^∞ ; and (ii) $\varphi_s \circ \varphi_t = \varphi_{s+t}$ for $s, t \in \mathbf{R}$.

Let φ_t be a one-parameter group of transformations of M . Then we can define a vector field X by $X_p f = \lim_{t \rightarrow 0} (f(\varphi_t(p)) - f(p))/t$, where $p \in M$ and $f \in \mathfrak{F}(M)$. The vector field X thus defined is called the **infinitesimal transformation** of φ_t . We also say that φ_t is generated by X , and sometimes we denote φ_t by the symbol $\exp tX$. In this case, if (x^1, \dots, x^n) is a local coordinate system, then at each point p of the coordinate neighborhood, we have $X_p = \sum_i (dx^i(\varphi_t(p))/dt)_{t=0} (\partial/\partial x^i)_p$.

If M is compact, then every vector field in M is the infinitesimal transformation of a one-parameter group of transformations; that is, every vector field generates a one-parameter group of transformations. For M noncompact, this is not always true. Nevertheless, for each vector field X we have the following result concerning local properties of X : For each point p of M , there exist a neighborhood U of p , a positive real number ε , and a family φ_t ($|t| < \varepsilon$) of mappings of U into M satisfying the following three conditions. (1) The mapping of $(-\varepsilon, \varepsilon) \times U$ into M defined by $(t, q) \rightarrow \varphi_t(q)$ is of class C^∞ , and for each fixed t , φ_t is a diffeomorphism of U onto an open set $\varphi_t(U)$ of M . (2) If $|s|$, $|t|$, and $|s+t|$ are all smaller than ε and q and $\varphi_t(q)$ both belong to U , then

$\varphi_s(\varphi_t(q)) = \varphi_{s+t}(q)$. (3) $X(q)f = \lim_{t \rightarrow 0} (f(\varphi_t(q)) - f(q))/t$ for $q \in U$ and $f \in \mathfrak{F}(M)$. We call φ_t the **local one-parameter group of local transformations** around p generated by X .

Let X and Y be vector fields in M , and let φ_t be the local one-parameter group of local transformations around p generated by X . Then $[X, Y]_p = \lim_{t \rightarrow 0} (Y_p - ((\varphi_t)_* Y)_p)/t$, where $(\varphi_t)_* Y$ is a vector field defined as follows: Let U be a neighborhood of the point p where φ_t ($|t| < \varepsilon$) is defined. Then $(\varphi_t)_* Y$ is the vector field on $\varphi_t(U)$ that is the image of Y under the diffeomorphism φ_t . In particular, if X generates a one-parameter group of transformations of M , then we have $[X, Y] = \lim_{t \rightarrow 0} (Y - (\varphi_t)_* Y)/t$ for any vector field Y in M .

O. Tensor Fields

Let $T_s^r(p)$ be the vector space consisting of all r -times contravariant and s -times covariant tensors over the tangent vector space T_p of a C^∞ -manifold M , that is,

$$T_s^r(p) = \left(\bigotimes^r T_p \right) \otimes \left(\bigotimes^s T_p^* \right),$$

where T_p^* denotes the dual linear space of T_p (\rightarrow 256 Linear Spaces). A **tensor field** (more precisely, **contravariant of order r and covariant of order s** , or simply a **tensor field of type (r, s)**) on a subset N of M is a mapping K that assigns to each point p of N an element K_p of the vector space $T_s^r(p)$. In particular, if $r = s = 0$, K is a real-valued function on N , and we call K a **scalar field**. If $r = 1$ and $s = 0$, K is a vector field, called a **contravariant vector field**. When $r = 0$ and $s = 1$, we call K a **covariant vector field** (or **differential form of degree 1**). If $r \neq 0$, $s = 0$ or $r = 0$, $s \neq 0$, we call K a **contravariant tensor field of order r** or a **covariant tensor field of order s** , respectively. A contravariant or covariant tensor field K is said to be **symmetric (alternating)** if K_p is a symmetric (alternating) tensor at every point p of M .

Let (x^1, \dots, x^n) be the local coordinate system in a coordinate neighborhood (U, ψ) . Then at each point p of U , the $(\partial/\partial x^i)_p$ ($i = 1, \dots, n$) form a basis of the tangent vector space T_p , the differentials $(dx^i)_p$ ($i = 1, \dots, n$) form a basis of the dual space T_p^* , and these bases are dual to each other. A tensor field K of type (r, s) defined on M is written at any point p of U in the following form:

$$K_p = \sum K_{j_1 \dots j_s}^{i_1 \dots i_r}(p) (\partial/\partial x^{i_1})_p \otimes \dots \otimes (\partial/\partial x^{i_r})_p \\ \otimes (dx^{j_1})_p \otimes \dots \otimes (dx^{j_s})_p.$$

The functions $K_{j_1 \dots j_s}^{i_1 \dots i_r}$ defined in U are called the **components** of the tensor field K of type (r, s) with respect to the local coordinate sys-

Differentiable Manifolds

tem (x^1, \dots, x^n) . If $\bar{K}_{j_1 \dots j_s}^{i_1 \dots i_r}$ are the components of K with respect to the local coordinate system $(\bar{x}^1, \dots, \bar{x}^n)$ in another coordinate neighborhood (U', ψ') such that $U \cap U' \neq \emptyset$, then for each $q \in U \cap U'$, the following relations hold:

$$\bar{K}_{j_1 \dots j_s}^{i_1 \dots i_r}(q) = \sum_{k_1, \dots, k_r} (\partial \bar{x}^{i_1} / \partial x^{k_1})_q \dots (\partial \bar{x}^{i_r} / \partial x^{k_r})_q \\ \times (\partial x^{j_1} / \partial \bar{x}^{j_1})_q \dots (\partial x^{j_s} / \partial \bar{x}^{j_s})_q K_{j_1 \dots j_s}^{k_1 \dots k_r}.$$

A tensor field K in M is called a **tensor field of class C^t** ($0 \leq t \leq \infty$) if the components are functions of class C^t for any coordinate neighborhood of M .

The sum $K + L$ and the tensor product $K \otimes L$ of two tensor fields K and L are defined by the rules $(K + L)_p = K_p + L_p$ and $(K \otimes L)_p = K_p \otimes L_p$, respectively. The contraction of two tensor fields is also defined by taking the contraction pointwise.

Let φ be a diffeomorphism of M into M' . Then the differential $(d\varphi)_q$ is an isomorphism of T_q onto T_p ($p = \varphi(q)$) for each $q \in M$ and hence induces an isomorphism $\tilde{\varphi}_q$ of the vector space $T_s^r(q)$ onto the vector space $T_s^r(p)$ (\rightarrow 256 Linear Spaces). For any tensor field K in M we can define a tensor field $\tilde{\varphi}K$ in M' by $(\tilde{\varphi}K)_p = \tilde{\varphi}_q(K_q)$, $p = \varphi(q)$, $q \in M$. Then $\tilde{\varphi}(K + L) = \tilde{\varphi}K + \tilde{\varphi}L$, $\tilde{\varphi}(K \otimes L) = \tilde{\varphi}K \otimes \tilde{\varphi}L$, and the mapping $\tilde{\varphi}$ commutes with contraction.

Let K be a tensor field and X be a vector field (both of class C^∞) in M . We define a tensor field $L_X K$ by $(L_X K)_p = \lim_{t \rightarrow 0} (K_p - (\tilde{\varphi}_t K)_p)/t$, where φ_t denotes the local one-parameter group of local transformations around p generated by X . We call $L_X K$ the **Lie derivative** of K with respect to the vector field X . The operator $L_X: K \rightarrow L_X K$ has the following six properties: (i) $L_X(K + K') = L_X K + L_X K'$; (ii) $L_X(K \otimes K') = (L_X K) \otimes K' + K \otimes L_X K'$; (iii) the operator L_X commutes with contraction; (iv) $L_X f = Xf$ for a scalar field f and $L_X Y = [X, Y]$ for a vector field Y ; (v) $L_{[X, Y]} = L_X L_Y - L_Y L_X$, that is, $L_{[X, Y]} K = L_X(L_Y K) - L_Y(L_X K)$; and (vi) K is invariant under φ_t , i.e., $\tilde{\varphi}_t K = K$ for all t , if and only if $L_X K = 0$.

Let K be a covariant tensor field of order r in M . We always assume that K is of class C^∞ . The value K_p of K at $p \in M$ is an element of the vector space $T_p^* \otimes \dots \otimes T_p^*$ (r times tensor product of T_p^*); hence we may consider K_p an r -linear mapping of T_p into \mathbf{R} (\rightarrow 256 Linear Spaces). If X_1, \dots, X_r are vector fields in M , we define a C^∞ -function $K(X_1, \dots, X_r)$ by $K(X_1, \dots, X_r)(p) = K_p((X_1)_p, \dots, (X_r)_p)$. Then the mapping that assigns to each r -tuple (X_1, \dots, X_r) of vector fields the C^∞ -function $K(X_1, \dots, X_r)$ is an r -linear mapping on the $\mathfrak{F}(M)$ -module $\mathfrak{X}(M)$ consisting of all vector fields of class C^∞ in M into $\mathfrak{F}(M)$; that is, $K(X_1, \dots, fX_i + gY_i, \dots, X_r) = fK(X_1, \dots, X_i,$

$\dots, X_r) + gK(X_1, \dots, Y_i, \dots, X_r)$ ($i = 1, \dots, r$) for $f, g \in \mathfrak{F}(M)$. Conversely any r -linear mapping of the $\mathfrak{F}(M)$ -module $\mathfrak{X}(M)$ into $\mathfrak{F}(M)$ can be interpreted as a covariant tensor field of order r in M . If the tensor field K is symmetric (alternating), the corresponding r -linear mapping $K(X_1, \dots, X_r)$ is symmetric (alternating) with respect to X_1, \dots, X_r . For the Lie derivative $L_X K$ of a covariant tensor field of order r of K , we have the following formula: $(L_X K)(X_1, \dots, X_r) = X(K(X_1, \dots, X_r)) - \sum_{i=1}^r K(X_1, \dots, [X, X_i], \dots, X_r)$.

P. Riemannian Metrics

A symmetric covariant tensor field g of order 2 and of class C^∞ in M is called a **pseudo-Riemannian metric** if the symmetric bilinear form g_p on the tangent vector space T_p is non-degenerate at each point $p \in M$; and g is called a **Riemannian metric** if g_p is positive definite for all p . If g is a Riemannian metric, the length $\|L\|$ of a tangent vector $L \in T_p$ is defined by $\|L\|^2 = g_p(L, L)$. On a paracompact C^∞ -manifold there always exists a Riemannian metric. A pair consisting of a differentiable manifold and a Riemannian metric on it is called a **Riemannian manifold** (\rightarrow 364 Riemannian Manifolds).

Q. Differential Forms

An alternating covariant tensor field in M of order r and of class C^t ($0 \leq t \leq \infty$) is also called a **differential form** (or **exterior differential form**) of degree r . A differential form of degree 1 is sometimes called a **Pfaffian form**. Let ω be a differential form of degree r . Since each alternating covariant tensor of order r at a point p is an element of $\wedge^r T_p^*$, the r -fold exterior product of T_p^* , the form ω is a mapping that sends each point p of M to an element ω_p of $\wedge^r T_p^*$. We can also regard ω as an alternating r -linear mapping of $\mathfrak{X}(M)$ into $\mathfrak{F}(M)$. Let (x^1, \dots, x^n) be the local coordinate system in a local coordinate neighborhood (U, ψ) . Since $(dx^i)_p$ ($i = 1, \dots, n$) is a basis of T_p^* at each point p of U , we can express ω_p ($p \in U$) uniquely in the form

$$\omega_p = \sum_{i_1 < \dots < i_r} a_{i_1 \dots i_r}(p) (dx^{i_1})_p \wedge \dots \wedge (dx^{i_r})_p,$$

where the sum extends over all ordered r -tuples (i_1, \dots, i_r) of indices such that $1 \leq i_1 < i_2 < \dots < i_r \leq n$. For an ordered r -tuple (i_1, \dots, i_r) of indices with repeated indices we put $a_{i_1 \dots i_r} = 0$, and for (i_1, \dots, i_r) with r distinct indices we put $a_{i_1 \dots i_r} = (\text{sgn } \sigma) a_{j_1 \dots j_r}$, where (j_1, \dots, j_r) ($j_1 < \dots < j_r$) is a permutation of (i_1, \dots, i_r) and $\text{sgn } \sigma$ denotes the sign of the permutation $\sigma: i_k \rightarrow j_k$

($k = 1, \dots, r$). Then we can write

$$\omega_p = \frac{1}{r!} \sum_{i_1, \dots, i_r=1}^n a_{i_1 \dots i_r}(p) (dx^{i_1})_p \wedge \dots \wedge (dx^{i_r})_p.$$

The functions $a_{i_1 \dots i_r}$ are the components of the tensor field ω , and ω is of class C^t if these components are of class C^t for any coordinate neighborhood. By the **support** (or **carrier**) of a differential form ω we mean the closure of the subset of M consisting of all p such that $\omega_p \neq 0$.

In the rest of this article, differential forms are always of class C^∞ , and we denote by $\mathfrak{D}^r(M)$ the real vector space consisting of all differential forms of degree r and of class C^∞ . In particular, $\mathfrak{D}^0(M) = \mathfrak{F}(M)$ and $\mathfrak{D}^r(M) = \{0\}$ for $r > n$, $n = \dim M$.

For differential forms we have the following five important operations.

(1) Exterior product. Let ω and θ be differential forms of degree r and s , respectively. The **exterior product** $\omega \wedge \theta$ of ω and θ is the differential form of degree $r+s$ defined by $(\omega \wedge \theta)_p = \omega_p \wedge \theta_p$, $p \in M$. Let X_1, \dots, X_{r+s} be $r+s$ vector fields in M . Then we have

$$(\omega \wedge \theta)(X_1, \dots, X_{r+s}) = \sum \text{sgn}(i; j) \omega(X_{i_1}, \dots, X_{i_r}) \theta(X_{j_1}, \dots, X_{j_s}),$$

where the summation runs over all possible partitions of $(1, 2, \dots, r+s)$ such that $i_1 < i_2 < \dots < i_r$, and $j_1 < j_2 < \dots < j_s$, and $\text{sgn}(i; j)$ means the sign of the permutation $(1, 2, \dots, r+s) \rightarrow (i_1, \dots, i_r, j_1, \dots, j_s)$. In particular, if $\omega_1, \dots, \omega_r$ are differential forms of degree 1, then we have $(\omega_1 \wedge \dots \wedge \omega_r)(X_1, \dots, X_r) = \det(\omega_i(X_j))$.

(2) Exterior differentiation. Let ω be a differential form of degree r , and let $\omega = (1/r!) \sum a_{i_1 \dots i_r} dx^{i_1} \wedge \dots \wedge dx^{i_r}$ in a coordinate neighborhood (U, ψ) . Then we can define a differential form $d\omega$ of degree $r+1$ by the condition $d\omega = (1/r!) \sum da_{i_1 \dots i_r} \wedge dx^{i_1} \wedge \dots \wedge dx^{i_r}$ in U . The differential form $d\omega$ is called the **exterior derivative** (or **exterior differential**) of ω . A differential form ω satisfying the condition $d\omega = 0$ is called a **closed differential form**, and a differential form η that can be expressed as $\eta = d\omega$ for some ω is called an **exact differential form**. If $a, b \in \mathbf{R}$ and $\omega, \omega' \in \mathfrak{D}^r(M)$, then we have $d(a\omega + b\omega') = ad\omega + bd\omega'$. Therefore the set $\mathfrak{C}^r(M)$ of all closed differential forms of degree r and the set $\mathfrak{E}^r(M)$ of all exact differential forms of degree r are linear subspaces of $\mathfrak{D}^r(M)$.

For the exterior derivative $d\omega$, we have the following formula:

$$\begin{aligned} (d\omega)(X_1, \dots, X_r) &= \sum_{i=1}^{r+1} (-1)^{i+1} X_i(\omega(X_1, \dots, \hat{X}_i, \dots, X_{r+1})) \\ &\quad + \sum_{i < j} (-1)^{i+j} \omega([X_i X_j], X_1, \dots, \hat{X}_i, \dots, \hat{X}_j, \dots, X_{r+1}), \end{aligned}$$

where the variables under the sign \wedge are to be omitted.

(3) Interior product with vector field. Let ω be a differential form of degree r and X a vector field. When $r \geq 1$, we can define a differential form $\iota(X)\omega$ of degree $r-1$ by the formula $(\iota(X)\omega)(X_1, \dots, X_{r-1}) = \omega(X, X_1, \dots, X_{r-1})$ for any $r-1$ vector fields X_1, \dots, X_{r-1} ; if $r=0$, we put $\iota(X)\omega=0$. The differential form $\iota(X)\omega$ is called the **interior product** of ω with X .

(4) Lie derivative. The **Lie derivative** $L_X\omega$ of a differential form of degree r with respect to a vector field X is a differential form of the same degree. For any r vector fields X_1, \dots, X_r , we have, by definition, $(L_X\omega)(X_1, \dots, X_r) = X(\omega(X_1, \dots, X_r)) - \sum_{i=1}^r \omega(X_1, \dots, [X, X_i], \dots, X_r)$.

(5) Let φ be a C^∞ -mapping of M into M' , and let $\varphi_p^*: T_{\varphi(p)}^* \rightarrow T_p^*$ be the \dagger transpose (or \dagger dual) of the linear mapping $(d\varphi)_p: T_p \rightarrow T_{\varphi(p)}$ for $p \in M$, i.e., the mapping defined by the condition $((d\varphi)_p L, \alpha) = (L, \varphi_p^* \alpha)$ for each $L \in T_p$, $\alpha \in T_{\varphi(p)}^*$. We denote the linear mapping of $\wedge T_{\varphi(p)}^*$ into $\wedge T_p^*$ induced by φ_p^* by φ_p^* also. Let ω be a differential form of degree r in M . Then a differential form $\varphi^*\omega$ in M , the **pullback** by φ of ω , is defined by $(\varphi^*\omega)_p = \varphi_p^* \omega_{\varphi(p)}$, $p \in M$.

The operations defined previously satisfy the following six important relations: (i) $d^2 = 0$, that is, $d(d\omega) = 0$; (ii) $d(\omega \wedge \theta) = d\omega \wedge \theta + (-1)^r \omega \wedge d\theta$, where ω is of degree r ; (iii) $\varphi^*(\omega \wedge \theta) = \varphi^*\omega \wedge \varphi^*\theta$, $\varphi^*(d\omega) = d(\varphi^*\omega)$; (iv) $L_X(\omega \wedge \theta) = (L_X\omega) \wedge \theta + \omega \wedge (L_X\theta)$; (v) $L_X = \iota(X) \cdot d + d \cdot \iota(X)$, $L_X(d\omega) = d(L_X\omega)$; and (vi) $L_{[X, Y]} = L_X \cdot L_Y - L_Y \cdot L_X$, $\iota([X, Y]) = L_X \cdot \iota(Y) - \iota(Y) \cdot L_X$.

R. De Rham Cohomology

Let $\mathfrak{D}(M) = \sum_{r=0}^n \mathfrak{D}^r(M)$, where $n = \dim M$. Then $\mathfrak{D}(M)$ is a \dagger cochain complex with \dagger coboundary operator d . We denote by $H^r(\mathfrak{D})$ the r -dimensional cohomology group of this cochain complex, and we call it the r -dimensional **de Rham cohomology group** of the differentiable manifold M . If we denote by $\mathfrak{C}^r(M)$ and $\mathfrak{E}^r(M)$ the subspaces of $\mathfrak{D}^r(M)$ consisting of closed differential forms and exact differential forms, respectively, then $H^r(\mathfrak{D}) = \mathfrak{C}^r(M)/\mathfrak{E}^r(M)$ ($0 \leq r \leq n$) by definition. If $\omega \in \mathfrak{C}^i(M)$ and $\theta \in \mathfrak{E}^r(M)$, then $\omega \wedge \theta \in \mathfrak{E}^{i+r}(M)$, and if $\omega \in \mathfrak{C}^i(M)$ and $\theta \in \mathfrak{E}^r(M)$ (or $\omega \in \mathfrak{E}^i(M)$ and $\theta \in \mathfrak{E}^r(M)$), then $\omega \wedge \theta \in \mathfrak{E}^{i+r}(M)$. So if we put $H(\mathfrak{D}) = \sum_{r=1}^n H^r(\mathfrak{D})$ (direct sum), we can define a product in $H(\mathfrak{D})$ by $[\omega] \cdot [\theta] = [\omega \wedge \theta]$ for each $[\omega] \in H^i(\mathfrak{D})$, $[\theta] \in H^r(\mathfrak{D})$. With respect to this product, $H(\mathfrak{D})$ forms an algebra over \mathbf{R} called the **de Rham cohomology ring** of M .

S. Partitions of Unity

Let M be a paracompact C^∞ -manifold, and let $\{V_i\}_{i \in I}$ be a \dagger locally finite open covering of M such that the closure of V_i is compact for each index i . Then there exists a C^∞ -function f_i in M for each i satisfying the following three conditions: (i) $0 \leq f_i \leq 1$, (ii) the support of f_i is contained in V_i , and (iii) $\sum_{i \in I} f_i(x) = 1$ for every $x \in M$. The family of C^∞ -functions f_i , $i \in I$, is called a **partition of unity of class C^∞** subordinate to the open covering $\{V_i\}_{i \in I}$.

T. Integrals of Differential Forms

Integrals over an Oriented Manifold. Let M be an n -dimensional paracompact oriented C^∞ -manifold and ω a differential form of degree n in M with compact support. We can choose a positively oriented atlas $S = \{(U_\alpha, \psi_\alpha)\}_{\alpha \in A}$ such that $\{U_\alpha\}_{\alpha \in A}$ is a locally finite covering; \bar{U}_α is compact for each α . Suppose first that the support of ω is contained in U_α for some index α . Then $(\psi_\alpha^{-1})^* \omega_\alpha$ is a differential form of degree n in $\psi_\alpha(U_\alpha)$, and we can express $(\psi_\alpha^{-1})^* \omega_\alpha$ in the form $adx^1 \wedge \dots \wedge dx^n$, where (x^1, \dots, x^n) are the coordinates in \mathbf{R}^n such that $x_\alpha^i = x^i \circ \psi_\alpha$ ($i = 1, \dots, n$) give a local coordinate system compatible with the orientation of M and a is a C^∞ -function with compact support. Then we define the integral of ω over M by

$$\int_M \omega = \int_{\psi_\alpha(U_\alpha)} a dx^1 \dots dx^n.$$

For the general case let $\{f_\alpha\}_{\alpha \in A}$ be a partition of unity of class C^∞ subordinate to $\{U_\alpha\}_{\alpha \in A}$. Then the support of $f_\alpha \omega$ is contained in U_α , and except for a finite number of the indices α , $f_\alpha \omega$ vanishes identically. Therefore we may define the integral of ω over M by

$$\int_M \omega = \sum_\alpha \int_M f_\alpha \omega,$$

and we can show that this definition of the integral is independent of the choice of oriented atlas S and of a partition of unity subordinate to S .

Integrals over a Singular Chain. We fix rectangular coordinates in \mathbf{R}^r . Let d_0 be the origin and d_i be the unit point on the i th coordinate axis. Let S^r denote the oriented r -simplex (d_0, d_1, \dots, d_r) with vertices d_0, d_1, \dots, d_r . When we regard S^r as a point set, we denote it by $|S^r|$. An **oriented singular r -simplex of class C^∞** in M is, by definition, a pair (S^r, φ) consisting of S^r and a C^∞ -mapping φ of an open neighborhood of $|S^r|$ into M . An element of the free \mathbf{Z} -module generated by singular r -simplexes of class C^∞ is called an **integral singular r -chain**

Differentiable Manifolds

of class C^∞ in M . We define a real singular r -chain of class C^∞ analogously. Let ω be a differential form of degree r and (S^r, φ) be an oriented singular r -simplex of class C^∞ in M . Then $\varphi^*\omega$ is a differential form of degree r in a neighborhood of $|S^r|$, and we can express $\varphi^*\omega$ in the form $\varphi^*\omega = a dx^1 \wedge dx^2 \wedge \dots \wedge dx^r$. We define the integral of ω over (S^r, φ) by

$$\int_{(S^r, \varphi)} \omega = \int_{|S^r|} a dx^1 \dots dx^r,$$

and the integral of ω over a singular r -chain C of class C^∞ by

$$\int_C \omega = \sum_i m_i \int_{(S^r, \varphi_i)} \omega,$$

where $C = \sum_i m_i (S^r, \varphi_i)$, $m_i \in \mathbf{Z}$ (or $m_i \in \mathbf{R}$).

When $r=0$, then ω is a function in M , and S^0 is a point o . In this case we put $\int_C \omega = \sum_i m_i \omega(\varphi_i(o))$.

Let $C_r(S, \mathbf{Z})$ ($C_r(S, \mathbf{R})$) be the \mathbf{Z} -module (vector space over \mathbf{R}) of integral (real) singular r -chains of class C^∞ in M , and let $\omega(C)$ be the value of the integral of ω over a chain C . Then ω is a linear function in the vector space $C_r(S, \mathbf{R})$, and hence we can consider ω a **singular r -cochain of class C^∞** .

U. Stokes's Formulas

(1) Let D be a domain in an n -dimensional C^∞ -manifold M , and let ∂D and \bar{D} be the boundary and the closure of D , respectively. Let $S = \{(U_\alpha, \psi_\alpha)\}_{\alpha \in A}$ be an atlas of class C^∞ of M , $U'_\alpha = U_\alpha \cap \bar{D}$, ψ'_α be the restriction of ψ_α to U'_α , and $T = \{(U'_\alpha, \psi'_\alpha)\}_{\alpha \in A}$. If the pair (\bar{D}, T) is a C^∞ -manifold with boundary under a suitable choice of S , then the domain D is called a **domain with regular (or smooth) boundary**.

The boundary ∂D of (\bar{D}, T) is then an $(n-1)$ -dimensional closed submanifold of M , and if M is orientable, ∂D is also orientable. Now let M be a paracompact and oriented manifold and D be a domain with regular boundary. Let C be a characteristic function of D in M , i.e., a function defined by the condition $C(p) = 1$ for $p \in D$ and $C(p) = 0$ for $p \notin D$. Let θ be a differential form of degree n in M with compact support. We define the integral of θ over D by

$$\int_D \theta = \int_M C \cdot \theta.$$

Let ω be a differential form of degree $n-1$ in M with compact support. We then have **Stokes's formula**:

$$\int_D d\omega = \int_{\partial D} i^* \omega,$$

where i denotes the identity mapping of the

submanifold ∂D into M with ∂D having the orientation induced naturally from that of M .

(2) Let C be a singular r -chain of class C^∞ in M , and let ∂C be the boundary of C . Then for any differential form ω of degree $r-1$, we have

$$\int_C d\omega = \int_{\partial C} \omega.$$

This formula is also called **Stokes's formula**.

V. De Rham's Theorem

Let M be a connected paracompact C^∞ -manifold. If we consider ω as a singular cochain, we have $(d\omega)(C) = \omega(\partial C)$; by Stokes's formula, this means that the exterior differential $d\omega$ of ω is equal to the coboundary of the singular cochain ω . Let ω and C be a closed differential form of degree r and a singular r -cycle of class C^∞ , respectively, and let $[\omega]$ and $[C]$ be the de Rham cohomology class and the singular homology class represented by ω and C . Using Stokes's formula, we can define the inner product $([\omega], [C])$ by

$$([\omega], [C]) = \int_C \omega.$$

Through this inner product, it follows that the de Rham cohomology group $H^r(\mathfrak{D})$ is isomorphic to the r th singular cohomology group $H^r(M, \mathbf{R})$, the dual space of the r th homology group of the complex of real singular chains of class C^∞ . Moreover, the de Rham cohomology ring $H(\mathfrak{D})$ is isomorphic to the singular cohomology ring $H^*(M, \mathbf{R})$ (**de Rham's theorem**).

W. Divergence of a Vector Field

Let M be an n -dimensional oriented C^∞ -manifold, and let S be an oriented atlas. Let ω be a differential form of degree n , and let (x^1, \dots, x^n) be the local coordinate system in a coordinate neighborhood in S . Then we can express ω in the coordinate neighborhood uniquely in the form $\omega = a dx^1 \wedge \dots \wedge dx^n$. If the function a is positive for any coordinate neighborhood in S , we call ω a **volume element** of M . In a paracompact oriented manifold, there always exists a volume element. (We remark that an n -dimensional differentiable manifold M is orientable if and only if there exists an everywhere nonvanishing differential form of degree n .) Let f be a C^∞ -function in M with compact support. Then $f \cdot \omega$ is a differential form of degree n with compact support, and so the integral

$$\int_M f \cdot \omega$$

is defined. We call this integral the **integral of the function f with respect to the volume element ω** .

Let g be a Riemannian metric in M and g_{ij} the components of g with respect to the local coordinate system (x^1, \dots, x^n) as before. Then we can define a volume element ω in M by putting $\omega = \sqrt{G} dx^1 \wedge \dots \wedge dx^n$, $G = \det(g_{ij})$ in each coordinate neighborhood. The volume element thus defined is called the **volume element associated with the Riemannian metric g** .

Let ω be a volume element and X a vector field in M . Then the Lie derivative $L_X \omega$ is also a differential form of degree n , and we can express $L_X \omega$ in the form $L_X \omega = f_X \cdot \omega$, where f_X is a scalar field, i.e., a function in M . We call f_X the **divergence** of the vector field X with respect to the volume element ω and denote it by $\text{div } X$. If ω is associated with a Riemannian metric, then $\text{div } X$ is called the **divergence** of X with respect to the Riemannian metric.

If M is compact, we have

$$\int_M \text{div } X \cdot \omega = 0$$

for any vector field X . This result is known as **Green's theorem**.

X. Jets

Let M and N be C^∞ -manifolds. We define an equivalence relation in the set of all C^∞ -mappings of M into N . Let f and g be such mappings and p be a point of M . Choosing local coordinate systems, we write $f(p) = (f_1(x), \dots, f_n(x))$, $g(p) = (g_1(x), \dots, g_n(x))$, $x = (x_1, \dots, x_m)$. We say f and g are equivalent at p if $f(p)$, $g(p)$, and the values at p of all the partial derivatives of f_i and g_i up to the order r (r an integer, $r \geq 0$) are equal ($i = 1, \dots, n$). An equivalence class with respect to this equivalence relation is called a **jet of order r at p** . A jet of order r at p represented by a function f is denoted by $j_p^r f$, and the points p and $f(p)$ are called the **source** and the **target** of the jet $j_p^r f$, respectively. We denote by $J_p^r(M, N)$ the set of all jets of order r with source at p and target in N and let $J^r(M, N) = \bigcup_{p \in M} J_p^r(M, N)$. For any jet j , let $\pi_s(j)$ and $\pi_t(j)$ denote the source and the target of j , respectively. We can introduce the structure of a C^∞ -manifold in $J^r(M, N)$ in a natural way such that the projections $\pi_s: J^r(M, N) \rightarrow M$ and $\pi_t: J^r(M, N) \rightarrow N$ are both of class C^∞ and $J^r(M, N)$ is a fiber bundle over $M(N)$ with projection $\pi_s(\pi_t)$. As examples, we have:

- (1) $J_0^1(\mathbf{R}, N)$ is identified with the tangent vector bundle of N .
- (2) The set $J^r(\xi)$ of all jets of order r deter-

mined by the sections of a vector bundle ξ of class C^∞ is also a vector bundle of class C^∞ .

Let $f: M \rightarrow N$ and $g: N \rightarrow L$ be C^∞ -mappings. We define a composition of jets by $j_{f(p)}^r g \cdot j_p^r f = j_p^r(g \circ f)$. A jet $j_p^r f \in J^r(M, N)$ is **invertible** if there exists a mapping $g: N \rightarrow M$ such that $j_{f(p)}^r g \cdot j_p^r f = j_p^r(1_M)$, where 1_M denotes the identity mapping of M onto itself. We denote by $I^r(M, N)$ the set of all invertible jets in $J^r(M, N)$, and put $I_p^r(M, N) = I^r(M, N) \cap J_p^r(M, N)$.

(3) Let $G^r(n)$ be the set of all invertible jets in $I^r(\mathbf{R}^n, \mathbf{R}^n)$ whose source and target are the origin of \mathbf{R}^n . Then with respect to the composition of jets, $G^r(n)$ forms a Lie group that is an extension of $G^1(n) = \text{GL}(n, \mathbf{R})$ by a simply connected nilpotent Lie group. The projection $G^r(n) \rightarrow G^1(n)$ is a special example of the natural projection $J^r(M, N) \rightarrow J^s(M, N)$ ($r \geq s$), which is defined in general.

(4) We can identify $I_0^1(\mathbf{R}^m, M)$ ($m = \dim M$) with the tangent m -frame bundle over M . More generally, $I_0^r(\mathbf{R}^m, M)$ is a $G^r(m)$ -bundle over M .

Y. Pseudogroup Structure

Let X be a topological space, and let Γ be a set consisting of homeomorphisms $f: U_f \rightarrow V_f$, where U_f, V_f are open subsets of X . We call Γ a **pseudogroup** of topological transformations if Γ satisfies the following four conditions: (i) Γ contains the identity mapping of X onto X ; (ii) if $f \in \Gamma$, then the restriction of f onto any open subset U of U_f is also contained in Γ ; (iii) if f and g are in Γ and $V_f \subset U_g$, then $g \circ f$ is contained in Γ ; and (iv) if $f \in \Gamma$, then $f^{-1}: V_f \rightarrow U_f$ is also in Γ .

Following the definition of differentiable manifolds we define a **pseudogroup structure** of M (or, more precisely, a Γ -structure of M) as a set A of bijections, with each member α defined on a subset U_α of M onto an open set V_α of X , satisfying the following three conditions: (i) $\bigcup_\alpha U_\alpha = M$; (ii) if $\alpha, \beta \in A$, then $\alpha \circ \beta^{-1} \in \Gamma$, where the domain of definition of $\alpha \circ \beta^{-1}$ is $\beta(U_\alpha \cap U_\beta)$; and (iii) A is the maximal set of bijections that satisfies conditions (i) and (ii). We introduce in M the weakest (coarsest) topology such that every bijection α is a homeomorphism. If Γ' is a pseudogroup of X containing Γ and A' is a Γ' -structure of M such that $A \subset A'$, then we say that A' is subordinate to A . If $X = \mathbf{R}^n$ (or H^n , a half-space of \mathbf{R}^n), Γ is the totality of diffeomorphisms of class C^r of open sets of X onto open sets of X , and M is a space with Hausdorff topology, then the Γ -structure is the C^r -structure with or without boundary which we have already defined. We give three examples of Γ -

structures subordinate to Γ' , where Γ' is the totality of local transformations of class C^r ($r \geq 1$) in \mathbf{R}^n .

(1) When n is even, we identify \mathbf{R}^n with $\mathbf{C}^{n/2}$ and denote the totality of holomorphic transformations of connected open domains by Γ . The Γ -structure in this case is called a **complex structure**.

(2) When n is odd, we define Γ as the totality of transformations of connected open domains in \mathbf{R}^n that leave invariant a Pfaffian form $\sum_{i=1}^m x^i dx^{m+i} + dx^{2m+1}$ ($n = 2m + 1$) up to scalar factors. The Γ -structure in this case is called a **contact structure**.

(3) We consider $\mathbf{R}^n = \mathbf{R}^p \times \mathbf{R}^{n-p}$ and define Γ as the set of all diffeomorphisms $U \rightarrow V$ (where U, V are open in \mathbf{R}^n) such that each set of the form $U \cap (\mathbf{R}^p \times \{y\})$ is mapped onto a set of the form $V \cap (\mathbf{R}^p \times \{y'\})$. The Γ -structure in this case is called a **foliated structure**.

The problem of determining whether there exists a Γ -structure for given Γ and M involves widely ranging problems of topology and analysis. The classification of Γ with reasonable conditions is another important open problem.

Haefliger has constructed the classifying space $B\Gamma$ for Γ -structures.

Z. Infinite-Dimensional Manifolds

Let B and B' be Banach spaces and φ be a mapping from an open set of B to B' . Then, using the notion of Fréchet derivatives, we can define φ to be smooth. For a smooth mapping φ , the Jacobian $J(\varphi)$ at each point x is a linear mapping from B to B' , for which the inverse function theorem holds true as a straightforward extension of the corresponding one in the finite-dimensional case. Similar extension also holds for the existence and the uniqueness theorems of solution of ordinary differential equations with value in B . These facts permit us to generalize the notion of differentiable manifolds to infinite-dimensional ones. Actually, infinite-dimensional manifolds can be defined in a way similar to the finite-dimensional case, taking open sets of a certain Banach space as local coordinate neighborhoods. Such a manifold is called a **Banach manifold**. Various formal definitions of differentiable manifolds can also be stated for Banach manifolds in extended form. However, while differentiable manifolds are locally compact and admit a partition of unity by smooth functions subordinate to a locally finite open covering, Banach manifolds generally lack these properties. Actually, local compactness gives a criterion for whether a manifold is finite-dimensional or not. Banach manifolds

often provide a basic functional-analytic view to nonlinear analysis and global analysis.

The most important category of Banach manifolds is provided by the **Hilbert manifold**, that is, a Banach manifold whose local coordinates are modeled on a Hilbert space. For a Hilbert manifold, a partition of unity subordinate to a locally finite open covering can be taken from smooth functions. In the following, we refer to a separable Hilbert manifold simply as a Hilbert manifold. An infinite-dimensional Hilbert manifold M can be smoothly embedded as an open set of a Hilbert space and thus covered by a single coordinate neighborhood. Hence, in particular, the tangent bundle of M is trivial. Historically, this fact was the first instance showing that the distinguishing properties are shared by infinite-dimensional manifolds; this was first recognized as a consequence of the theorem stating that the unitary group of an infinite-dimensional Hilbert space is contractible. Two infinite-dimensional Hilbert manifolds are diffeomorphic if and only if they are homotopically equivalent. A typical example of a Hilbert manifold is provided by the space of L^2 -loops on a compact Riemannian manifold. Morse theory can be extended in a suitable way to a Riemannian Hilbert manifold under the Palais-Smale condition, which makes it possible for the integral curve of $\text{grad } f$ to tend to a critical point, where f is a Morse function.

AA. Gelfand-Fuks Cohomology

The space $\mathfrak{X}(M)$ consisting of all the smooth vector fields on a smooth manifold M has the structure of a Lie algebra under the bracket operation $[X, Y] = XY - YX$, where the vector fields X and Y are regarded as derivations on the algebra $C^\infty(M)$ of smooth functions on M . $\mathfrak{X}(M)$ is a topological Lie algebra when endowed with the topology defined by uniform convergence of the components of vector fields and all their partial derivatives on each compact set of M . When $\mathfrak{X}(M)$ acts continuously on a topological vector space V , the continuous cohomology $H^*(\mathfrak{X}(M), V)$ of $\mathfrak{X}(M)$ with coefficients in V is the cohomology of the cochain complex $\bigoplus \{C^p = C^p(\mathfrak{X}(M), V), d\}$. Here $C^0 = V$, C^p ($p \geq 1$) is the space of all the alternating p -linear continuous mapping φ of $\mathfrak{X}(M) \times \dots \times \mathfrak{X}(M)$ (p -times) into V , and $d: C^p \rightarrow C^{p+1}$ is defined for $\varphi \in C^p$ and $X_i \in \mathfrak{X}(M)$ by $d\varphi(X_1) = X_1\varphi$ ($p=0$) and $d\varphi(X_1, \dots, X_{p+1}) = \sum_{i < j} (-1)^{i+j} \varphi([X_i, X_j], X_1, \dots, \hat{X}_i, \dots, \hat{X}_j, \dots, X_{p+1}) + \sum_i (-1)^{i+1} X_i \varphi(X_1, \dots, \hat{X}_i, \dots, X_{p+1})$ ($p \geq 1$). When V is a topological algebra and the elements of $\mathfrak{X}(M)$ act on V as derivations, the exterior multiplication of cochains induces

a graded algebra structure in $H^*(\mathfrak{X}(M), V)$. When $V = \mathbf{R}$ is the trivial $\mathfrak{X}(M)$ -module, then $H^*(\mathfrak{X}(M)) = H^*(\mathfrak{X}(M), \mathbf{R})$ is called the **Gel'fand-Fuks cohomology** of M . Gel'fand and Fuks proved that, for any compact oriented manifold M , we have $\dim H^p(\mathfrak{X}(M)) < +\infty$ for all p and $H^p(\mathfrak{X}(M)) = 0$ for $1 \leq p \leq n$ ($n = \dim M$). For example, if M is the circle S^1 , then the algebra $H^*(\mathfrak{X}(S^1))$ is generated by two generators $\alpha \in H^2$, $\beta \in H^3$, which are explicitly described as cochains in the following way:

$$\alpha\left(f \frac{d}{dt}, g \frac{d}{dt}\right) = \int_{S^1} \begin{vmatrix} f' & f'' \\ g' & g'' \end{vmatrix} dt,$$

$$\beta\left(f \frac{d}{dt}, g \frac{d}{dt}, h \frac{d}{dt}\right) = \int_{S^1} \begin{vmatrix} f & f' & f'' \\ g & g' & g'' \\ h & h' & h'' \end{vmatrix} dt.$$

Localization of the concept of Gel'fand-Fuks cohomology naturally yields the cohomology of **formal vector fields**. Here a formal vector field means the expression $\sum f_\mu(x_1, \dots, x_n) \partial / \partial x_\mu$, f_μ being formal power series in x_1, \dots, x_n . The set of all the formal vector fields forms a Lie algebra \mathfrak{a}_n and the continuous cohomology of \mathfrak{a}_n with respect to the Krull topology is denoted by $H^*(\mathfrak{a}_n)$. Let B_U be the universal classifying space of the unitary group $U(n)$, let $(B_U)_{2n}$ be its $2n$ -skeleton, and let P_{2n} be the canonical principal $U(n)$ -bundle restricted to $(B_U)_{2n}$. Then there is an algebra isomorphism $H^*(\mathfrak{a}_n) \cong H^*(P_{2n}; \mathbf{R})$. This cohomology and its variants play important roles in the theory of foliations.

An important subcomplex $\bigoplus \{C_\lambda^p, d\}$ of $\bigoplus \{C^p, d\}$, the diagonal complex, is defined as $C_\lambda^p = \{\varphi \in C^p \mid \varphi(X_1, \dots, X_p) = 0 \text{ if } \text{supp } X_1 \cap \dots \cap \text{supp } X_p = \emptyset\}$. Here, $\text{supp } X_i$ denotes the support of X_i , that is, $\{x \mid X_i(x) \neq 0\}$. Let P_M be the principal $U(n)$ -bundle associated with the complexified tangent bundle of M . $U(n)$ acts freely on the product $P_M \times P_{2n}$ and the quotient space $E_M = P_M \times P_{2n} / U(n)$ is a fiber bundle over M with fiber P_{2n} . Then, if M is a compact oriented manifold, the cohomology $H_\lambda^p(\mathfrak{X}(M))$ of the diagonal complex is completely determined by the isomorphisms $H_\lambda^p(\mathfrak{X}(M)) \cong H^{p+n}(E_M; \mathbf{R})$ for all p . In particular, if all the Pontryagin classes of M vanish, then $H_\lambda^p(\mathfrak{X}(M)) = \sum_{i+j=p+n} H^i(M; \mathbf{R}) \otimes H^j(\mathfrak{a}_n)$.

The Gel'fand-Fuks cohomology has a topological interpretation: $H^*(\mathfrak{X}(M)) \cong H^*(\Gamma(E_M), \mathbf{R})$ as graded algebras, where $\Gamma(E_M)$ denotes the space of all the continuous cross-sections of $E_M \rightarrow M$ with the compact open topology. Moreover the differential graded algebra $C^*(\mathfrak{X}(M))$ has a model in the sense of Sullivan constructed purely algebraically from a model of the de Rham algebra of M and the Pon-

tryagin classes of M . This model shows in particular that $H^*(\mathfrak{X}(M))$ is not necessarily finitely generated as a graded algebra.

The cohomology theory of $\mathfrak{X}(M)$ in the case where the representation is nontrivial has also been investigated. The natural representation on $C^\infty(M)$ is a typical example. There is also a topological interpretation: $H^*(\mathfrak{X}(M), C^\infty(M)) \cong H^*(Y_M, \mathbf{R})$, where Y_M is the fiber product of the evaluation mapping $M \times \Gamma(E_M) \rightarrow E_M$ and the inclusion $P_M \hookrightarrow E_M$ corresponding to a fiber inclusion $U(n) \hookrightarrow P_{2n}$.

106 (X.6) Differential Calculus

A. First-Order Derivatives

Let $y = f(x)$ be a real-valued function of x defined on an interval I of the real line \mathbf{R} . If for a fixed $x_0 \in I$, the limit

$$\lim_{\substack{h \rightarrow 0 \\ x_0 + h \in I}} \frac{f(x_0 + h) - f(x_0)}{h}$$

exists and is finite, then f is called **differentiable at the point** x_0 , and the limit is the **derivative (differential coefficient or differential quotient)** of f at the point x_0 . If f is differentiable at every point of a set $A \subset I$, then f is said to be **differentiable on** A . The function that assigns the derivative of f at x to $x \in A$ is called the **derivative (or derived function)** of $f(x)$, which is denoted by dy/dx , y' , \dot{y} , $df(x)/dx$, $(d/dx)f(x)$, $f'(x)$, or $D_x f(x)$. The process of determining f' is known as the **differentiation** of f . The derivative of f at the point x_0 is written $f'(x_0)$, $(df/dx)(x_0)$, $D_x f(x_0)$, $[dy/dx]_{x=x_0}$, etc. We say that f is **right (left) differentiable** or **differentiable on the right (left)** if the limit on the right, $\lim_{h \rightarrow +0} (f(x_0 + h) - f(x_0))/h$ (the limit on the left, $\lim_{h \rightarrow +0} (f(x_0 - h) - f(x_0))/h$), exists and is finite. This limit is called the **right (left) derivative** or **derivative on the right (left)** and is

denoted by $D_x^+ f(x_0)$ or $f'_+(x_0)$ ($D_x^- f(x_0)$ or $f'_-(x_0)$). For instance, if f is defined on $I = [a, b]$, then $D_x f(a)$ is identical to $D_x^+ f(a)$.

B. Differentials

In the definitions given above, neither dx nor dy in dy/dx has a meaning by itself. In the following, however, we give a definition of dx and dy , using the concept of increment, so that $dy = f'(x)dx$. Let Δy denote the **increment** $f(x + \Delta x) - f(x)$ of f corresponding to the increment Δx of x . Suppose that $f(x)$ is differentiable at x . We set $\Delta y/\Delta x = f'(x) + \varepsilon$. Then we have $\lim_{\Delta x \rightarrow 0} \varepsilon = 0$. This can be written utilizing Landau's notation as $\Delta y = f'(x)\Delta x + o(|\Delta x|)$ ($\Delta x \rightarrow 0$); in other words, Δy is the sum of two terms, of which the first, $f'(x)\Delta x$, is proportional to Δx and the second is an infinitesimal of an order higher than Δx . Here the principal part $f'(x)\Delta x$ of Δy is called the **differential** of $y = f(x)$ and is denoted by dy . The differential dy thus defined is a function of two independent variables x and Δx . In particular, if $f(x) = x$, from the definition we get $dx = 1 \cdot \Delta x = \Delta x$. Hence, in general, we have $dy = f'(x)dx$ and $f'(x) = dy/dx$.

With respect to the rectangular coordinates (x, y) , the straight line with slope $f'(x_0)$ through a point $(x_0, f(x_0))$ on the graph of $y = f(x)$ is the **tangent line** of the graph at the point $(x_0, f(x_0))$. A function is continuous at a point where the function is differentiable, but the converse of this proposition does not hold. In fact, Weierstrass showed that the function defined by the infinite series $\sum_{n=0}^{\infty} a^n \cos b^n \pi x$, where $0 < a < 1$ and b is an odd integer with $ab > (3/2)\pi + 1$, is continuous everywhere and nowhere differentiable on $(-\infty, \infty)$ [3].

C. Differentiation

For two differentiable functions f and g defined on the interval I , the following formulas hold: $(\alpha f + \beta g)' = \alpha f' + \beta g'$, where α and β are constants; $(fg)' = f'g + fg'$; and $(f/g)' = (f'g - fg')/g^2$ (at every point where $g \neq 0$). Let $y = f(x)$ be a function of x defined on the interval (a, b) and $x = \varphi(t)$ a function of t defined on (α, β) . If $\varphi(t) \in (a, b)$ whenever $t \in (\alpha, \beta)$, then the composite function $y = F(t) = f(\varphi(t)) = (f \circ \varphi)(t)$ is well defined. Assume further that f and φ are differentiable on (a, b) and (α, β) , respectively. Then the composite function $F(t) = (f \circ \varphi)(t)$ is differentiable on (α, β) , and we have the **chain rule**, $F'(t) = f'(x)\varphi'(t)$ ($x = \varphi(t)$), or $dy/dt = (dy/dx)(dx/dt)$. Assume that a function $y = f(x)$ is **strictly increasing** or **decreasing** and differentiable at x_0 . If furthermore we have

$f'(x) \neq 0$, then the inverse function $x = f^{-1}(y)$ is also differentiable at $y_0 (= f(x_0))$ and satisfies $(dx/dy)_{y=y_0} (dy/dx)_{x=x_0} = 1$. However, if $f'(x_0) = 0$, then even though $f^{-1}(y)$ is not differentiable at y_0 , $\lim_{\Delta y \rightarrow 0} (f^{-1}(y_0 + \Delta y) - f^{-1}(y_0))/\Delta y$ exists and is $+\infty$ or $-\infty$.

D. Higher-Order Derivatives

If the derivative $f'(x)$ of a function $y = f(x)$ is again differentiable on I , then $(f'(x))' = f''(x)$ is well defined as a function of x on I . In general, if $f^{(n-1)}(x)$ is differentiable on I , then $f(x)$ is called **n -times differentiable** on I , and the **n th derivative** (or **n th derived function**) $f^{(n)}(x)$ of $f(x)$ is defined by $f^{(n)}(x) = (f^{(n-1)}(x))'$ and is also denoted by $d^n y/dx^n$ or $D^{(n)}y$. The n th derivative for $n \geq 2$ is called a **higher-order derivative**.

Concerning the n th derivative of the product of two functions, **Leibniz's formula** holds:

$$(fg)^{(n)} = f^{(n)}g + \binom{n}{1}f^{(n-1)}g' + \dots + \binom{n}{k}f^{(n-k)}g^{(k)} + \dots + fg^{(n)}.$$

Analogous to $dy = y'\Delta x$, which is a function of x and Δx , we can define d^2y in the notation d^2y/dx^2 by $d^2y = d(dy) = d(y'\Delta x) = (y'\Delta x)'\Delta x = y''\Delta x^2$. Since $\Delta x = dx$, it follows from the above that $d^2y = y''dx^2$. Similarly, $d^n y = y^{(n)}dx^n$ and is called the **n th differential** (or **differential of n th order**) of $f(x)$.

E. The Mean Value Theorem

Let $f(x)$ be a continuous function defined on $[a, b]$, and suppose that for every point x_0 on (a, b) there exists a limit $\lim_{h \rightarrow 0} (f(x_0 + h) - f(x_0))/h$, which may be infinite. (These conditions are satisfied if $f(x)$ is differentiable on $[a, b]$.) Then there exists a point ξ such that

$$\frac{f(b) - f(a)}{b - a} = f'(\xi), \quad a < \xi < b.$$

This proposition is called the **mean value theorem**. A special case of the theorem under the further condition that $f(a) = f(b)$ is called **Rolle's theorem**. If we put $b - a = h$, $\xi = a + \theta h$, then the conclusion of the theorem may be written as $f(a + h) = f(a) + h \cdot f'(a + \theta h)$ ($0 < \theta < 1$).

This theorem implies the following: Let $f(x)$ be a function as in the hypothesis of the mean value theorem, and assume further that $A \leq f'(x) \leq B$ holds for all x with $a < x < b$. Then $A \leq (f(b) - f(a))/(b - a) \leq B$. (French mathematicians sometimes call this the "thé-

ème des accroissements finis.") Using the mean value theorem, the following theorem can be proved: If $f(x)$ is continuous on $[a, b]$ and $f'(x)$ exists and is positive on (a, b) , then $f(b) > f(a)$. Accordingly, if $f'(x) > 0$ at every point x of an interval I , then $f(x)$ is **strictly increasing** on that interval. (If $f'(x) < 0$ on I , then f is **strictly decreasing**.) The converse of the previous statement does not always hold ($f'(x) = x^3$ is a counterexample, since $f'(0) = 0$). Furthermore, from the mean value theorem it follows that if $f'(x) = 0$ everywhere in an interval, then $f(x)$ is constant on that interval. Consequently, two functions with the same derivative on an interval differ only by a constant.

Suppose that $f(x)$ is n -times differentiable on an open interval I . For a fixed $a \in I$ and an arbitrary $x \in I$, we put

$$f(x) = f(a) + \frac{f'(a)}{1!}(x-a) + \dots + \frac{f^{(n-1)}(a)}{(n-1)!}(x-a)^{n-1} + R_n.$$

Then $R_n = f^{(n)}(\xi)(x-a)^n/n!$ for some ξ between a and x . This is called **Taylor's formula**, where R_n is the **remainder** of the n th order given by Lagrange. We also have several other forms for R_n (\rightarrow Appendix A, Table 9). If $f^{(n)}(x)$ is continuous at $x = a$, then $\xi \rightarrow a$ as $x \rightarrow a$, and accordingly, $f^{(n)}(\xi) \rightarrow f^{(n)}(a)$. Hence $f(x) = \sum_{k=0}^n (f^{(k)}(a)/k!)(x-a)^k + o((x-a)^n)$. If $f^{(n)}(x)$ is continuous at $x = a$, then, by Taylor's formula, the value of the polynomial $\sum_{k=0}^n (f^{(k)}(a)/k!)(x-a)^k$ can be considered an approximate value of $f(x)$ for x near a . This approximation is called the **n th approximation** of $f(x)$, and its error is given by $|R_{n+1}|$. By applying this formula, it is sometimes possible to calculate a limit such as $A = \lim_{x \rightarrow a} f(x)/g(x)$, where $f(x) \rightarrow 0$ and $g(x) \rightarrow 0$ as $x \rightarrow a$. For instance, if $f'(x)$ and $g'(x)$ are both continuous at $x = a$ and $g'(a) \neq 0$, then by taking the first approximations of $f(x)$ and $g(x)$ it is easily seen that $A = f'(a)/g'(a)$. A limit of this type is often called a **limit of an indeterminate form** $0/0$. Similarly, we can calculate limits of such indeterminate forms as $0 \cdot \infty$ or 0^∞ (for limits of indeterminate forms \rightarrow [6]).

F. Partial Derivatives

Let $w = f(x, y, \dots, z)$ be a real-valued function of n independent real variables x, y, \dots, z defined on a domain G contained in n -dimensional Euclidean space \mathbf{R}^n . We obtain a function of a single variable from f by keeping $n-1$ variables (say, (x, y, \dots, z) , i.e., all except y) fixed. If

such a function $\varphi(y) = f(x_0, y, \dots, z_0)$ is differentiable, that is, if

$$\begin{aligned}\varphi'(y_0) &= \lim_{\Delta y \rightarrow 0} \frac{\varphi(y_0 + \Delta y) - \varphi(y_0)}{\Delta y} \\ &= \lim_{\Delta y \rightarrow 0} \frac{f(x_0, y_0 + \Delta y, \dots, z_0) - f(x_0, y_0, \dots, z_0)}{\Delta y}\end{aligned}$$

exists and is finite, then f is called **partially differentiable** with respect to y at (x_0, y_0, \dots, z_0) , and the derivative is called the **partial derivative** (or **partial differential coefficient**) of $f(x, y, \dots, z)$ with respect to y at (x_0, y_0, \dots, z_0) . It is denoted by $[\partial w / \partial y]_{x=x_0, \dots, z=z_0}$, $(\partial / \partial y)f(x_0, y_0, \dots, z_0)$, $f_y(x_0, y_0, \dots, z_0)$, or $D_y f(x_0, y_0, \dots, z_0)$, etc. We usually assume that the point (x, y, \dots, z) where partial derivatives are considered is an interior point of the domain of the function. Since in a space of dimension higher than 1, the boundary of a domain may be complicated, partial derivatives at boundary points are usually not considered. If a function f possesses a partial derivative with respect to x at every point of an open set G , then f_x is a function on G and is called a **partial derivative** of f with respect to x . The process of determining partial derivatives of f is called the **partial differentiation** of f .

G. Total Differential

Let $w = f(x, y, \dots, z)$ be a function defined on a domain G , and let $P = (x, y, \dots, z)$ be an interior point of the domain G of a function $w = f(x, y, \dots, z)$. Put $\Delta w = f(x_0 + \Delta x, y_0 + \Delta y, \dots, z_0 + \Delta z) - f(x_0, y_0, \dots, z_0)$. If there exist constants $\alpha, \beta, \dots, \gamma$ such that $\Delta w = \alpha \Delta x + \beta \Delta y + \dots + \gamma \Delta z + o(\rho)$ ($\rho \rightarrow 0$), where $\rho = \sqrt{\Delta x^2 + \Delta y^2 + \dots + \Delta z^2}$, then f is called **totally differentiable** (or **differentiable in the sense of Stolz**) at P . In this case, f is partially differentiable at P with respect to each of the variables x, y, \dots, z , and $\alpha = f_x(x_0, y_0, \dots, z_0)$, $\beta = f_y(x_0, y_0, \dots, z_0)$, \dots , $\gamma = f_z(x_0, y_0, \dots, z_0)$. The principal part of Δw as $\rho \rightarrow 0$ is $\alpha \Delta x + \beta \Delta y + \dots + \gamma \Delta z$, which is called the **total differential** of w at P . If f is totally differentiable at every point of G , then f is said to be totally differentiable on G . The total differential of w is denoted by dw . Since the total differentials of x, y, \dots, z are $dx = \Delta x, dy = \Delta y, \dots, dz = \Delta z$, respectively, we can write $dw = f_x dx + f_y dy + \dots + f_z dz$; and dw is a function of independent variables $x, y, \dots, z, dx, dy, \dots, dz$. The total differentiability of f implies the continuity of f , whereas the partial differentiability of f with respect to each variable does not imply that f is continuous. (Example: Define $f(x, y) = xy/(x^2 + y^2)$ for $(x, y) \neq (0, 0)$, and $f(0, 0) = 0$; then the func-

tion f is not continuous at $(0, 0)$, even though both f_x and f_y exist at $(0, 0)$.) The function f is totally differentiable on G if all f_x, f_y, \dots, f_z exist and are continuous on G , or, more weakly, if all f_x, f_y, \dots, f_z exist and, with possibly one exception, are continuous. Suppose that $w = f(x, y)$ is totally differentiable at (x, y) , and let $\Delta x = \rho \cos \theta, \Delta y = \rho \sin \theta$. As $\rho \rightarrow 0$, for a fixed θ there exists the limit $\lim_{\rho \rightarrow 0} (\Delta w / \rho) = f_x(x, y) \cos \theta + f_y(x, y) \sin \theta$. This limit is called the **directional derivative** in the direction θ at (x, y) . The partial derivatives f_x and f_y are special cases of the directional derivative for $\theta = 0$ and $\pi/2$, respectively. Suppose that we are given a curve lying in the interior of the domain of f and that the curve passes through the point (x, y) , where the curve is differentiable. Then the partial derivative of $w = f(x, y)$ in the direction of the normal to the curve at (x, y) is called the **normal derivative** of w at the point (x, y) on the curve and is denoted by $\partial w / \partial n$. Analogous definitions and notations have been introduced for functions of more than two variables.

To see the geometric significance of the total differentiability of $w = f(x, y)$, we consider the graph of the function $w = f(x, y)$ and a point $(a, b, f(a, b))$ on the graph. Then the plane represented by $w - f(a, b) = \alpha(x - a) + \beta(y - b)$ is the tangent plane to the surface at $(a, b, f(a, b))$ if and only if $\alpha = f_x(a, b)$ and $\beta = f_y(a, b)$. The existence of f_x and f_y depends on the choice of coordinate axes, while the total differentiability of f does not.

H. Higher-Order Partial Derivatives

Suppose that a partial derivative of a function $w = f(x, y, \dots, z)$ defined on an open set G again admits partial differentiation. The latter partial derivative is called a second-order partial derivative of f . We can similarly define the n th order partial derivatives. Higher-order partial derivatives are denoted as follows:

$$\frac{\partial}{\partial x} \left(\frac{\partial w}{\partial x} \right) = \frac{\partial^2 w}{\partial x^2} = f_{xx}(x, y, \dots, z),$$

$$\frac{\partial}{\partial y} \left(\frac{\partial w}{\partial x} \right) = \frac{\partial^2 w}{\partial x \partial y} = f_{xy}(x, y, \dots, z),$$

$$\frac{\partial}{\partial x} \left(\frac{\partial^2 w}{\partial x \partial y} \right) = \frac{\partial^3 w}{\partial x \partial y \partial x} = f_{xyx}(x, y, \dots, z), \dots$$

In general, f_{xy} and f_{yx} are not equal. (Peano's example: Let $f(x, y) = xy(x^2 - y^2)/(x^2 + y^2)$ for $(x, y) \neq (0, 0)$ and $f(0, 0) = 0$. Then $f_{xy} = -1$, $f_{yx} = 1$ at $(0, 0)$.) However, if both f_{xy} and f_{yx} are continuous on an open set G' , then they coincide in G' . Furthermore, if f_x, f_y , and f_{xy} exist in a neighborhood U of a point P belonging to the domain of f and f_{xy} is continuous

at P , then f_{yx} exists at P and $f_{xy} = f_{yx}$ (H. A. Schwarz). If f_x and f_y exist in U and are totally differentiable at P , then $f_{xy} = f_{yx}$ at P (W. H. Young). Similarly, if the partial derivatives of order ≥ 3 $f_{\dots xy \dots}$ and $f_{\dots yx \dots}$ are all continuous, then $f_{\dots xy \dots} = f_{\dots yx \dots}$. Hence we can change the order of differentiation if all the derivatives concerned are continuous.

I. Composite Functions of Several Variables

Let w be a function of x, y, \dots, z , and let each x, y, \dots, z be a function of t . Suppose that the range of $(x(t), y(t), \dots, z(t))$ is contained in the domain of w . Then w is a function of t . If further w is totally differentiable and x, y, \dots, z are all differentiable, then w as a function of t is differentiable, and we have

$$\frac{dw}{dt} = \frac{\partial w}{\partial x} \frac{dx}{dt} + \frac{\partial w}{\partial y} \frac{dy}{dt} + \dots + \frac{\partial w}{\partial z} \frac{dz}{dt}.$$

If partial derivatives of order ≥ 2 are totally differentiable, then $d^2w/dt^2, d^3w/dt^3, \dots$ are obtained by repeating the above procedure. A similar consideration is valid when x, y, \dots, z are functions of several variables.

J. Taylor's Formula for Functions of Several Variables

Suppose that $f(x, y)$ is defined on an open domain G , $f(x, y)$ has continuous partial derivatives of orders up to n , and the line segment $(a + (x-a)t, b + (y-b)t)$ ($0 \leq t \leq 1$) is contained in the domain G . Then there exists a number θ ($0 < \theta < 1$) such that

$$\begin{aligned} f(x, y) &= f(a, b) + \left((x-a) \frac{\partial}{\partial x} + (y-b) \frac{\partial}{\partial y} \right) f(a, b) \\ &+ \frac{1}{2!} \left((x-a) \frac{\partial}{\partial x} + (y-b) \frac{\partial}{\partial y} \right)^2 f(a, b) + \dots \\ &+ \frac{1}{(n-1)!} \left((x-a) \frac{\partial}{\partial x} + (y-b) \frac{\partial}{\partial y} \right)^{n-1} f(a, b) \\ &+ \frac{1}{n!} \left((x-a) \frac{\partial}{\partial x} + (y-b) \frac{\partial}{\partial y} \right)^n \\ &\quad \times f(a + (x-a)\theta, b + (y-b)\theta), \end{aligned}$$

where, for instance, the third term $((x-a) \cdot (\partial/\partial x) + (y-b)(\partial/\partial y))^2 f(a, b)$ means $(x-a)^2 (\partial^2 f / \partial x^2)(a, b) + 2(x-a)(y-b) \cdot (\partial^2 f / \partial x \partial y)(a, b) + (y-b)^2 (\partial^2 f / \partial y^2)(a, b)$, with $(\partial^2 f / \partial x^2)(a, b)$, $(\partial^2 f / \partial x \partial y)(a, b)$, and $(\partial^2 f / \partial y^2)(a, b)$ denoting the values of $(\partial^2 f / \partial x^2)$, $(\partial^2 f / \partial x \partial y)$, and $(\partial^2 f / \partial y^2)$ at (a, b) , respectively. The displayed formula is called **Taylor's formula** for a function of two variables. A similar

formula is valid for a function of n variables ($n \geq 3$). As in the case of functions of one variable, we can derive approximation formulas for f from Taylor's formula.

K. Classes of Functions

If all the partial derivatives of order n of $f(P)$ are continuous on an open set G , then f is said to be a **function of class C^n** (or **n -times continuously differentiable**) on G . The set of all n -times continuously differentiable functions is denoted by C^n ($n = 1, 2, \dots$). A continuous function is of class C^0 . A **function of class C^1** is also called a **smooth function**. It is obvious that $C^0 \supset C^1 \supset C^2 \supset \dots$. A partial derivative of order $r \leq s$ of a function belonging to class C^s does not depend on the order of the differentiation. A function belonging to $C^\infty = \bigcap_{r=1}^\infty C^r$ is said to be of class C^∞ or **infinitely differentiable**. We sometimes say that a function has a certain "nice" property or is "well behaved" if it belongs to some C^r ($r \geq 1$).

Let $w = f(x, y, \dots, z)$ be a function defined on an open set G in \mathbf{R}^n and $P = (a, b, \dots, c) \in G$. If

$$f(x, y, \dots, z) = f(a, b, \dots, c) + \sum_{r_1=1}^\infty \dots \sum_{r_n=1}^\infty \alpha_{r_1 r_2 \dots r_n} (x-a)^{r_1} (y-b)^{r_2} \dots (z-c)^{r_n}$$

holds in some open neighborhood U of P , where the right-hand side of the equality is an absolutely convergent series, then f is said to be **real analytic** at P . In this case, f is r -times differentiable at P for any r , and we have

$$\begin{aligned} \alpha_{r_1 r_2 \dots r_n} &= \frac{r_1! r_2! \dots r_n!}{(r_1 + r_2 + \dots + r_n)!} \\ &\quad \times \frac{\partial^{r_1+r_2+\dots+r_n} f}{\partial x^{r_1} \partial y^{r_2} \dots \partial z^{r_n}}(a, b, \dots, c). \end{aligned}$$

If f is real analytic at every point P of the domain G , then f is called a **real analytic function** on G . Sometimes, a real analytic function is called a function of class C^∞ . A real analytic function belongs to C^∞ , but the converse is not true (\rightarrow 58 C^∞ -Functions and Quasi-Analytic Functions E).

L. Extrema

Let f be a real-valued function defined on a domain G in an n -dimensional Euclidean space \mathbf{R}^n that has the point P_0 in its interior. If there exists a neighborhood U of P_0 such that for every point P ($\neq P_0$) of U we have $f(P) \geq f(P_0)$, then we say that f has a **relative minimum** at P_0 , and $f(P_0)$ is a **relative minimum** of f . Replacing \geq by \leq , we obtain the definition of a **relative maximum**. $f(P_0)$ is

called a **relative extremum** if it is either a relative maximum or a relative minimum.

To find relative extrema, the following facts concerning the sign of the derivative are useful. Suppose that a function of a single variable is differentiable on an interval I . Then we have the following: (1) If f has a relative extremum at an interior point x_0 of I , then $f'(x_0) = 0$. (2) If $f'(x_0) = 0$ and $f'(x)$ changes its sign at x_0 from positive (negative) to negative (positive), then f has a relative maximum (minimum) at x_0 . (3) If $f'(x_0) = 0$ and f is twice differentiable on some neighborhood of x_0 , then f has a relative maximum or minimum according as $f''(x_0) < 0$ or > 0 . If $f''(x_0) = 0$, then nothing definite can be concluded about a relative extremum of f at x_0 . In general, if there exists a neighborhood of x_0 in which f is r -times differentiable (r is even) and $f^{(r)}$ is continuous, and if $f'(x_0) = f''(x_0) = \dots = f^{(r-1)}(x_0) = 0$, $f^{(r)}(x_0) > 0$ (or < 0), then f has a relative minimum (maximum) at x_0 . On the other hand, if this condition holds with odd r , then $f(x_0)$ is not a relative extremum. If $f'(x_0) = 0$, then $f(x_0)$ is called a **stationary value** of f .

If a function f on n variables x, y, \dots, z has a relative extremum at (x_0, y_0, \dots, z_0) , then we have $f_x(x_0, y_0, \dots, z_0) = 0$, $f_y(x_0, y_0, \dots, z_0) = 0$, \dots , $f_z(x_0, y_0, \dots, z_0) = 0$, provided that the partial derivatives of f exist. Assume that for a function f of class C^2 of two variables x and y , we have $f_x(x_0, y_0) = 0$ and $f_y(x_0, y_0) = 0$, and let $\delta = f_{xx}(x_0, y_0)f_{yy}(x_0, y_0) - f_{xy}^2(x_0, y_0)$. Then we have the following: (1) If $\delta > 0$, then according as $f_{xx}(x_0, y_0) < 0$ or > 0 , f has a relative maximum or minimum at (x_0, y_0) . (2) If $\delta < 0$, then f does not have a relative extremum at (x_0, y_0) . (3) If $\delta = 0$, then without further information nothing definite can be said about a relative extremum of f at the point.

Let x_1, \dots, x_n be independent variables. If a function f of variables x_1, \dots, x_n has a relative extremum at a point $P_0 = (x_1^0, \dots, x_n^0)$, then $f_i = f_{x_i}(P_0) = 0$ ($i = 1, \dots, n$), provided that all the partial derivatives of f exist. In general, a point P_0 where f is totally differentiable and these conditions are satisfied is called a **critical point** of f . The value $f(P_0)$ at a critical point is called a **stationary value**. If further f is of class C^2 , then consider a *quadratic form of n variables $Q = Q(X_1, \dots, X_n) = \sum_{i,k} f_{i,k} X_i X_k$, where $f_{i,k} = f_{x_i x_k}(P_0)$. Suppose that $|f_{i,k}| \neq 0$. Then according to whether Q is *positive definite, *negative definite, or *indefinite, f has a relative minimum, relative maximum, or no relative extremum at P_0 . If $|f_{i,k}| = 0$, then nothing can be said in general. A critical point P of f is said to be **nondegenerate** if $|f_{i,k}| \neq 0$ and **degenerate** if $|f_{i,k}| = 0$.

We can also apply the method of differenti-

ation of *implicit functions to find relative extrema of functions defined implicitly. Given functions $\varphi_1, \dots, \varphi_m$ ($m < n$), the problem of finding a relative extremum of $f(x_1, \dots, x_n)$ under the condition that $\varphi_1(x_1, \dots, x_n) = 0, \dots, \varphi_m(x_1, \dots, x_n) = 0$ is called the problem of finding a **conditional relative extremum**.

This problem can be reduced to the problem of finding a relative extremum of an implicit function. Actually, if the functions $f, \varphi_1, \dots, \varphi_m$ are of class C^1 and the *Jacobian $\partial(\varphi_1, \dots, \varphi_m)/\partial(x_{n-m+1}, \dots, x_n)$ does not vanish in the domain considered, then $y_1 = x_{n-m+1}, \dots, y_m = x_n$ can be regarded as implicit functions of x_1, \dots, x_l ($l = n - m$). Hence we can set $f(x_1, \dots, x_l, y_1, \dots, y_m) = f^*(x_1, \dots, x_l)$. Then f has a relative extremum at (x_1^0, \dots, x_n^0) under the condition $\varphi_1 = \dots = \varphi_m = 0$ if and only if f^* has a relative extremum at $P_0 = (x_1^0, \dots, x_l^0)$. The latter condition implies that all $\partial f^*/\partial x_j$ ($j = 1, \dots, l$) vanish at P_0 , which holds if and only if for arbitrary constants $\lambda_1, \dots, \lambda_m$ the function $F(x_1, \dots, x_n) = f + \lambda_1 \varphi_1 + \dots + \lambda_m \varphi_m$ satisfies $\partial F/\partial x_i = 0$ ($i = 1, \dots, n$), and further $\varphi_1 = 0, \dots, \varphi_m = 0$ at (x_1^0, \dots, x_n^0) . From this system of equations we can often find the values of x_1^0, \dots, x_n^0 . This method of finding conditional relative extrema is called **Lagrange's method of indeterminate coefficients** or the **method of Lagrange multipliers** (\rightarrow 208 Implicit Functions; 216 Integral Calculus H; 379 Series H).

107 (XIII.1) Differential Equations

A. Ordinary Differential Equations

It was Galileo who found that the acceleration of a falling body is a constant and thence derived his law of a falling body $x(t) = gt^2/2$ as what we would now view as a solution of the differential equation $x''(t) = g$, where $x(t)$ denotes the distance the body has fallen during the time interval t and g is the constant gravitational acceleration. This pioneering work may be regarded as the first example of solution of a differential equation. Also, the \dagger equations of motion, proposed by I. \dagger Newton as the mathematical formulation of the law of motion, including Galileo's law as a special case, are differential equations of the second order. Thus differential equations appeared, simultaneously with differential and integral calculus, as an indispensable tool for the unified and concise expression of the laws of nature. Such laws are generally called **differential laws**.

Newton completely solved the equations of the \dagger two-body problem proposed by himself; G. W. \dagger Leibniz also succeeded in solving many simple differential equations.

In the 18th century, many mathematicians, such as the \dagger Bernoullis, A. C. Clairaut, J. F. Riccati, L. \dagger Euler, and J. L. \dagger Lagrange, attacked and solved differential equations of various types independently. In that period, the emphasis was on solution by **quadrature**, that is, applying to \dagger elementary functions a finite number of algebraic operations, transformations of variables, and indefinite integrations. It was toward the end of the 18th century that new methods, such as integration by infinite series, came to be discussed. A method of variation of constants for the solution of linear ordinary differential equations was invented by Lagrange in 1775. At the beginning of the 19th century, C. F. \dagger Gauss

initiated the study of differential equations satisfied by \dagger hypergeometric series.

The problem of existence of solutions, which supplies a foundation of modern differential equation theory, was first treated by A. L. \dagger Cauchy. His proof of the existence theorem was later improved by R. L. Lipschitz (1869).

Pioneers in the function-theoretic treatment of differential equations were C. A. A. Briot and J. C. Bouquet, who investigated the singular points of a function defined by an analytic differential equation. Also, B. \dagger Riemann proposed a new viewpoint which influenced L. Fuchs in his development of the theory of linear ordinary differential equations in the complex domain (1865). Works of A. M. Legendre on \dagger elliptic functions and of H. \dagger Poincaré on \dagger automorphic functions should also be mentioned in this connection.

After the Cauchy-Lipschitz existence theorem for the equation $y' = f(x, y)$ was known, efforts were directed toward weakening the conditions imposed on $f(x, y)$. G. Peano first succeeded in giving a proof under the continuity assumption only (1890), and his results were sharpened by O. Perron (1915).

Regarding the uniqueness of solutions of \dagger initial value problems, there are various results by W. F. Osgood (1898), Perron (1925), and many Japanese mathematicians. In the course of this work the necessary and sufficient condition for uniqueness was successfully formulated in a concise form (\rightarrow 316 Ordinary Differential Equations (Initial Value Problems)).

For linear differential equations with periodic coefficients, investigations were carried out by C. Hermite (1877), E. Picard (1881), G. Floquet (1883), G. W. Hill (1886), and others. For instance, solutions satisfying $y(x + \omega) = \lambda y(x)$ were found to exist, where ω is the period of the coefficients. Analogous results followed in the case of doubly periodic coefficients.

Techniques of factorization of linear differential equations developed by G. Frobenius (1873) and E. Landau (1920) should also be noted. Picard (1883), J. Drach (1898), and E. Vessiot (1903, 1904) established a remarkable result on the solvability (in the sense of solution by quadrature) of linear differential equations, successfully extending the \dagger Galois theory in this new direction.

The concept of \dagger asymptotic series, which in a sense approximate the solution of differential equations, was introduced by Poincaré (1886) and extended by M. A. Lyapunov (1892), J. C. C. Kneser (1896), J. Horn (1897), C. E. Love (1914), and others. Poincaré was also the founder of topological methods in differential

equation theory, and his ideas were developed extensively by I. Bendixson (1900), Perron (1922, 1923), G. D. Birkhoff, and others (→ 126 Dynamical Systems).

In 1890, Picard invented an ingenious technique of [†]successive approximation for the proof of existence theorems, and his technique is now widely used in every application of functional equations. The technique of reducing linear differential equations to linear [†]integral equations of Volterra type was also developed.

On the [†]boundary value problems and [†]eigenvalue problems that appear in many areas of physics, there was extensive research by mathematicians such as J. C. F. Sturm (1836), J. Liouville, L. Tonelli, Picard, M. Bôcher (1898, 1921), Birkhoff (1901, 1911), and others. In this connection the problem arises of expanding a given function by an [†]orthogonal system of functions obtained as [†]eigenfunctions of a given boundary value problem. Those problems were brought into unified form by D. [†]Hilbert (1904) in his theory of [†]integral equations. Subsequently boundary value problems of ordinary and partial differential equations came to be discussed in this framework.

Finally, it should be mentioned that the [†]calculus of variations created by Euler and Lagrange gave rise to the study of a certain class of differential equations bearing the name of Euler (→ 46 Calculus of Variations).

B. Partial Differential Equations

The origin of partial differential equations can be traced back to the study of hydrodynamic problems by J. d'Alembert (1744) and Euler. However, perhaps Lagrange and P. S. [†]Laplace were the first to investigate the general theory. Subsequently, during the 18th and 19th centuries, it was developed by G. Monge, A.-M. Ampère, J. F. Pfaff, C. G. [†]Jacobi, Cauchy, S. [†]Lie, and many other mathematicians. The fundamental existence theorem for the initial value problem, now called the Cauchy-Kovalevskaya theorem, was proved by S. Kovalevskaya in 1875 (→ 321 Partial Differential Equations (Initial Value Problems) B).

Because of their close connection with problems of physics, linear equations of the second order have been a chief object of research. Up to the 19th century, classification into [†]elliptic, [†]hyperbolic, and [†]parabolic types and the study of boundary and initial value problems for each of these types constituted the main part of the theory.

In the 20th century, more complicated

problems—[†]nonlinear problems appearing in the study of viscous or compressible fluids, or the study of equations of [†]mixed type in connection with supersonic flow—have emerged as important topics; and the newly developed techniques of functional analysis have brought about remarkable changes. Especially in the study of the [†]Schrödinger equations of quantum mechanics and of more general [†]evolution equations, this method has proved to be a powerful tool.

Finally, we should not fail to mention that the development of electronic computers has made it possible to obtain numerical solutions and to discover many important facts. [†]Numerical analysis is now becoming an indispensable part of the theory (→ 304 Numerical Solution of Partial Differential Equations).

108 (XIX.10) Differential Games

A. Introduction

The study of differential games arose from the study of pursuit and evasion problems and various tactical problems. The first work was done by R. P. Isaacs [1] in a series of RAND Corporation memoranda that appeared in 1954. He applied to many illustrative examples the method of Hamilton-Jacobi differential equations (\rightarrow eq. (4) below). The heuristic results of Isaacs were made rigorous by W. H. Fleming [2], L. D. Berkovitz [3], A. Friedman [4, 5], and others.

B. Zero-Sum Two-Person Games

Suppose that there are two antagonists, each exerting partial control over the state of a system. One wishes to maximize a given payoff that is a functional of the state and the control exerted, while the other wishes to minimize this payoff. Let the state of a differential game at time t be represented by an n -dimensional vector $x(t) \in \mathbf{R}^n$. In a zero-sum differential game between two players I and II, we are given a system of n differential equations

$$dx/dt = f(t, x, u, v) \quad (1)$$

with an initial condition $x(\tau) = \xi \in \mathbf{R}^n$, where $u \in \mathbf{R}^p$ is chosen at each instant of time by player I and $v \in \mathbf{R}^q$ is chosen by player II. We assume that the function $f(t, x, u, v)$ is continuous in t and continuously differentiable on the entire (x, u, v) -space.

It is usually assumed that both players know the present state of the game and that they know how the game proceeds; that is, they know the system (1). Each player can take the state of the game into account in making his choice. Thus player I can let his choice of u be governed by a vector function $u(t, x)$ defined on D , where $D \subset [0, \infty) \times \mathbf{R}^n$ is a fixed region of the (t, x) -space. Similarly, player II can let his choice of v be governed by a vector function $v(t, x)$ defined on D .

A finite collection of subregions D_1, \dots, D_r of a region D is said to constitute a decomposition of D whenever the following conditions hold: (i) Each D_i ($i = 1, \dots, r$) is connected and has a piecewise smooth boundary; (ii) $D_i \cap D_j = \emptyset$ if $i \neq j$. A function defined on \bar{D} is said to be piecewise C^1 in x on \bar{D} if there is a decomposition of D such that on each D_i the function and all its derivatives with respect to x are continuous in (t, x) on \bar{D}_i . Let U and V be fixed closed subsets of \mathbf{R}^p and \mathbf{R}^q , respectively.

Let S_u denote the class of functions $u(t, x)$ that are piecewise C^1 in x on \bar{D} and have their range in U . Similarly, let S_v denote the class of functions $v(t, x)$ that are piecewise C^1 in x on \bar{D} and have their range in V .

Let $u \in S_u$ and $v \in S_v$, and consider the differential equation

$$dx/dt = f(t, x, u(t, x), v(t, x)), \quad (2)$$

subject to the initial condition

$$x(\tau) = \xi. \quad (3)$$

We say that a pair $(u, v) \in S_u \times S_v$ is **playable** if for every (τ, ξ) in D every solution of (2) satisfying (3) stays in D and reaches a terminal manifold F in finite time, where F is a smooth manifold contained in \bar{D} . Let $\Omega_u \subset S_u$, $\Omega_v \subset S_v$ be the maximal pair of subclasses such that each pair $(u, v) \in \Omega_u \times \Omega_v$ is playable. We call the functions in Ω_u and Ω_v the **strategies** for the players.

For each strategy pair (u, v) we can define a functional

$$J(\tau, \xi, u, v) = g(t_1, x(t_1)) + \int_{t_0}^{t_1} h(t, x(t), u(t, x(t)), v(t, x(t))) dt,$$

where $x(t)$ is a solution of (2) and (3) and t_1 is the first time that $(t, x(t))$ reaches the terminal manifold F . The functional J is called the **payoff**.

Let $(u^*, v^*) \in \Omega_u \times \Omega_v$ be a strategy pair. Suppose that for any $u \in \Omega_u$ and $v \in \Omega_v$, the inequalities

$$J(\tau, \xi, u, v^*) \leq J(\tau, \xi, u^*, v^*) \leq J(\tau, \xi, u^*, v)$$

hold for all $(\tau, \xi) \in D$. We say that (u^*, v^*) is a **saddle point** relative to the classes Ω_u and Ω_v . The function

$$W(t, x) = J(t, x, u^*, v^*)$$

defined on D is called the **value function** of the game. Berkovitz [3] proved that the value function $W(t, x)$ is continuous on D and continuously differentiable on each D_i and satisfies

$$\begin{aligned} & \max_{u \in U} [h(t, x, u, v^*) + W_x(t, x)f(t, x, u, v^*)] \\ &= \min_{v \in V} [h(t, x, u^*, v) + W_x(t, x)f(t, x, u^*, v)] \\ &= h(t, x, u^*, v^*) + W_x(t, x)f(t, x, u^*, v^*) \\ &= -W_t(t, x). \end{aligned} \quad (4)$$

Equation (4) is called the **Hamilton-Jacobi equation**.

Let $x^*(t; \tau, \xi)$ be the optimal trajectory corresponding to the saddle-point strategies (u^*, v^*) and resulting from an initial point $(\tau, \xi) \in D$. Then there exists an n -dimensional continuous

vector function $\lambda(t; \tau, \xi)$ such that the following hold [3]:

(i) The functions x^* and λ satisfy the system of differential equations

$$dx/dt = f(t, x, u^*(t, x), v^*(t, x)),$$

$$d\lambda/dt = -H_x(t, x, \lambda, u^*(t, x), v^*(t, x)),$$

where

$$H(t, x, \lambda, u, v) = h(t, x, u, v) + \lambda f(t, x, u, v).$$

(ii) If $x = x^*(t; \tau, \xi)$, $t \geq \tau$, then

$$W_x(t, x) = \lambda(t; \tau, \xi).$$

(iii) At $t = t_1$, the transversality condition

$$H \frac{\partial T}{\partial \sigma} + \frac{\partial g}{\partial t} \frac{\partial T}{\partial \sigma} + \frac{\partial g}{\partial x} \frac{\partial X}{\partial \sigma} - \lambda \frac{\partial X}{\partial \sigma} = 0$$

holds, where the terminal manifold F is given parametrically by the relations

$$t = T(\sigma), \quad x = X(\sigma),$$

σ ranging over a cube in some finite-dimensional Euclidean space.

(iv) For all $\tau \leq t \leq t_1$,

$$\max_{u \in U} \min_{v \in V} H(t, x^*(t), \lambda(t), u, v)$$

$$= \min_{v \in V} \max_{u \in U} H(t, x^*(t), \lambda(t), u, v)$$

$$= H(t, x^*(t), \lambda(t), u^*(t, x^*(t)), v^*(t, x^*(t))).$$

P. Varaiya and J. Lin [6] and Friedman [4, 5] have defined certain special classes of differential games, and have shown that under their definitions the games have nonzero value functions.

C. N-Person Differential Games

In a differential game between many players, the state vector $x(t) \in \mathbf{R}^n$ is governed by

$$dx/dt = f(t, x, u_1, \dots, u_N), \quad x(\tau) = \xi,$$

where $u_i \in \mathbf{R}^{p_i}$ is chosen at each instant of time by player i . Each u_i is constrained to lie in a fixed closed subset U_i of \mathbf{R}^{p_i} . Let S_i be the class of functions $u_i(t, x)$ that are piecewise C^1 in x on \bar{D} and have their range in U_i .

We say that an element $u = (u_1, \dots, u_N)$ of $S_1 \times \dots \times S_N$ is **playable** if, for every $(\tau, \xi) \in D$, every solution of the differential equation

$$dx/dt = f(t, x, u_1(t, x), \dots, u_N(t, x)), \quad x(\tau) = \xi, \quad (5)$$

stays in D and reaches a terminal manifold F in finite time. Let $\Omega_i \subset S_i$ ($i = 1, \dots, N$) be the maximal subclasses such that each element $u = (u_1, \dots, u_N) \in \Omega_1 \times \dots \times \Omega_N$ is playable. We call the functions $u_i \in \Omega_i$ ($i = 1, \dots, N$) the **strategies**. For each strategy N -tuple we define

a **payoff**

$$J_i(\tau, \xi, u_1, \dots, u_N) = g_i(t_1, x(t_1))$$

$$+ \int_{t_0}^{t_1} h_i(t, x(t), u_1(t, x(t)), \dots, u_N(t, x(t))) dt,$$

where $x(t)$ is a solution of (5) and t_1 is the first time that $(t, x(t))$ reaches the terminal manifold F . Each player i is to choose his strategy $u_i \in \Omega_i$ so as to maximize his own payoff J_i .

There are many definitions of "solution" for games involving more than two players. A strategy N -tuple $u^* = (u_1^*, \dots, u_N^*)$ is called an **equilibrium point** for the game if the inequalities

$$J_i(u_1^*, \dots, u_{i-1}^*, u_i, u_{i+1}^*, \dots)$$

$$\leq J_i(u_1^*, \dots, u_{i-1}^*, u_i^*, u_{i+1}^*, \dots) \quad (i = 1, \dots, N)$$

hold for any $u_i \in \Omega_i$, \dots , $u_N \in \Omega_N$. J. H. Case [9] has shown that the conclusions drawn for zero-sum two-person games also hold for N -person differential games.

109 (VII.1) Differential Geometry

In differential geometry in the classical sense, we use differential calculus to study the prop-

erties of figures such as curves and surfaces in Euclidean planes or spaces. Owing to his studies of how to draw tangents to smooth plane curves, P. †Fermat is regarded as a pioneer in this field. Since his time, differential geometry of plane curves, dealing with curvature, †circles of curvature, †evolutes, †envelopes, etc., has been developed as a part of calculus. Also, the field has been expanded to analogous studies of space curves and surfaces, especially of †asymptotic curves, †lines of curvature, †curvatures and †geodesics on surfaces, and †ruled surfaces. C. F. †Gauss founded the theory of surfaces by introducing concepts of the †geometry on surfaces (*Disquisitiones circa superficiem curvas*, 1827). Gauss recognized the importance of the intrinsic geometry of surfaces, and it is generally agreed that differential geometry as it is known today was initiated by him. Thus differential geometry came to occupy a firm position as a branch of mathematics. The influence that differential-geometric investigations of curves and surfaces have exerted upon branches of mathematics, physics, and engineering has been profound. For example, E. Beltrami discovered an intimate relation between the geometry on a †pseudo-sphere and †non-Euclidean geometry. The study of †geodesics is a fertile topic deeply related to dynamics, the calculus of variations, and topology, on which there is excellent work by J. Hadamard, H. †Poincaré, P. Funk, G. D. Birkhoff, M. Morse, R. Bott, W. Klingenberg, and M. Berger, among others. The theory of minimal surfaces initiated by J. L. Lagrange was an application of the calculus of variations. At the early stages of development, G. Monge, J. B. M. C. Meusnier, A. M. Legendre, O. Bonnet, B. Riemann, K. Weierstrass, H. A. Schwarz, Beltrami, and S. Lie contributed to the theory. Weierstrass and Schwarz established its relationship with the theory of functions. J. A. Plateau showed experimentally that †minimal surfaces can be realized as soap films by dipping wire in the form of a closed space curve into a soap solution (1873). The Plateau problem, i.e., the problem of proving mathematically the existence of a minimal surface with prescribed boundary curve, was solved by Tibor Radó in 1930 and independently by J. Douglas in 1931. Although the relationship to function theory is lost for higher-dimensional minimal submanifolds, their study is intimately related to the calculus of variations and topology.

Euclidean geometry is a geometry belonging to F. Klein's Erlangen program (→ 137 Erlangen Program). For other geometries in the sense of F. Klein we may also consider the corresponding differential geometries. For instance, in †projective differential geometry we study

by means of differential calculus the properties of curves and surfaces that are invariant under projective transformations. This subject was studied by E. J. Wilczynski, G. Fubini, and others; †affine differential geometry and †conformal differential geometry were studied by W. Blaschke and others (→ 110 Differential Geometry in Specific Spaces).

Influenced by Gauss's geometry on surfaces, in his inaugural address at Göttingen in 1854 Riemann advocated an intrinsic differential geometry completely independent of embeddings (*Über die Hypothesen, welche der Geometrie zugrund liegen*; *Werke*, 2nd ed. 1892, 272–287) (→ 364 Riemannian Manifolds). Removing the restriction to two dimensions and considering abstract manifolds of dimension n , he introduced what is now known as the Riemannian metric; actually he considered the more general metrics that had formed the subject matter of the dissertation of P. Finsler in 1918 (→ 152 Finsler Spaces). Riemannian geometry includes Euclidean and non-Euclidean geometry as special cases, and is important for the great influence it exerted on geometric ideas of the 20th century. Under the influence of the algebraic theory of invariants, Riemannian geometry was then studied as a theory of invariants of quadratic †covariant tensors by E. B. Christoffel, C. G. Ricci, and others. Riemannian geometry attracted wide attention after A. Einstein applied it to the †general theory of relativity in 1916.

In the same year, T. Levi-Civita introduced the notion of †Levi-Civita parallelism, which contributed greatly to the clarification of geometric properties of Riemannian spaces. Observing parallelism to be an affine-geometric concept, H. Weyl and A. S. Eddington developed a theory of Riemannian spaces “affinely” based on the notion of parallelism without using metrical methods. Such a geometry is called a geometry of an affine connection (→ 80 Connections).

Every straight line in a Euclidean space has the property that all tangents to the line are parallel. In a space with an affine connection, we may define a family of curves called †paths as an analog of straight lines. Such curves are solutions of a system of ordinary differential equations of the second order of a certain type. Coefficients of such differential equations determine a parallelism and hence an affine connection. H. Weyl discovered transformations of coefficients that leave the family of paths invariant as a whole, namely, projective transformations of an affine connection. A geometry that aims to study properties of paths or affine connections that are invariant under these transformations is called a **projective geometry of paths**. Such geometry was

studied by L. P. Eisenhart, O. Veblen, and others. The concept of projective connections was an outcome of such studies. Similarly, the concept of conformal connections was developed from the consideration of [†]conformal transformations of Riemannian spaces.

These geometries cannot in general be regarded as geometries in the sense of Klein. Actually, any one of these geometries generally has no transformations that correspond to [†]congruent transformations of geometries in the sense of Klein; even if it has such transformations, they do not act transitively on the space. Thus geometries are naturally divided into two categories, one consisting of geometries in the sense of Klein (based on the group concept) and the other of geometries based on Riemann's idea. Under such circumstances, E. Cartan unified the thoughts of Klein and Riemann from a higher standpoint and constructed his theory of connections in a series of papers published between 1923 and 1925. He developed the theory of affine, projective, and conformal connections from a viewpoint consistent with that of Klein. Just as each tangent space of a Riemannian manifold is viewed as a Euclidean space, an affine connection regards the tangent space at each point as an affine space and develops it onto the tangent space at an infinitesimally nearby point. In discussing projective connections Cartan attached a projective space to each point of a manifold as an infinitesimal approximation, and similarly for conformal connections. More generally, he attached to each point of a manifold a fixed Klein space, i.e., a homogeneous space of a Lie group, called the structure group. Thus Cartan introduced the concept of fiber bundle (\rightarrow 147 Fiber Bundles). Then he defined a connection as a development of the fiber, i.e., the generalized tangent space, at each point onto the fiber at an infinitesimally nearby point (\rightarrow 80 Connections B). If G is the group of congruent transformations in Euclidean space, a manifold with connection having G as its structural group is called a **manifold with Euclidean connection**. Among manifolds with Euclidean connection, Riemannian manifolds are characterized as those without [†]torsion. If we take the group of congruent transformations of projective (conformal) geometry as G , we have manifolds with projective (conformal) connection in the sense of Cartan. Among these, there are remarkable ones called manifolds with normal projective (or conformal) connections, which are essentially the same as the ones studied by Veblen and others. Cartan's idea had a profound influence on modern differential geometry. The method of moving frames, created by G. Darboux and extensively used by Cartan in his theory of connections, was a

forerunner of the theory of fiber bundles. Combining [†]Grassmann algebra with differential calculus, Cartan developed a powerful computational tool known as calculus of differential forms (\rightarrow 105 Differentiable Manifolds Q). Differential forms have become indispensable in topology, algebraic geometry, and in studies of functions of several complex variables, as well as in differential geometry.

The work of Lie on transformation groups also had a profound influence on Cartan. The latter's work on [†]Lie groups, particularly on simple Lie groups, and on differential geometry culminated in 1926 in his discovery of [†]Riemannian symmetric spaces. These spaces are natural generalizations of the spherical surface and the unit disk in the complex plane with Poincaré metric, and play essential roles in unitary representation theory and in other areas of mathematics.

A tangent line to a curve C at a point P of C is the limit line of the line PQ , where Q is a point on C approaching P ; hence we can define it locally. A concept (or property), such as this, that can be defined in an arbitrary small neighborhood of a point of a given figure or a space is called a **local concept** (or **local property**) or a concept (or property) **in the small**. In the early stages of the development of differential geometry, differential calculus was the main tool of study, so most of the results were local. On the other hand, a concept (or property) that is defined in connection with a whole figure or a whole space is called **global** or **in the large**. In modern differential geometry, the study of relations between local and global properties has attracted the interest of mathematicians. This view was emphasized by Blaschke, who worked on the differential geometry of [†]ovals and [†]ovaloids. The study of [†]rigidity of ovaloids by S. Cohn-Vossen belongs in this category, and many works on geodesics and minimal surfaces were done from this standpoint.

From the viewpoint of modern mathematics, the basic concepts on which we construct Riemannian geometry and geometries of connections are global concepts of [†]differentiable manifolds. However, in Riemann's time the theory of [†]Lie groups and topology were not yet developed; consequently, Riemannian geometry remained a local theory. In 1925, H. Hopf began to study the relations between local differential-geometric structures and the topological structures of Riemannian spaces. However, except for the work of Cartan, Hopf, and a few others, differential geometry in the 1920s was still largely concerned with surfaces in the 3-dimensional Euclidean space or local properties of Riemannian manifolds, and with affine, projective, and conformal connections.

Gradually the concept of differentiable manifolds was clarified, the global theory of Lie groups made progress, and topology developed; and the trend toward global differential geometry began slowly in the early 1930s. The dissertation of G.-W. de Rham published in 1931 showed that the cohomology of a manifold can be computed in terms of differential forms (\rightarrow 105 Differentiable Manifolds R). His theorem provides the theoretical foundation for expressing cohomological invariants of a manifold in terms of differential geometric invariants. In a series of papers immediately following de Rham's, W. V. D. Hodge established that, on a compact Riemannian manifold, every r -dimensional cohomology class can be uniquely represented by a harmonic form of degree r (\rightarrow 194 Harmonic Integrals).

An important class of complex manifolds with compatible Riemannian metric was discovered by J. A. Schouten, D. van Dantzig, and E. Kähler around 1929–1932. This class of manifolds, called Kähler manifolds today, comprises the projective algebraic manifolds. Hodge's theory of harmonic integrals is most effective when applied to compact Kähler manifolds, (\rightarrow 232 Kähler Manifolds).

The most celebrated global theorem in classical differential geometry of surfaces is the Gauss-Bonnet formula (1848) (\rightarrow 364 Riemannian Manifolds D). The formula was generalized to closed hypersurfaces of Euclidean space by Hopf in 1925, to closed submanifolds of Euclidean space by C. B. Allendoerfer and W. Fenchel in 1940, and finally to arbitrary closed Riemannian manifolds by Allendoerfer and A. Weil in 1943. But the simple proof given by S. S. Chern in 1944 contained the notion of transgression, which has become essential in the theory of characteristic classes (\rightarrow 56 Characteristic Classes). The discovery of Pontryagin classes for Riemannian manifolds (1944) and Chern classes for Hermitian manifolds (1946) culminated in the index theorem and the Riemann-Roch theorem of F. E. P. Hirzebruch, and finally in the Atiyah-Singer index theorem.

A simple but fruitful idea of S. Bochner, relating harmonic forms to curvature, established vanishing theorems for harmonic forms of Riemannian manifolds and for holomorphic forms of Kähler manifolds under suitable positivity conditions for curvature. His idea has led to the vanishing theorems of K. Kodaira and others (\rightarrow 232 Kähler Manifolds D).

The work of C. Ehresmann in 1950 on connections in principal fiber bundles established a solid foundation to Cartan's theory of connections. Gauge theory in physics is largely

based on the theory of connections in principal fiber bundle.

R. H. Nevanlinna's value distribution theory and its subsequent generalization by Chern and others can be best described in differential-geometric terms.

Differentiable manifolds are currently objects of research in both differential geometry and differential topology. While topology studies manifolds per se, differential geometry may be considered as the study of differentiable manifolds equipped with geometric structures, such as metric tensors, connections, (almost) complex structures, and various other tensors. Through these geometric structures, differential geometry enjoys close contact with many branches of mathematics. From its early days, differential geometry has had close ties to topology (as exemplified by the Gauss-Bonnet formula) and to partial differential equations and analytic functions (through, e.g., the study of minimal surfaces). The bonds with topology were strengthened by Morse theory and, more recently, by the theory of characteristic classes. In the most recent proof of the Atiyah-Singer index theorem, differential geometry is an important intermediary between topology and analysis. Differential geometry and algebraic geometry have enriched each other through Kähler manifolds. The theory of functions of several complex variables also has points of contact with differential geometry, such as value distribution theory and Cauchy-Riemann structures. Contact and symplectic structures are basic to mechanics. Lorentz manifolds and connections in principal bundles are essential mathematical tools in the general theory of relativity and in gauge theory. Topics such as minimal submanifolds, manifolds of positive curvature, and closed geodesics are active and important areas of research belonging to Riemannian geometry proper; at the same time, differential geometry provides a language and methods that are important in wider areas of mathematics.

110 (VII.17) Differential Geometry in Specific Spaces

A. The Method of Moving Frames

The main theme of this article is the theory of surfaces (i.e., submanifolds) in a differentiable

manifold V on which a t Lie transformation group G acts.

If a t Lie group G of dimension r acts t transitively on a space G_* and the t stability group for any point of G_* consists of the identity element only, then G_* is called the **group manifold** of G , and an element of G_* is called a **frame**. If f_0 is a fixed frame, then the mapping $a \rightarrow af_0 \in G_*$ ($a \in G$) gives a t diffeomorphism of G to G_* . Let $I(G)$ be the set of all t differential forms ω of degree 1 on G_* that are invariant under transformations of G . Then $I(G)$ is a linear space of dimension r and is the t dual space of the Lie algebra \mathfrak{g} of G . A basis $\{\omega_\lambda | 1 \leq \lambda \leq r\}$ of $I(G)$ is called a set of **relative components** of G . The **structure equations** hold:

$$d\omega_\lambda = \frac{1}{2} \sum_{\mu, \nu=1}^r c_{\lambda\mu\nu} \omega_\mu \wedge \omega_\nu,$$

where $c_{\lambda\mu\nu}$ are t structure constants of the Lie algebra \mathfrak{g} .

Let G be a Lie transformation group of a space E . Then a G -invariant submanifold of E on which G acts transitively is called an **orbit**. Each point $y \in E$ determines an orbit containing y . When there exist parameters k_j ($1 \leq j \leq t$) such that any G -invariant on E is a function of k_1, \dots, k_t , then these parameters are called the **fundamental invariants** of E . Let H ($\subset G$) be the stability group at a point y_0 on an orbit M ; then M is identified with the t homogeneous space G/H by the diffeomorphism $\varphi: M \rightarrow G/H$, $\varphi(ay_0) = aH$ ($a \in G$). Furthermore, a t principal fiber bundle (G_*, M, H, τ) is determined by the projection $\tau: G_* \rightarrow M$, $\tau(af_0) = ay_0$ ($a \in G$). The t fiber H_y on a point $y \in M$ is a group manifold of H . H_y is called the **family of frames** on y , and an element of H_y is a frame on y . Local coordinates θ_μ ($1 \leq \mu \leq s$) of the group H are called the **secondary parameters** and are used to indicate frames in H_y . When H is not connected, let H^0 be the connected component of the identity of H and \tilde{M} be the t covering manifold G/H^0 of M . An element $\tilde{y} \in \tilde{M}$ over $y \in M$ is called an **oriented element**. Now assume that the group H is connected. Then the family of frames H_y on each $y \in M$ is given as an t integral manifold of a t completely integrable system of total differential equations $\pi_i = 0$ ($1 \leq i \leq r-s$, $\pi_i \in I(G)$) on the group manifold G_* . Here the π_i are linearly independent and are called the **horizontal components** of M . The π_i are linear combinations of the relative components ω_λ of G , and their coefficients are generally functions of the fundamental invariants k_j . For simplicity, we assume that the relative components $\{\omega_\lambda\}$ are chosen such that the horizontal components π_i and components ω_α ($r-s < \alpha \leq r$) are linearly independent. Then the ω_β ($1 \leq \beta \leq s$) are called the **secondary com-**

ponents. The differentials $d\theta_\mu$ of the secondary parameters are linear combinations of the ω_μ . Furthermore, let $\{x_\sigma\}$ ($1 \leq \sigma \leq n$) be local coordinates of E ; then the differentials dx_σ are linear combinations of the differentials dk_j and the horizontal components π_i .

Let G be a Lie transformation group of a space V . We regard two m -dimensional surfaces W_1 and W_2 passing through $x \in V$ as equivalent if they have a \dagger contact of order p at x . Then an equivalence class of submanifolds is called a **contact element** of order p at the point x . Let E_p be the set of all contact elements of order p at x , where x runs over all the points in V . A contact element of order p naturally determines a contact element of order $p-1$, and we denote this correspondence by $\psi: E_p \rightarrow E_{p-1}$. Thus we obtain the series of correspondences

$$V = E_0 \xleftarrow{\psi} E_1 \leftarrow \dots \leftarrow E_{p-1} \xleftarrow{\psi} E_p \leftarrow \dots,$$

where a contact element of order 0 is identified with a point of V . Since a transformation on the space V induces a transformation on E_p , G is also a Lie transformation group of E_p , and this transformation commutes with the mapping ψ . The fundamental invariants k_j of E_p are said to be of order p . We use similar terminology (such as frames of order p , etc.) throughout this article. The fundamental invariants k_j of order p ($1 \leq j \leq t_p$) can be chosen such that they contain the fundamental invariants k_i ($1 \leq i \leq t_{p-1}$) of order $p-1$. The additional $t_p - t_{p-1}$ invariants k_α ($t_{p-1} < \alpha \leq t_p$) are called the **invariants of order p** . The family H_y^p ($y \in E_p$) of frames of order p can be chosen such that H_y^p is contained in the family H_z^{p-1} ($z = \psi y \in E_{p-1}$) of frames of order $p-1$. If necessary, the family H_y^p of frames of order p can be made connected by defining an **orientation** of contact elements of order p . Furthermore, the horizontal components π_j ($1 \leq j \leq r - s_p$) of order p can be chosen such that they contain the horizontal components π_i ($1 \leq i \leq r - s_{p-1}$). The additional $s_{p-1} - s_p$ components π_α ($r - s_{p-1} < \alpha \leq r - s_p$) are called the **principal components of order p** .

Let W be an m -dimensional surface of a space V . The contact element of order p (≥ 0) is determined at every point of W and expressed by the family of frames of order p and the values of invariants of orders less than or equal to p . Let $\{u_i\}$ ($1 \leq i \leq m$) be local coordinates on W . Then the differentials du_i are given as linear combinations of linearly independent differential forms π_i ($1 \leq i \leq m$), where the π_i , called the **basic components** of W , are certain linear combinations of the differentials of the fundamental invariants of V and of the horizontal components of orbits of V . Let $F^p(W)$ be the set of all families of frames of order p ; then

$F^p(W)$ depends on m parameters u_i and s_p secondary parameters θ_μ of order p . On the space $F^p(W)$, the differentials of invariants of orders less than or equal to $p-1$ and the principal components of orders less than or equal to $p-1$ are linear combinations of the basic components, whose coefficients are functions of the invariants of orders less than or equal to p . The differentials of invariants of order p and the principal components of order p are linear combinations of the basic components:

$$dk_\alpha = h_{\alpha 1} \pi_1 + \dots + h_{\alpha m} \pi_m, \quad t_{p-1} < \alpha \leq t_p,$$

$$\pi_\alpha = b_{\alpha 1} \pi_1 + \dots + b_{\alpha m} \pi_m, \quad r - s_{p-1} < \alpha \leq r - s_p,$$

where the coefficients $h_{\alpha i}$, $b_{\alpha i}$ are functions of the invariants of orders less than or equal to p and, in general, the secondary parameters θ_μ of order p . These coefficients are called the **coefficients of order p** . Let Γ_p be a subgroup of G preserving a family of frames of order p and D_p be a space whose coordinates are coefficients $(h_{\alpha i}, b_{\alpha i})$ of order p . Then Γ_p acts on D_p as a transformation group. Knowledge of the properties of contact elements of order less than or equal to p can be utilized to obtain information about the invariants of order $p+1$, etc. In fact, if we can choose in the Γ_p -space D_p a subspace C_p that intersects each orbit in D_p at one and only one point, then in general the secondary parameters of order p associated with the points in C_p correspond to the frames of order p , and the parameters associated with the points in C_p are the invariants of order $p+1$. The restrictions of the coefficients of order p to C_p are functions of the invariants of orders less than or equal to $p+1$; they are independent of the secondary parameters of order p . Thus the frames of order $p+1$ and the invariants of orders less than or equal to $p+1$ determine the contact elements of order p of W and their differentials; generally, the latter can be utilized to determine the contact elements of order $p+1$.

This process of obtaining information of "order $p+1$ " utilizing a suitable subspace C_p of D_p is the so-called general **method of moving frames**. However, the surface W may contain points for which the general method does not apply. Actually, there are surfaces W for which the method does not apply for any point in W . Thus various methods of moving frames are necessary to cope with different kinds of surfaces. In the actual application of the method of moving frames, we use certain devices that help to simplify the calculations. In fact, an infinitesimal transformation $(\delta h_{\alpha i}, \delta b_{\alpha i})$ of the group Γ_p acting on the space D_p is expressed as a linear combination of the secondary components of order p ; this expression is easily obtained by means of the structure equations of

G. The group Γ_{p+1} is a subgroup of Γ_p fixing every point of the subspace C_p , and its infinitesimal transformation is such that $\delta h_{xi}=0$, $\delta b_{xi}=0$. The secondary components of order $p+1$ are immediately obtained from the equations for dk_x and π_x . Furthermore, when $m \geq 2$, the condition for the principal components of every order to satisfy the structure equations of G is essential to the problem of the existence of (m -dimensional) surfaces.

As we apply the method of moving frames consecutively to a surface W , we eventually arrive at the order q having the following properties: The families of frames of order $q+1$ coincide with those of order q , and the invariants k_β of order $q+1$ are expressed as functions $\varphi_\beta(k_x)$ of invariants k_x of order less than or equal to q . In this case, the families of frames of orders $q+j$ ($j \geq 1$) are all equal, and the invariants of orders $q+j$ are partial ($j-1$)-derivatives of functions $\varphi_\beta(k_x)$. The family of frames of order q is called the **Frenet frame**. The **differential invariants** on a surface are defined to be differential forms generated by the basic components and the invariants of each order.

Specifically, assume that the group G is an analytic transformation group of V , and the m -dimensional surfaces W_1, W_2 are analytic. Then there exists an element g of G such that $gW_1 = W_2$ if and only if W_1 and W_2 are of the same kind and have the same relations among the invariants of orders less than or equal to $q+1$. These relations are called the **natural equations** of the surface. The theory of surfaces based on the analysis of the natural equations of surfaces is called **natural geometry**. The **reduction formula** can be obtained by utilizing the Frenet frame; it gives the equation of the surface in the form of power series containing the invariants of each order.

Various results are known concerning the theory of surfaces of the spaces V_1, V_2 sharing the same transformation group G . We also have a theory of **special surfaces** whose invariants satisfy specific functional relations. Furthermore, we have problems concerning the **deformation of a surface** (preserving some differential invariants). Actually, the theory of surfaces of dimension m other than curves and hypersurfaces is in general quite difficult. The methods of tensor calculus can be applied to the study of surfaces. The theory of \dagger connections can be considered to be an outgrowth of the study of surfaces by means of the method of moving frames and tensor calculus.

B. Projective Differential Geometry

The rudiments of differential geometry subordinated to the \dagger projective transformation

group, or **projective differential geometry**, can be found in the *Theory of surfaces* by J. G. Darboux. The subject has been systematically studied by H. G. H. Halphen, E. J. Wilczynski, and G. Fubini. The Fubini theory was enriched substantially by E. Cartan, E. Čech, E. Bompiani, and J. Kanitani.

In this section we consider a surface S in a 3-dimensional projective space. Let $A(u^1, u^2)$ (u^1, u^2 are parameters on S) be a point of S , and associate with A all the frames $[A, A_1, A_2, A_3]$ ($|A, A_1, A_2, A_3| = 1$), where A_1, A_2, A_3 are points of the tangent plane to S at A . A family of such frames is called the **family of frames of order 1**, and we express its differential by

$$dA_\alpha = \sum_{\beta=0}^3 \omega_\alpha^\beta A_\beta, \quad \alpha=0, 1, 2, 3, \quad A_0 = A.$$

The ω_α^β are \dagger Pfaffian forms that depend on two principal parameters determining the origin A and ten secondary parameters determining the frame. We have $\omega_0^0 + \omega_1^1 + \omega_2^2 + \omega_3^3 = 0$, $\omega_0^3 = 0$. Furthermore, $\omega^1 = \omega_0^1$, $\omega^2 = \omega_0^2$ are independent of each other and depend on the principal parameters only. Let z^1, z^2, z^3 be \dagger nonhomogeneous coordinates with respect to a frame of order 1. Then in a neighborhood of the origin, S is expressed by $z^3 = \sum_{r=2}^\infty f_r$, where the f_r are homogeneous functions of degree r with respect to z^1, z^2 .

If we write $f_2 = (a_0(z^1)^2 + 2a_1 z^1 z^2 + a_2(z^2)^2)/2$, then it follows from the structure equations of the projective transformation group that $\omega_1^3 = a_0 \omega^1 + a_1 \omega^2$, $\omega_2^3 = a_1 \omega^1 + a_2 \omega^2$. If we put $\varphi_2 = a_0(\omega^1)^2 + 2a_1 \omega^1 \omega^2 + a_2(\omega^2)^2$, then a curve on S defined by $\varphi_2 = 0$ is called the **asymptotic curve** and its tangent the **asymptotic tangent**. At any point of this curve, the plane tangent to S is in contact of order 2 with this curve, and there are in general two asymptotic curves through any point of S . Equations of the asymptotic tangent at A are given by $z^3 = 0$, $f_2 = 0$. A point of S at which the asymptotic tangents coincide is called a **parabolic point**. If every point of S is parabolic, then S is a \dagger developable surface, and the general theory is not applicable to such a surface.

Among the family of frames of order 1, a frame satisfying $a_0 = a_2 = 0$, $a_1 = 1$ is called the **frame of order 2**. For this frame, the straight lines $\overline{AA_1}, \overline{AA_2}$ are asymptotic tangents. With respect to this frame, if $f_3 = -(b_0(z^1)^3 + 3b_1(z^1)^2 z^2 + 3b_2 z^1(z^2)^2 + b_3(z^2)^3)/3$, then $\omega_1^2 = b_0 \omega^1 + b_1 \omega^2$, $-\omega_0^0 + \omega_1^1 + \omega_2^2 - \omega_3^3 = 2(b_1 \omega^1 + b_2 \omega^2)$, $\omega_2^1 = b_2 \omega^1 + b_3 \omega^2$, and the quadric surface $z^3 = z^1 z^2 - z^3(b_1 z^1 + b_2 z^2 + p z^3)$ (with p arbitrary) is called **Darboux's quadric** at A , an especially interesting one among contact quadrics of S . **Darboux's curve** is a curve on S such

that Darboux's quadric is in contact of order 3 at any point of it. Its tangent is called **Darboux's tangent** and is given by $z^3=0$, $b_0(z^1)^3 + b_3(z^2)^3=0$.

We have $b_0 b_3 \neq 0$, except in the case of ruled surfaces. We take special frames of order 2 determined by $b_1=b_2=0$, $b_0=b_3=1$ and call them the **frames of order 3**. If a frame of order 3 satisfies $f_4 = -(c_0(z^1)^4 + 4c_1(z^1)^3 z^2 + 6(c_2-1)(z^1 z^2)^2 + 4c_3 z^1 (z^2)^3 + c_4(z^2)^4)/12$, then $\omega_0^0 - 2\omega_1^1 + \omega_2^2 = c_0 \omega^1 + c_1 \omega^2$, $\omega_3^2 - \omega_1^0 = c_1 \omega^1 + c_2 \omega^2$, $\omega_3^1 - \omega_2^0 = c_2 \omega^1 + c_3 \omega^2$, $\omega_0^0 + \omega_1^1 - 2\omega_2^2 = c_3 \omega^1 + c_4 \omega^2$. With respect to this family of frames of order 3, $((\omega^1)^3 + (\omega^2)^3)/2\omega^1 \omega^2$ is an invariant associated with two neighboring points of S , called the **projective line element**. Also with respect to this frame, two straight lines $\overline{AA_3}$, $\overline{A_1 A_2}$ are polar with respect to Darboux's quadric.

Among the families of frames of order 3, a frame satisfying $c_1=c_2=c_3=0$ is called a **frame of order 4**. With respect to this frame, there exist λ, μ, ν, ρ such that $\omega_1^0 = \lambda \omega^1 + \mu \omega^2$, $\omega_2^0 = \nu \omega^1 + \rho \omega^2$, $\omega_3^0 = \rho \omega^1 + \lambda \omega^2$. Hence if we put $c_0 = -3a$, $c_4 = -3b$, it follows that

$$(\omega_a^b) = \begin{pmatrix} \tau_0^0 & \omega^1 & \omega^2 & 0 \\ \omega_1^0 & \tau_1^1 & \omega^1 & \omega^2 \\ \omega_2^0 & \omega^2 & -\tau_1^1 & \omega^1 \\ \omega_3^0 & \omega_2^0 & \omega_1^0 & -\tau_0^0 \end{pmatrix},$$

$$\tau_0^0 = -(3/2)(a\omega^1 + b\omega^2), \quad \tau_1^1 = (1/2)(a\omega^1 + b\omega^2).$$

Thus the frame of order 4 is the Frenet frame and is attached to every point of S . This frame is called the **normal frame**, and the invariants $a, b, \lambda, \mu, \nu, \rho$ are called the **fundamental differential invariants**. The straight lines $\overline{AA_3}$ and $\overline{A_1 A_2}$ associated with the normal frame are called **directrices of Wilczynski** of the first and second kind, respectively. With respect to the normal frame, S is expressed by

$$z^3 = z^1 z^2 - ((z^1)^3 + (z^2)^3)/3 + (a(z^1)^4 + b(z^2)^4)/4 + (z^1 z^2)^2/2 + \dots$$

A necessary and sufficient condition for two surfaces S, \bar{S} to be projectively equivalent is that there be normal frames having the same ω^1, ω^2 and the same six fundamental differential invariants. For six quantities $a, b, \lambda, \mu, \nu, \rho$ to be fundamental differential invariants of a surface, they must satisfy a certain condition of existence [6].

A frame of order 1 such that $\overline{AA_3}$ and $\overline{A_1 A_2}$ are polar with respect to Darboux's quadric is called **Darboux's frame**. With respect to this frame also, a theory of surfaces has been established.

Consider a pointwise correspondence between two surfaces S, \bar{S} , and denote by $\bar{A} \in \bar{S}$ the point corresponding to $A \in S$. If there exists a projective transformation φ that transforms

A into \bar{A} and the image $\varphi(S)$ is in contact of order 2 with \bar{S} at \bar{A} , then the pointwise correspondence is called a **projective deformation**. A necessary and sufficient condition for the existence of a projective deformation between two surfaces is that these surfaces have the same projective line element [6]. A ruled surface is projectively deformable only to a ruled surface. Given an arbitrary surface S , it is generally impossible to find a surface that is different from S and projectively deformable to S ; some conditions must be satisfied [6, 8].

Let $p^{01}, p^{02}, p^{03}, p^{12}, p^{13}, p^{23}$ be Plücker coordinate of a straight line in a 3-dimensional projective space P^3 . Then we have $p^{01} p^{23} - p^{02} p^{13} + p^{03} p^{12} = 0$, and there is a one-to-one correspondence between the ratios of $\{p^{ij}\}$ and straight lines (\rightarrow 90 Coordinates B). If the p^{ij} are regarded as homogeneous coordinates of a 5-dimensional projective space P^5 , then the previous equation defines a hyperquadric Q in P^5 . Thus there is a one-to-one correspondence between points of Q and straight lines in P^3 . A curve on Q corresponds to a set of one-parameter families of straight lines, or a ruled surface. Sets of 2-parameter or 3-parameter families of straight lines corresponding to surfaces of 2 or 3 dimensions on Q in P^5 are called **congruences of lines** or **complexes of lines**, respectively. Thus by using a theory of surfaces in P^5 , it is possible to establish the theory of congruences and complexes [2, 6, 8], which is an important part of projective differential geometry.

Specifically, if the surface is either a curve or a hypersurface, there are numerous interesting results [2, 4, 6].

C. Affine Differential Geometry

The theme of general affine differential geometry is the study of differential-geometric properties of a point or set of points in a space that are invariant under the action of the affine transformation group. **Affine differential geometry** is the study of the properties invariant under the action of the equivalent affine transformation group, i.e., a subgroup of the affine transformation group formed by elements sending (x_i) to (\bar{x}_i) such that

$$\bar{x}_i = a_i + \sum_{j=1}^n a_{ij} x_j, \quad i = 1, \dots, n, \quad \det(a_{ij}) = 1.$$

The latter transformation leaves invariant the volume surrounded by an oriented closed hypersurface. The method of moving frames is effective in affine differential geometry.

Let C be a plane curve, and associate with any point $A = A(t)$ of C a family of frames $[A, e_1, e_2]$, where the area of the parallelogram

Differential Geometry in Specific Spaces

determined by the two vectors $\mathbf{e}_1, \mathbf{e}_2$ is equal to 1. This frame is called the **frame of order 0**. Its differential is expressed by

$$dA = \sum_{s=1}^2 \omega^s \mathbf{e}_s, \quad d\mathbf{e}_r = \sum_{s=1}^2 \omega_r^s \mathbf{e}_s, \quad r=1, 2,$$

$$\omega_1^1 + \omega_2^2 = 0.$$

The frames of order 1, 2, and 3 are characterized by $\omega^2 = 0$; $\omega^2 = 0, \omega_1^1 = \omega^1$; and $\omega^2 = 0, \omega_1^2 = \omega^1, \omega_1^1 = 0$, respectively. Then a frame of order 3 can be associated with each point of C and coincides with the Frenet frame. We call $\omega^1 = d\sigma$ the **affine arc element**; the **affine curvature** κ is defined by $\omega_2^1 = -\kappa d\sigma$. Then the Frenet formula is given by

$$dA = d\sigma \mathbf{e}_1, \quad d\mathbf{e}_1 = d\sigma \mathbf{e}_2, \quad d\mathbf{e}_2 = -\kappa d\sigma \mathbf{e}_1.$$

With respect to this frame, C is expressed as

$$y = x^2/2 + \kappa x^4/8 + (d\kappa/d\sigma)x^5/40 + \dots$$

Further, $d\sigma$ and κ are given analytically by

$$d\sigma = |dA, d^2A|^{1/3}, \quad \kappa = |d^2A/d\sigma^2, d^3A/d\sigma^3|,$$

where $|M, N| = \det(M, N)$. M, N are column vectors with two entries. We call σ the **affine arc length**. The straight line on which \mathbf{e}_2 is situated is called the **affine normal**, the diameter of the parabola osculating C at A . If κ is constant, then C is a conic section. Furthermore, C is an ellipse, hyperbola, or parabola according as the constant κ is positive, negative, or zero. In affine geometry, parabolas play a role similar to that played by straight lines in Euclidean geometry.

There are numerous results concerning the theory of skew curves and surfaces [1]. Concerning the theory of skew curves, results on **affine length**, **affine curvature**, **affine torsion**, **affine principal normals**, and **affine binormals** are similar to those in Euclidean geometry. The affine transformation group is situated between the projective transformation group and the congruent transformation group and hence has properties analogous to theirs. The theory of surfaces has a character similar to that of projective differential geometry [1]. We may also consider the variation of the affine area of a surface surrounded by a closed skew curve C . We call the extremal surface the **affine minimal surface**. W. Blaschke and others obtained many results on the global properties of such surfaces.

D. Conformal Differential Geometry

Let S^n be a conformal space of dimension n , and associate with each point $A_0 \in S^n$ a frame $\mathfrak{R}[A_0, A_1, \dots, A_n, A_\infty]$ of the $(n+2)$ -hyperspherical coordinates with origin A_0 (\rightarrow 76 Conformal Geometry). Then denoting

by $A \cdot B$ the inner product of hyperspheres A, B , we obtain

$$A_\alpha \cdot A_\beta = g_{\alpha\beta}, \quad \alpha, \beta = 0, 1, \dots, n, \infty,$$

where

$$(g_{\alpha\beta}) = \begin{pmatrix} 0 & 0 & -1 \\ 0 & g_{ij} & 0 \\ -1 & 0 & 0 \end{pmatrix},$$

$$i, j = 1, \dots, n, \quad g_{ij} = g_{ji}.$$

Let z^α be homogeneous coordinates with respect to \mathfrak{R} . Then the Möbius transformation $z \rightarrow \bar{z}$ of S^n is characterized by $\bar{z}^\alpha = c_\beta^\alpha z^\beta$, where $g_{\alpha\beta} c_\alpha^\sigma c_\beta^\tau = g_{\sigma\tau}$, $|c_\beta^\alpha| \neq 0$. The differential of the family of the frames is defined by

$$dA_\alpha = \sum_{\beta=0,1}^{n,\infty} \omega_\alpha^\beta A_\beta, \quad (1)$$

where

$$(\omega_\alpha^\beta) = \begin{pmatrix} \omega_0^0 & \omega_0^j & 0 \\ \sum g_{ik} \omega_k^\infty & \omega_i^j & \sum g_{ik} \omega_0^k \\ 0 & \omega_\infty & -\omega_0^0 \end{pmatrix},$$

$$\sum (g_{ik} \omega_j^k + g_{jk} \omega_i^k) = dg_{ij}.$$

There are $(n+1)(n+2)/2$ linearly independent forms among ω , and this is the number of parameters of the Möbius transformation group. The structure equations of this group are

$$d\omega_\alpha^\beta = \sum \omega_\alpha^\sigma \wedge \omega_\sigma^\beta. \quad (2)$$

The theme of **conformal differential geometry** is the properties of Pfaffian forms ω_α^β satisfying (1) and (2).

Consider a transformation $c: \sum z^\alpha A_\alpha \rightarrow \sum z^\alpha (A_\alpha + dA_\alpha)$. (1) If all ω vanish except ω_0^0 , then all the circles through A_0, A_∞ are invariant, and any point P is transformed to a neighboring point \bar{P} on the circle, such that the cross ratio $(P, \bar{P}; A_0, A_\infty)$ is constant. This transformation is called the **homothety** with centers A_0, A_∞ . (2) If all ω vanish except ω_0^j , $\omega_i^\infty = \sum g_{ik} \omega_0^k$, then all the circles tangent to a fixed direction at A_∞ are transformed into themselves, and any hypersphere through A_∞ and orthogonal to those circles is transformed into a hypersphere having the same property. This transformation is called the **elation** with center A_∞ . (3) If all ω vanish except $\omega_i^j = \sum g_{ik} \omega_\infty^k, \omega_\infty^j$, then the transformation is an elation with center A_0 . (4) If all ω vanish except ω_i^j , then the transformation is an infinitesimal rotation with center A_0 , with A_∞ regarded as a point at infinity. Thus any infinitesimal Möbius transformation is decomposed into the previous four types of transformation.

To study the theory of curves and hypersurfaces in S^n , we again utilize the Frenet frame chosen from a family of frames associated with

A_0 . For example, the Frenet formula of a curve in S^3 is given by

$$(\omega_\alpha^\beta) = \begin{pmatrix} 0 & d\sigma & 0 & 0 & 0 \\ \kappa d\sigma & 0 & 0 & 0 & d\sigma \\ -d\sigma & 0 & 0 & \tau d\sigma & 0 \\ 0 & 0 & -\tau d\sigma & 0 & 0 \\ 0 & \kappa d\sigma & -d\sigma & 0 & 0 \end{pmatrix}.$$

We call $d\sigma$, κ , and τ the **conformal arc element**, **conformal curvature**, and **conformal torsion**, respectively. There are many results on conformal deformation [5].

Concerning Laguerre differential geometry, we have results dual to those in conformal differential geometry (a point is replaced by a straight line and an angle by a distance between the points of contact of the common tangents of two oriented circles).

E. Contact Manifolds

Consider a $(2n+1)$ -dimensional differentiable manifold M^{2n+1} with a 1-form η such that $\eta \wedge (d\eta)^n \neq 0$, where $d\eta$ is the exterior derivative of η and \wedge denotes exterior multiplication. (Note that this is true for the 1-form in the left-hand side of eq. (2) in 82 Contact Transformations A.) Such a manifold is called a **contact manifold** with **contact form** η . The structure group of the tangent bundle of a contact manifold M^{2n+1} reduces to $U(n) \times 1$, where $U(n)$ is the unitary group; hence every contact manifold is orientable. Simple but typical examples are given by the unit sphere S^{2n+1} in Euclidean space E^{2n+2} and the tangent sphere bundle of an $(n+1)$ -dimensional Riemannian manifold M^{n+1} , both with natural contact forms (S. S. Chern [9]). Every 3-dimensional compact orientable differentiable manifold is a contact manifold (J. Martinet [12]).

Now a differentiable manifold M^{2n+1} is said to be an **almost contact manifold** if it admits a tensor field φ of type $(1, 1)$, a vector field ξ , and a 1-form η such that

$$\varphi^2 X = -X + \eta(X)\xi, \quad \eta(\xi) = 1, \quad (3)$$

where X is an arbitrary vector field on M^{2n+1} ; and the triple (φ, ξ, η) is then called an **almost contact structure**. (3) implies that $\varphi\xi = 0$ and $\eta(\varphi X) = 0$ (S. Sasaki [14, I]). The structure group of the tangent bundle of an almost contact manifold M^{2n+1} reduces to $U(n) \times 1$. Indeed, J. W. Gray [10] took this property as his definition of almost contact structure. For any pair of vector fields X and Y on M^{2n+1} , let

$$\begin{aligned} N(X, Y) = & [X, Y] + \varphi[\varphi X, Y] \\ & + \varphi[X, \varphi Y] - [\varphi X, \varphi Y] \\ & - \{X \cdot \eta(Y) - Y \cdot \eta(X)\}\xi, \end{aligned}$$

where $[,]$ is the Poisson bracket; then N is a tensor field of type $(1, 2)$ over M^{2n+1} , which we call the **torsion tensor** of the almost contact structure (φ, ξ, η) . When N vanishes identically on M^{2n+1} , we say that the almost contact structure is **normal**.

An almost contact structure (φ, ξ, η) on M^{2n+1} induces naturally an almost complex structure J on $M^{2n+1} \times R$ (resp. $M^{2n+1} \times S^1$), which reduces to a complex structure if and only if (φ, ξ, η) is normal. A similar statement is also valid for the product space of two almost contact manifolds (A. Morimoto [13]).

If M^{2n+1} is an almost contact manifold with structure tensor (φ, ξ, η) , we can find a positive definite Riemannian metric g so that $g(\varphi X, \varphi Y) = g(X, Y) - \eta(X)\eta(Y)$ for any pair of vector fields X and Y , and the set (φ, ξ, η, g) is then said to be an **almost contact metric structure**.

When M^{2n+1} is a contact manifold with contact form η , there exists a unique vector field ξ which satisfies $d\eta(X, \xi) = 0$, $\eta(\xi) = 1$ for any vector field X . We can then find a tensor field φ of type $(1, 1)$ and a positive definite metric tensor g so that (i) $d\eta(X, Y) = g(X, \varphi Y)$ is satisfied for any pair of vector fields X and Y , and (ii) (φ, ξ, η, g) is an almost contact metric structure. The almost contact metric structure determined in this way by a contact form η is called a **contact metric structure**. A differentiable manifold with normal contact metric structure is called a **normal contact Riemannian manifold** or a **Sasakian manifold**. Brieskorn manifolds are examples of such manifolds. They include, besides the standard sphere S^{2n+1} , all exotic $(2n+1)$ -spheres that bound compact oriented parallelizable manifolds. An almost contact manifold is said to be **regular** or **nonregular** according as the integral curve of ξ is regular or not as a submanifold. A compact regular contact manifold is a principal circle bundle over a symplectic manifold, and it admits a normal contact metric structure if and only if the base manifold is a Hodge manifold (Boothby and Wang [8], Hatakeyama [11]).

Many research papers on the topology and differential geometry of manifolds with the structures defined above have been published by S. Tanno, S. Tachibana, D. E. Blair, M. Okumura, K. Ogiue, S. I. Goldberg, and others.

111 (VII.12) Differential Geometry of Curves and Surfaces

A. General Remarks

Let f be an m -dimensional \dagger differentiable manifold M of class C^r into an n -dimensional Euclidean space E^n . More precisely, f is a differentiable mapping of class C^r such that the \dagger differential df_p is injective at every point p of M . The pair (M, f) is called

an **immersed submanifold** (or a **surface**) of E^n . When $m = 1$, we call it a **curve** of E^n , and when $m = n - 1$, a **hypersurface** in E^n . The cases of $n = 2$ and $n = 3$ have been the main objects of study in differential geometry of curves and surfaces. The differential-geometric properties for the general case of immersion are discussed in 365 Riemannian Submanifolds.

B. Frames in E^n

Every \dagger Euclidean motion in E^n can be expressed as the product of a parallel translation and an \dagger orthogonal transformation that keeps the origin of E^n fixed. The set of all parallel translations is a commutative group that can be identified with \mathbf{R}^n . It is a normal subgroup of the group of motions $I(E^n)$ of E^n . So we see that $I(E^n)$ is a \dagger semidirect product of \mathbf{R}^n and the \dagger orthogonal group $O(n)$. The Lie algebra of $I(E^n)$ is the direct sum of \mathbf{R}^n and the Lie algebra $\mathfrak{o}(n)$ of the orthogonal group, where both are regarded as additive groups. Corresponding to this decomposition, we can write the \dagger Maurer-Cartan differential form over $I(E^n)$ as $\omega + \Omega$, where ω belongs to \mathbf{R}^n and Ω to $\mathfrak{o}(n)$. The \dagger structural equation $d(\omega + \Omega) = -(1/2)(\omega + \Omega) \wedge (\omega + \Omega)$ can be divided into the following two parts: $d\omega = \Omega \wedge \omega$; $d\Omega = -(1/2)\Omega \wedge \Omega$. These are known as the **structure equations** of E^n . By an **orthogonal frame** in E^n we mean an ordered set $(x, \mathbf{e}_1, \dots, \mathbf{e}_n)$ consisting of a point x and a set of \dagger orthonormal vectors $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n$. We denote by $\mathcal{O}(n)$ the set of all orthogonal frames in E^n . If we denote the translation identified with $x \in \mathbf{R}^n$ by T_x , then there is a one-to-one correspondence $\varphi: I(E^n) \rightarrow \mathcal{O}(n)$ given by $\varphi(T_x A) = (x, A\mathbf{e}_1, \dots, A\mathbf{e}_n)$ ($A \in O(n)$). We can make $\mathcal{O}(n)$ into a differentiable manifold so that φ is a \dagger diffeomorphism. We denote the differential forms over $\mathcal{O}(n)$, which are images of ω and Ω under the \dagger dual mapping of φ^{-1} , by the same letters ω and Ω , respectively. For $\mathcal{O}(n)$ as a \dagger principal fiber bundle over \mathbf{R}^n with the projection $\pi: \pi(x, \mathbf{e}_1, \dots, \mathbf{e}_n) = x$ and n vector-valued functions $\varphi_i: \varphi_i(x, \mathbf{e}_1, \dots, \mathbf{e}_n) = \mathbf{e}_i$ over $\mathcal{O}(n)$, we have

$$\begin{aligned} \omega &= \sum_i \omega^i \mathbf{e}_i, & \Omega &= \sum_{i < j} \Omega^{ij} E_{ij}, \\ \omega^i &= (d\pi, \varphi_i), & \Omega^{ij} &= (d\varphi_i, \varphi_j), \end{aligned} \quad (1)$$

$$d\omega^i = \sum_j \Omega^{ij} \wedge \omega^j, \quad d\Omega^{ij} = \sum_k \Omega^{ik} \wedge \Omega^{kj},$$

where $\{E_{ij}\}$ is a basis of $\mathfrak{o}(n)$ defined by $E_{ij}\mathbf{e}_j = \mathbf{e}_i$, $E_{ij}\mathbf{e}_i = -\mathbf{e}_j$, $E_{ij}\mathbf{e}_k = 0$ ($k \neq i, j$) and $(\ , \)$ is the scalar product of vector-valued forms induced from the scalar product of E^n . Any diffeomorphism of $\mathcal{O}(n)$ onto itself preserving ω and Ω must be a Euclidean motion.

C. Theory of Curves

Let (M, f) be an immersion of a 1-dimensional differentiable manifold M into E^n . We identify the tangent space of E^n at each point with E^n itself. Then df_x maps the origin of the tangent space M_x to $f(x)$, and the image $df_x(M_x)$ of M_x by df_x is a straight line passing through $f(x)$ in E^n , called the **tangent line** of $f(M)$ at $f(x)$. By $\mathcal{O}_f(M)$ we mean the set of all ordered sets $(x, \mathbf{e}_1, \dots, \mathbf{e}_n)$, where $x \in M$ and $\{\mathbf{e}_i\}$ is an orthonormal basis of E^n such that $\mathbf{e}_1 \in df_x(M_x)$. Then $\mathcal{O}_f(M)$ can be naturally immersed in $\mathcal{O}(n)$ by the mapping $\hat{f}: \hat{f}(x, \mathbf{e}_1, \dots, \mathbf{e}_n) = (f(x), \mathbf{e}_1, \dots, \mathbf{e}_n)$. We can pull back the differential forms $\omega, \Omega, \omega', \Omega^i$ over $\mathcal{O}(n)$ to $\mathcal{O}_f(M)$ \hat{f}^* and denote them by θ, Θ, θ^i , and Θ^i , respectively; then we have $\theta^i = 0$ ($i > 1$). Let f_1 and f_2 be two immersions of M into E^n . Then in order for there to exist a Euclidean motion α of E^n such that $f_1 = \alpha \circ f_2$, it is necessary and sufficient that there exist a diffeomorphism φ of $\mathcal{O}_{f_1}(M)$ onto $\mathcal{O}_{f_2}(M)$ such that $\theta_{f_1} = \varphi^*(\theta_{f_2})$, $\Theta_{f_1} = \varphi^*(\Theta_{f_2})$. Let π_f be the projection of the fiber bundle $\mathcal{O}_f(M)$, and let φ_i be naturally defined vector-valued functions over $\mathcal{O}_f(M)$. Then we have $d(f \circ \pi_f) = \theta^1 \varphi_1$, $d\varphi_i = \sum_{j=1}^n \Theta^{ij} \varphi_j$. If we put $ds^2(X) = \|df_x(X)\|^2$ ($X \in M_x$), then we have $(\theta^1)^2 = \pi_f^*(ds^2)$. For each point $x \in M$ there are two possibilities for the choice of \mathbf{e}_1 corresponding to two orientations of the curve. But since $(d\varphi_1, d\varphi_1) = \pi_f^*(\rho^2 ds^2)$, ρ^2 depends only on the point x of M . We call ρ (≥ 0) the **absolute curvature**. We now choose an orientation of the curve and then \mathbf{e}_1 in accordance with the orientation. Thus we get a submanifold of $\mathcal{O}_f(M)$, which we again express by the notation $\mathcal{O}_f(M)$. If we define the form ds by $ds(X) = (df(X), \mathbf{e}_1)$, we have $\theta^1 = \pi_f^*(ds)$, and ds is called the **line element**. Any t local cross section $R: \pi_f \circ R = 1$ of the bundle $\mathcal{O}_f(M)$ is called a **moving frame**. Putting

$$R^*(\theta^1) = ds, \quad R^*(\Theta^i) = \rho^i ds,$$

we see that the following equation holds over M :

$$d\mathbf{e}_i = \sum_j \rho^{ij} ds \mathbf{e}_j. \quad (2)$$

For two immersions (M, f_1) and (M, f_2) , we have $f_1 = \alpha \circ f_2$ (α is a Euclidean motion) if and only if they have the same ds and ρ^{ij} for some moving frames.

D. Frenet's Formulas

In order to study local properties of curves it is sufficient to consider them on t Jordan arcs of class C^r . With respect to orthogonal coordinates (x^1, \dots, x^n) in E^n , such a curve is represented parametrically by $x^i = f^i(t)$ ($t \in [a, b]$, $\sum (dx^i/dt)^2 > 0$) or by a vector representation

$\mathbf{x} = \mathbf{x}(t)$. If φ is a diffeomorphism of a closed interval $[a', b']$ onto $[a, b]$, then $f \circ \varphi$ and f are representations of the same arc in E^n , and φ is called a **transformation of the parameter**. Any curve of class C^1 is t rectifiable, and its **arc length** is given by $s = \int_a^b (\sum_{i=1}^n (dx^i/dt)^2)^{1/2} dt$. We may choose the arc length s measured from a point on the arc as a parameter, called the **canonical parameter** of the arc. Consider an arc C of class C^n given by the vector representation $\mathbf{x} = \mathbf{x}(s)$, $s \in [a, b]$. We assume that its t Wronskian $|\mathbf{x}'(s), \dots, \mathbf{x}^{(n)}(s)|$ is not identically zero (we denote by $'$ the derivative with respect to the canonical parameter), which means that the arc C is not contained in a hyperplane in E^n . A point at which the Wronskian vanishes is called a **stationary point**, and we assume that there exists no stationary point on C . By the t Gram-Schmidt orthonormalizing process we obtain an orthonormal basis $\mathbf{e}_1, \dots, \mathbf{e}_n$ ($|\mathbf{e}_1, \dots, \mathbf{e}_n| > 0$) from n vectors $\mathbf{x}'(s), \dots, \mathbf{x}^{(n)}(s)$ at each point of C . We call the frame thus determined the **Frenet frame**. With respect to the Frenet frame, (2) is rewritten as

$$\begin{aligned} \mathbf{e}_i'(s) &= -\kappa_{i-1}(s)\mathbf{e}_{i-1}(s) + \kappa_i(s)\mathbf{e}_{i+1}(s), \\ i &= 1, \dots, n; \\ \kappa_0(s) &= \kappa_n(s) = 0; \\ \kappa_j(s) &> 0, \quad j &= 1, \dots, n-2. \end{aligned} \quad (3)$$

These are called **Frenet's formulas** (or the **Frenet-Serret formulas**). We call $\kappa_1, \kappa_2, \dots, \kappa_{n-2}$ the first, second, \dots , $(n-2)$ nd **curvature**, respectively, while we call κ_{n-1} the **torsion** for $n \geq 3$. For a curve in a lower-dimensional subspace $E^m \subset E^n$, we set $\kappa_i = 0$ ($i > m$). The curvatures and the torsion of a straight line are zero. To get Frenet's formulas in these special cases, we fix \mathbf{e}_i ($i > m$) in the subspace orthogonally complementary to E^m in E^n and proceed as in the general case. Suppose that C_1, C_2 are arcs such that both of their Frenet frames are of class C^1 . If there exists a diffeomorphism of C_1 to C_2 that preserves arc length and the κ_i ($i = 1, \dots, n-1$) are equal at corresponding points, C_1 and C_2 are mapped onto each other by a motion of E^n . This is the **fundamental theorem of the theory of curves**.

Given $n-1$ functions of class C^1 $\kappa_1(s) \geq 0, \dots, \kappa_{n-2}(s) \geq 0$ (we assume that the equality signs occur at most at a finite number of points) and $\kappa_{n-1}(s)$ for $0 \leq s \leq L$, there exists an arc that has $\kappa_1, \dots, \kappa_{n-2}, \kappa_{n-1}$ as its first, \dots , $(n-2)$ nd curvatures and its torsion, respectively. The equations $\kappa_i = \kappa_i(s)$ are called the **natural equations** of the curve.

E. Plane Curves

Let $\mathbf{x} = \mathbf{x}(s)$ be a curve of class C^2 in E^2 , and $(\mathbf{x}(s), \mathbf{e}_1, \mathbf{e}_2)$ its Frenet frame. The tangent and

the normal of this curve at $\mathbf{x}(s)$ have parametric representations $\mathbf{x}(s) + t\mathbf{e}_1$, $\mathbf{x}(s) + t\mathbf{e}_2$, respectively (with parameter t). Frenet's formulas are written as $\mathbf{x}' = \mathbf{e}_1$, $\mathbf{x}'' = \mathbf{e}_1' = \kappa\mathbf{e}_2$, and ρ is called the **curvature** of the curve C . The natural equation is given by $\kappa = \kappa(s)$. If $\kappa(s) = \text{constant} \neq 0$ along C , C must be a portion of a circle. Another way of defining the curvature is as follows: We take a fixed direction (for example, the positive direction of the x -axis on E^2) and denote by $\theta(s)$ the angle made by the tangent T_s of the curve C at $\mathbf{x}(s)$ with the direction. Then we have $\kappa(s) = d\theta/ds$. If $n=2$, the curvature can take both positive and negative values. Figs. 1 and 2 suggest a geometric meaning of $\kappa > 0$ and $\kappa < 0$, respectively. The circle with center $\mathbf{x} = \mathbf{x}(s) + (1/\kappa)\mathbf{e}_2$ and radius $1/\kappa$ has a contact of higher order than any other circle in E^2 . We call this circle the **osculating circle** (or **circle of curvature**) at the point $\mathbf{x} = \mathbf{x}(s)$, its center the **center of curvature**, and $1/\kappa$ the **radius of curvature**. The locus C' of the center of curvature of a curve C is called an **evolute** of C . Conversely, C is called an **involute** of C' , the envelope of the family of normal lines of C . When a curve is given in terms of its canonical parameter s , the curvature is given by $|\mathbf{x}'(s), \mathbf{x}''(s)|$; when the curve is given by another parameter t as $\mathbf{x} = \mathbf{x}(t)$, the curvature is given by $\kappa(t) = |\mathbf{x}'(t), \mathbf{x}''(t)|/|\mathbf{x}'(t)|^3$, where $'$ means d/dt .

Fig. 1
 $\kappa > 0$.

Fig. 2
 $\kappa < 0$.

The facts we have just stated concern local properties of plane curves. We shall now discuss the global theory of curves, which deals with properties of each curve as a whole. Let $C: \mathbf{x} = \mathbf{x}(s)$, $a \leq s \leq b$, be a closed curve. Let $\theta(s)$, $0 \leq \theta(s) < 2\pi$, be the angle that $\mathbf{e}_1(s)$ makes with the x axis. Put $\Theta = \int_a^b \theta'(s) ds$. Intuitively, Θ measures the total rotation of $\mathbf{e}_1(s)$ as we run along the curve C from a to b . Since C is closed, Θ is an integer multiple I of 2π . The integer I is called the **rotation number** of C , and is equal to $(1/2\pi) \int_a^b \kappa(s) ds$. Let \bar{D} be a closed domain consisting of points in the interior and on the boundary of a simple closed curve C . C is called a **closed convex curve** or an **oval** if \bar{D} is convex in E^2 . Among all ovals of given length, the circle has the maximum area. Various generalizations of this theorem have been obtained, and the collection of

problems of this kind is called the **isoperimetric problem**. This problem has intimate connections with fields such as integral geometry. The oval has a convenient parameter other than the arc length parameter s . Given a number t , $0 \leq t \leq 2\pi$, there exists a unique point $\mathbf{x}(t)$ in the oval such that $\mathbf{e}_2 = (\cos t, \sin t)$ at $\mathbf{x}(t)$. When we describe the oval in terms of the parameter t , the tangent vector at $\mathbf{x}(t)$ is parallel to that at $\mathbf{x}(t + \pi)$, and we can define the width $W(t)$ at $\mathbf{x}(t)$. $W(t)$ is called the **width of the oval**. A curve is called a **curve of constant width** if the curve is an oval whose width $W(t)$ does not depend on t . The circle is a typical example of a curve of constant width. Reuleaux's triangle is another well-known example of a curve of constant width (Fig. 3). For a curve of constant width of width W and length L , we have $L = \pi W$.

Fig. 3

There are also some results concerning the relations between local properties (for example, curvature) and properties of the whole figure. An example is given by the **four-vertex theorem**. A vertex on a curve C is by definition a point where $d\kappa/ds = 0$. Then there are at least four vertices on an oval of class C^3 . A simple closed curve with $\kappa \geq 0$ (≤ 0) must be convex (\rightarrow 89 Convex Sets).

F. Space Curves

Let $\mathbf{x} = \mathbf{x}(s)$ ($s \in [a, b]$) be a curve C of class C^3 in E^3 defined in terms of the canonical parameter s . Let $(\mathbf{x}(s), \mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$ be Frenet frames along C . Then we have the Frenet formulas

$$\mathbf{e}_1' = \kappa_1 \mathbf{e}_2, \quad \mathbf{e}_2' = -\kappa_1 \mathbf{e}_1 + \kappa_2 \mathbf{e}_3, \quad \mathbf{e}_3' = -\kappa_2 \mathbf{e}_2.$$

We call $1/\kappa_1$, $1/\kappa_2$ the **radius of curvature** and the **radius of torsion**, respectively. The line $\mathbf{x} = \mathbf{x}(s_0) + t\mathbf{e}_1$ is the tangent of C at $\mathbf{x}(s_0)$. The two straight lines through the point $\mathbf{x}(s_0)$ defined by $\bar{\mathbf{x}} = \mathbf{x}(s_0) + t\mathbf{e}_2$ and $\bar{\mathbf{x}} = \mathbf{x}(s_0) + t\mathbf{e}_3$ are called the **principal normal** and the **binormal** of C at $\mathbf{x}(s_0)$, respectively. The three planes through $\mathbf{x}(s_0)$ defined by $\bar{\mathbf{x}} = \mathbf{x}(s_0) + t\mathbf{e}_2 + t\mathbf{e}_3$, $\bar{\mathbf{x}} = \mathbf{x}(s_0) + t\mathbf{e}_3 + t\mathbf{e}_1$, and $\bar{\mathbf{x}} = \mathbf{x}(s_0) + t\mathbf{e}_1 + t\mathbf{e}_2$ are called the **normal plane**, the **rectifying plane**, and the **osculating plane**, respectively.

At a point $\mathbf{x}(s_0)$ of a curve $\mathbf{x} = \mathbf{x}(s)$ of class C^ω , we take $\mathbf{e}_1(s_0)$, $\mathbf{e}_2(s_0)$, and $\mathbf{e}_3(s_0)$ as unit vectors of the coordinate axes. Substituting the Frenet formulas into the Taylor expansion of $\mathbf{x}(s)$, we see that the new coordinate $\mathbf{x}_1(s)$, $\mathbf{x}_2(s)$, $\mathbf{x}_3(s)$ of C are given by

$$x_1 = (s - s_0) - (\kappa_1(s_0)/6)(s - s_0)^3 + \dots,$$

$$x_2 = (\kappa_1(s_0)/2)(s - s_0)^2 + (\kappa'_1(s_0)/6)(s - s_0)^3 + \dots,$$

$$x_3 = (\kappa_1(s_0)\kappa_2(s_0)/6)(s - s_0)^3 + \dots$$

These are called **Bouquet's formulas**. Utilizing these formulas we can see the nature of the curve with given κ_1 and κ_2 . A curve and its osculating plane at a point on it have contact of order higher than any other plane through that point. The family of osculating planes of C envelopes a developable surface S and coincides with the locus of tangent lines to C . We call S the **tangent surface** of C , and C the **line of regression** of S . The family of rectifying planes of C also envelopes a developable surface called the **rectifying surface**, and C is a geodesic on this surface. The family of normal planes of C envelopes either a cone or a tangent surface of another curve \bar{C} . When the natural equation of a space curve has a special form, the shape of the curve is simple. For example, $\kappa_1(s) = \text{constant}$, $\kappa_2(s) = \text{constant}$ represent a curve, called an **ordinary helix**, on a cylinder which cuts all the generators of the cylinder at a constant angle. More generally, it is known that if $\kappa_1/\kappa_2 = \text{constant}$, the tangent at each point of the curve makes a constant angle with a fixed direction. Such a curve is called a **generalized helix** or a **curve of constant inclination**. Each curve satisfying $ak_1 + bk_2 = c$ ($ab \neq 0$) is called a **Bertrand curve**. For a Bertrand curve there exists another curve \bar{C} and a correspondence of C onto \bar{C} such that they have a common principal normal at corresponding points. Conversely, this property is also a sufficient condition for C to be a Bertrand curve. A **Mannheim curve** is defined analogously as a curve having a correspondence with another curve \bar{C} such that the principal normal of C and the binormal of \bar{C} coincide at corresponding points. When a correspondence of C and \bar{C} has the property that tangents at corresponding points are parallel, then the correspondence is called a **correspondence of Combesure**.

We have stated mainly local properties of space curves. There are also several results about global properties of curves in E^3 analogous to the case of plane curves. For a simple closed curve C of length L , we call $K = \int_0^L \kappa_1(s) ds$ the **total curvature** of C . Generally we have $K \leq 2\pi$, while $K = 2\pi$ if and only if C is a closed convex curve lying in a plane (W. Fenchel) [5, 6]. The total curvature is deeply

related to the properties of knots. If a simple closed curve in E^3 is knotted, then the total curvature is at least 4π [7, 8]. We fix an origin O in E^3 and draw a unit tangent vector with initial point O parallel to the unit tangent vector at each point of a space curve C ; then the endpoint of this vector traces a curve \bar{C} on the unit sphere with the center O . We call \bar{C} the **spherical indicatrix** of C and the correspondence of C to \bar{C} a **spherical representation**. The total curvature K of a curve C is equal to the length of \bar{C} . Consequently, we have $K = \oint_C d\theta$, where θ is the angular deflection of the tangent line along the closed curve C .

G. Theory of Hypersurfaces

Let (M, f) be an immersion of an $(n-1)$ -dimensional differentiable manifold M of class C^r into E^n . Then we can define on the hypersurface M a positive definite differential form g of degree 2 induced from the inner product of E^n : $g_x(X, X) = (df_x(X), df_x(X))$, $X \in M_x$. Then M becomes a Riemannian manifold with Riemannian metric g . We call g the **first fundamental form** of (M, f) . The Riemannian geometry on a surface with its first fundamental form as Riemannian metric is called **geometry on a surface** (\rightarrow 364 Riemannian Manifolds).

By $\mathcal{O}_f(M)$ we mean the set of all the ordered sets $(x, \mathbf{e}_1, \dots, \mathbf{e}_n) \in \mathcal{O}(n)$, where $x \in M$ and $\{\mathbf{e}_i\}$ ($i = 1, 2, \dots, n$) is an orthonormal system of E^n such that $\mathbf{e}_i \in df_x(M_x)$ ($i = 1, \dots, n-1$). Then $\mathcal{O}_f(M)$ with natural projection π_f and natural differentiable structure is a principal fiber bundle over M and has a natural immersion $\hat{f}: \hat{f}(x, \mathbf{e}_1, \dots, \mathbf{e}_n) = (f(x), \mathbf{e}_1, \dots, \mathbf{e}_n)$ in the principal fiber bundle $\mathcal{O}(n)$. We can pull back the forms on $\mathcal{O}(n)$ to $\mathcal{O}_f(M)$ by \hat{f}^* and put $\theta = \hat{f}^*(\omega)$, $\Theta = \hat{f}^*(\Omega)$; then the structural equations of E^n are transformed to $d\theta = \Theta \wedge \theta$, $d\Theta = (-1/2)\Theta \wedge \Theta$. Furthermore, if we put $\theta^i = \hat{f}^*(\omega^i)$, $\Theta^{ij} = \hat{f}^*(\Omega^{ij})$, then $\theta^n = 0$ and θ^i , Θ^{ij} ($i, j < n$) depend only on the first fundamental form of (M, f) . Let f_1 and f_2 be two immersions of M into E^n . Then in order that there exist a Euclidean motion α of E^n such that $f_1 = \alpha \circ f_2$, it is necessary and sufficient that there exist a diffeomorphism φ of $\mathcal{O}_{f_1}(M)$ onto $\mathcal{O}_{f_2}(M)$ such that $\theta_{f_1} = \varphi^*(\theta_{f_2})$ and $\Theta_{f_1} = \varphi^*(\Theta_{f_2})$. Suppose that M is orientable and oriented. Then the unit vector field normal to $df_x(M_x)$ at every point $x \in M$ in E^n defines a mapping of M into the unit sphere in E^n called the **spherical representation** of M or the **Gauss mapping** (**Gauss map**). Regarding the unit normal vector field ξ of M as a vector-valued function over M , we can define a symmetric product of df and $d\xi$ by $-(df, d\xi)(X, Y) =$

$(1/2)[(df(X), d\xi(Y)) + (df(Y), d\xi(X))]$, called the **second fundamental form** of (M, f) .

Two immersions f_1 and f_2 of M that induce the same first and second fundamental forms have a Euclidean motion α such that $f_1 = \alpha \circ f_2$; and the converse is also true. This fact is called the **fundamental theorem of the theory of surfaces**.

H. Theory of Surfaces in E^3 (\rightarrow 365 Riemannian Submanifolds; Appendix A, Table 4.I)

A surface in E^n is locally expressed by parametric equations $x_i = x_i(u_\alpha)$ ($i = 1, \dots, n$; $\alpha = 1, \dots, m$) or by a single vector equation $\mathbf{x} = \mathbf{x}(u_\alpha)$. We are mainly concerned with the case $n = 3$, $m = 2$, and we express the surface by a vector representation $\mathbf{x} = \mathbf{x}(u, v)$. The first and second fundamental forms are written as

$$E du^2 + 2F du dv + G dv^2,$$

$$L du^2 + 2M du dv + N dv^2.$$

If we use the usual notation of tensor analysis, then the first and second fundamental forms are also denoted by $g_{\alpha\beta} du^\alpha du^\beta$ and $H_{\alpha\beta} du^\alpha du^\beta$, respectively, where u^α ($\alpha = 1, 2$) are parameters (with Σ omitted by Einstein's convention). We call $\{g_{\alpha\beta}\}$, $\{H_{\alpha\beta}\}$ the **first** and **second fundamental quantities**, respectively (\rightarrow 365 Riemannian Submanifolds). At the point $p_0 = \mathbf{x}(u_0, v_0)$ on a surface S that corresponds to parameter values (u_0, v_0) , the curves expressed by $v = v_0$ and $u = u_0$ are called a ***u*-curve** and a ***v*-curve** through p_0 , respectively. Let $\mathbf{x}_u, \mathbf{x}_v$ denote the tangent vectors $\partial\mathbf{x}/\partial u, \partial\mathbf{x}/\partial v$ at p_0 to the *u*-curve and *v*-curve, respectively, through the given point p_0 and ξ denote the unit vector orthogonal to \mathbf{x}_u and \mathbf{x}_v . Then ξ is called the **normal vector** of S at p_0 and $(\mathbf{x}_u, \mathbf{x}_v, \xi)$ the **Gaussian frame** of S at p_0 . Although a Gaussian frame is not in general an orthogonal frame, it is intimately related to local parameters. The plane that passes through the point p_0 and is spanned by $\mathbf{x}_u, \mathbf{x}_v$ is called the **tangent plane** to S at p_0 . The coefficients of the second fundamental form $L(u, v)$, $M(u, v)$, $N(u, v)$ are expressed by the inner products $L = (-\mathbf{x}_u, \xi_u)$, $M = (-\mathbf{x}_u, \xi_v)$, $N = (-\mathbf{x}_v, \xi_v)$ ($\xi_u = \partial\xi/\partial u$, $\xi_v = \partial\xi/\partial v$).

Let (X, Y) be the coordinates of a point on the tangent space at p_0 with respect to the Gaussian frame. We call the curve of the second order defined by $LX^2 + 2MXY + NY^2 = \varepsilon$ (ε is a suitable constant) the **Dupin indicatrix**. The point p_0 is called an **elliptic point** or a **hyperbolic point** on S according as the Dupin indicatrix at the point is an ellipse or a hyperbola. If p_0 is an elliptic point, then points near p_0 on the surface lie on one side of the tangent plane at p_0 , whereas if p_0 is a hyperbolic point,

points near p_0 on the surface lie on both sides of the tangent plane at p_0 (Figs. 4, 5). A hyperbolic point is also called a **saddle point**, since in a neighborhood of the point the surface looks like a saddle. A point that is neither elliptic nor hyperbolic is called a **parabolic point**; at a parabolic point we have $LN - M^2 = 0$. If at least one of L, M, N does not vanish at p_0 , then there is a neighborhood of p_0 of the surface that lies on one side of the tangent plane at p_0 (Fig. 6). If a vector (X, Y) on the tangent plane of the surface at p_0 satisfies the equation $LX^2 + 2MXY + NY^2 = 0$, then the direction of the vector is called an **asymptotic direction**. If the point p_0 is elliptic, such a direction does not exist; if p_0 is hyperbolic, the direction is an asymptotic direction of the Dupin indicatrix on the tangent plane at p_0 . A curve C on a surface such that the tangent line at each point of the curve coincides with an asymptotic direction of the surface at the point is called an **asymptotic curve**.

Fig. 4
Elliptic point.

Fig. 5
Hyperbolic point.

Fig. 6
Parabolic point.

Let $C: \mathbf{x} = \mathbf{x}(u(t), v(t))$ be a curve through p_0 on the surface $\mathbf{x} = \mathbf{x}(u, v)$. Then the curvature κ of C as a space curve is given by

$$\kappa \cos \theta = \frac{L du^2 + 2M du dv + N dv^2}{E du^2 + 2F du dv + G dv^2},$$

where $du dv$ is the direction of C on the surface at p_0 and θ is the angle between the normal of the surface at p_0 and the principal normal of C at p_0 . The center of curvature at a point p_0 of a curve C of class C^2 on a surface of class C^2 is the projection on its osculating plane of the center of curvature of the section C^* (of the surface) cut by the plane determined by the tangent to the curve at p_0 and the normal of the surface at the point (**Meusnier's theorem**). The curvature of the curve C^* at p_0 is called the **normal curvature** of the surface at the point for the tangent direction. Since the normal curvature for a direction at a point is a continuous function of this direction that can be represented as a point on a unit circle, there exist two directions that realize the maximum and minimum of the normal curvature. These directions are given by the equation

$$\begin{vmatrix} E du + F dv & F du + G dv \\ L du + M dv & M du + N dv \end{vmatrix} = 0.$$

When this quadratic equation in du/dv has nonzero discriminant, it determines two directions defined by its two roots. These directions are called **principal directions** at the point. A curve C on a surface such that the tangent line at each point of the curve coincides with a principal direction at the point is called a **line of curvature**. When all lines of curvature of a surface are circles, the surface is called a **cyclide of Dupin**. The two normal curvatures corresponding to two principal directions are given by $1/R$, satisfying the following second-order equation:

$$\left(\frac{1}{R}\right)^2 - \frac{EN + GL - 2FM}{EG - F^2} \frac{1}{R} + \frac{LN - M^2}{EG - F^2} = 0.$$

They are called **principal curvatures**, and each of their inverses is called a **radius of principal curvature**. The mean value $H = (\kappa_1 + \kappa_2)/2$ of two principal curvatures $\kappa_i = 1/R_i$ ($i = 1, 2$) is called the **mean curvature** (or **Germain's curvature**), and the product $K = \kappa_1 \kappa_2$ is called the **total curvature** (or **Gaussian curvature**). These are given by

$$H = \frac{1}{2} \frac{EN + GL - 2FM}{EG - F^2}, \quad K = \frac{LN - M^2}{EG - F^2}.$$

A point on a surface is elliptic, hyperbolic, or parabolic according as $K > 0$, $K < 0$, or $K = 0$ at the point. A point where the second fundamental form is proportional to the first fundamental form is called an **umbilical point**, and a point where the second fundamental form vanishes is called a **flat point** or a **geodesic point**. If a surface consists of umbilical points only, the ratio $(L(du)^2 + 2M du dv + N(dv)^2)/(E(du)^2 + 2F du dv + G(dv)^2)$ is a constant, and the surface is either a sphere or a portion of it. If a surface consists of flat points

only, the surface must be either a plane or a portion of it. The mean curvature and the Gaussian curvature of a sphere are constant, and those of a plane are both equal to zero. If we use the spherical representation of a surface stated in Section G, we can give to the Gaussian curvature the following geometric meaning: Let A be the area of the domain enclosed by a closed curve C around a point p_0 on a surface, and let A^* be the area of the domain on the unit sphere enclosed by the curve that is the image of C under the spherical representation of the surface. Then the limit of A^*/A as the closed curve C tends to the point p_0 is equal to K at p_0 .

Let us denote by $(g^{\alpha\beta})$ the inverse matrix of the matrix $(g_{\alpha\beta})$ whose elements are coefficients of the first fundamental form $g_{\alpha\beta} du^\alpha du^\beta$. We easily see that $g^{11} = G/(EG - F^2)$, $g^{12} = g^{21} = -F/(EG - F^2)$, $g^{22} = E/(EG - F^2)$. We introduce the symbols

$$[\beta\gamma, \alpha] = \frac{1}{2} \left(\frac{\partial g_{\alpha\beta}}{\partial u^\gamma} + \frac{\partial g_{\gamma\alpha}}{\partial u^\beta} - \frac{\partial g_{\beta\gamma}}{\partial u^\alpha} \right),$$

$$\begin{Bmatrix} \alpha \\ \beta\gamma \end{Bmatrix} = g^{\alpha\delta} [\beta\gamma, \delta],$$

which are called the **Christoffel symbols** of the first and second kinds, respectively. Suppose that a surface is given by the vector representation $\mathbf{x} = \mathbf{x}(u_1, u_2)$, and put $\mathbf{x}_\alpha = \partial \mathbf{x} / \partial u^\alpha$, $\mathbf{x}_{\alpha\beta} = \partial \mathbf{x}_\alpha / \partial u^\beta$. Then for the derivatives of the Gauss frame, we obtain

$$\mathbf{x}_{\alpha\beta} = \begin{Bmatrix} \gamma \\ \alpha\beta \end{Bmatrix} \mathbf{x}_\gamma + H_{\alpha\beta} \boldsymbol{\xi}, \quad \boldsymbol{\xi}_\alpha = -g^{\gamma\beta} H_{\beta\alpha} \mathbf{x}_\gamma.$$

We call the former **Gauss's formula** and the latter **Weingarten's formula**. The integrability conditions of these partial differential equations are

$$R^\alpha_{\beta\gamma\delta} = H_{\delta\beta} H_\gamma^\alpha - H_{\gamma\beta} H_\delta^\alpha, \quad H_\gamma^\alpha = g^{\alpha\sigma} H_{\gamma\sigma},$$

$$\frac{\partial H_{\alpha\beta}}{\partial u^\gamma} - \frac{\partial H_{\alpha\gamma}}{\partial u^\beta} + \begin{Bmatrix} \sigma \\ \alpha\beta \end{Bmatrix} H_{\sigma\gamma} - \begin{Bmatrix} \sigma \\ \alpha\gamma \end{Bmatrix} H_{\sigma\beta} = 0,$$

where

$$R^\alpha_{\beta\gamma\delta} = \frac{\partial}{\partial u^\gamma} \begin{Bmatrix} \alpha \\ \delta\beta \end{Bmatrix} - \frac{\partial}{\partial u^\delta} \begin{Bmatrix} \alpha \\ \gamma\beta \end{Bmatrix} + \begin{Bmatrix} \sigma \\ \delta\beta \end{Bmatrix} \begin{Bmatrix} \alpha \\ \gamma\sigma \end{Bmatrix} - \begin{Bmatrix} \sigma \\ \gamma\beta \end{Bmatrix} \begin{Bmatrix} \alpha \\ \delta\sigma \end{Bmatrix}$$

are components of the curvature tensor. The former are called the **Gauss equations**, and the latter the **Codazzi-Mainardi equations**. In connection with these equations, **Bonnet's fundamental theorem** states the following: Suppose that a positive definite symmetric matrix $(g_{\alpha\beta})$ and a symmetric matrix $(H_{\alpha\beta})$ are given that are functions of class C^2 and C^1 , respectively, defined over a simply connected domain D in \mathbf{R}^2 . If they satisfy the Gauss

equations and the Codazzi-Mainardi equations, then there exists a surface $\mathbf{x} = \mathbf{x}(u_1, u_2)$ with the given $(g_{\alpha\beta})$ and $(H_{\alpha\beta})$ as coefficients of its first and second fundamental forms, respectively. Such a surface is determined uniquely if, for an arbitrary fixed point (u_1^0, u_2^0) of D , we assign an arbitrary point p_0 and a frame $(\mathbf{x}_1^0, \mathbf{x}_2^0, \xi^0)$ at p_0 so that $\mathbf{x}_1^0, \mathbf{x}_2^0$ are orthogonal to the unit vector ξ^0 and $(\mathbf{x}_\alpha^0, \mathbf{x}_\beta^0) = g_{\alpha\beta}(u_1^0, u_2^0)$ as the Gaussian frame at p_0 . On the other hand, we can investigate surfaces as Riemannian manifolds defined by the first fundamental form.

A \dagger diffeomorphism between two surfaces preserving arc length is called an **isometric mapping**. The condition of preserving arc length is equivalent to the condition that the first fundamental quantities of the surfaces coincide at each pair of corresponding points, provided that we have introduced parameters on the two surfaces so that corresponding points have the same parameter values. In such a case two surfaces are said to be **isometric**. From the Gauss equation we can see that the total curvature depends only on the first fundamental quantities. So K is a quantity that is preserved under isometric mappings (**Gauss's theorema egregium**).

A vector field $\lambda^\alpha(t)\mathbf{x}_\alpha$ defined along a curve $u^\alpha = u^\alpha(t)$ on a surface is said to be **parallel in the sense of Levi-Civita** along the curve if its \dagger covariant derivative along the curve vanishes, i.e., if

$$d\lambda^\alpha/dt = d\lambda^\alpha/dt + \left\{ \begin{matrix} \alpha \\ \beta\gamma \end{matrix} \right\} \lambda^\beta du^\gamma/dt = 0.$$

The length of a vector belonging to a vector field that is parallel along a curve C is constant along C . The angle of two vectors both belonging to vector fields that are parallel along C is also constant along C . Choose two vector fields $\lambda_{(a)}^\alpha$ parallel along a curve C on a surface that satisfy $g_{\alpha\beta}\lambda_{(a)}^\alpha\lambda_{(b)}^\beta = \delta_{ab}$. Then the tangent vector to C is expressed by $du^\alpha/dt = \lambda_{(a)}^\alpha v^a(t)$. Take a 2-plane and fix an orthogonal coordinate system on it; then the integral curve C of a set of ordinary differential equations $dx^\alpha/dt = C_{(a)}^\alpha v^a(t)$ ($C_{(a)}^\alpha = \lambda_{(a)}^\alpha(P_0)$) is called the **development** of C (\rightarrow 80 Connections). We denote by κ the curvature of a curve C of class C^2 on a surface S of class C^2 and by σ the angle between the binormal of C and the normal of S at the same point. Then the quantity $\kappa_g = \kappa \cos \sigma$, belonging to the geometry on the surface, is called the **geodesic curvature** of the curve at the point. A curve with vanishing geodesic curvature is called a **geodesic**. It satisfies the differential equations

$$\frac{d^2 u^\alpha}{ds^2} + \left\{ \begin{matrix} \alpha \\ \beta\gamma \end{matrix} \right\} \frac{du^\beta}{ds} \frac{du^\gamma}{ds} = 0.$$

The development of a geodesic is a straight line (\rightarrow 364 Riemannian Manifolds).

Let us consider a simply connected, orientable bounded domain D on a surface such that the boundary of D is a simple closed curve C that consists of a finite number of arcs of class C^2 . If we denote by α_i ($i = 1, 2, \dots, m$) the external angles at vertices of the curvilinear polygon C (Fig. 7), we have

$$\int_C \kappa_g ds + \sum_{i=1}^m \alpha_i + \iint_D K d\sigma = 2\pi.$$

This is called the **Gauss-Bonnet formula**. In particular, if all the arcs of C are geodesics, we have

$$\sum_{i=1}^m \alpha_i + \iint_D K d\sigma = 2\pi.$$

This formula implies as special cases the following well-known theorems in Euclidean geometry and spherical trigonometry: (i) The sum of interior angles of a triangle is equal to π . (ii) The area of a spherical triangle is proportional to its spherical excess. The formula also implies the following theorem: On any closed orientable surface we have $\iint K d\sigma = 2\pi\chi$, where χ is the \dagger Euler characteristic of the surface. We call $\iint K d\sigma$ the **integral curvature** (or **total Gaussian curvature**).

Fig. 7

1. Special Surfaces in E^3

A surface is called a **surface of revolution** if it is generated by a curve C on a plane π when π is rotated around a straight line l in π . Then l and C are called an **axis of rotation** and a **generating curve**, respectively. A surface of revolution having the x_3 -axis as the axis of rotation is given by the equations $x_1 = r \cos \theta$, $x_2 = r \sin \theta$, $x_3 = \varphi(r)$; its first fundamental form is $(1 + \varphi'^2)dr^2 + r^2 d\theta^2$. The section of a surface of revolution by a half-plane through its axis of rotation is called a **meridian**. According as the meridian is a straight line parallel to the axis of rotation or a straight line intersecting the axis nonorthogonally, the surface of revolution is called a **circular cylinder** or a **circular cone**, respectively. If the

meridian is a circle that does not intersect the axis of rotation, it is called a **torus**.

A surface of class C^2 whose mean curvature H vanishes everywhere is called a **minimal surface** (\rightarrow 275 Minimal Submanifolds). A surface of class C^1 realizing a relative minimum of areas among all surfaces of class C^1 with a given closed curve as their boundaries is an \dagger analytic surface such that $H=0$. Conversely, a surface of class C^2 with vanishing mean curvature is an analytic surface. The equation of a surface of revolution with a catenary as its generating line is given by $x_1^2 + x_2^2 = a(e^{x_3/a} + e^{-x_3/a})/2$. This surface is called a **catenoid** and is a minimal surface. Conversely, a minimal surface of revolution is necessarily a catenoid. For a surface obtained by rotating a \dagger Delaunay curve around its base line, the mean curvature H is equal to a constant ($\neq 0$). Conversely, a surface of revolution with nonzero constant mean curvature must be such a surface. A surface with constant Gaussian curvature is called a **surface of constant curvature**, and is a 2-dimensional Riemannian space of constant curvature (\rightarrow 364 Riemannian Manifolds). A non-Euclidean plane can be represented locally as a surface of constant curvature (\rightarrow 285 Non-Euclidean Geometry). Two surfaces of the same constant curvature are locally isometric to each other.

Surfaces of revolution of constant curvature are classified. The simplest surface of constant negative curvature is a **pseudosphere**, which is a surface of revolution obtained by rotating a \dagger tractrix $x_1 = a \cos \varphi$, $x_3 = a \log \tan((\varphi/2) + (\pi/4)) - a \sin \varphi$ ($-\pi/2 < \varphi < \pi/2$) around the x_3 -axis. A surface generated by a 1-parameter family of straight lines is called a **ruled surface**; a hyperboloid of one sheet, a hyperbolic paraboloid, a circular cylinder, and a circular cone are examples. The first two can be regarded as ruled surfaces in two ways. Each of the straight lines that generate a ruled surface is called a **generating line**. A surface consisting of straight lines parallel to a fixed line and passing through each point of a space curve C is called a **cylindrical surface** with the director curve C . A surface generated by a straight line that connects a certain point o with each point of a curve C is called a **conical surface**. Both a cylindrical surface and a conical surface are ruled surfaces such that $K=0$ everywhere. For ruled surfaces we have $K \leq 0$. In particular, a surface such that $H \neq 0$ and $K=0$ everywhere is called a **developable surface**. A developable surface must be either a cylindrical surface, a conical surface, or a tangent surface of a space curve. There exist ruled surfaces that are not developable, for example, hyperboloids of one sheet and hyperbolic paraboloids. A nondevelopable ruled surface is called a **skew surface**. A

ruled surface generated by a straight line that moves under a certain rule intersecting a fixed straight line l orthogonally is called a **right conoid**. If we take l as the x_3 -axis, the surface is given by the equations $x_1 = u \cos v$, $x_2 = u \sin v$, $x_3 = f(v)$. A surface generated by a curve C (C may be chosen as a plane curve) that moves in the direction of a fixed line l with constant velocity and turns around l with certain constant angular velocity is called a **helicoidal surface**. If we take l as the x_3 -axis, the surface is given by the equations $x_1 = u \cos v$, $x_2 = u \sin v$, $x_3 = f(u) + kv$, where k is a constant and $x_3 = f(x_1)$ is the equation of C . In particular, if C is a straight line that intersects l orthogonally, then $f(u)=0$, and the surface is called a **right helicoid** (or **ordinary helicoid**). A right conoid is both a ruled surface and a minimal surface. Conversely, a ruled surface that is also a minimal surface is necessarily a right conoid. A helicoidal surface with a tractrix as the curve C is called a **Dini surface** and is a surface of constant negative curvature. On the normal of a surface S two points q_i ($i=1, 2$) are centers of principal curvature at p . The locus of each of these points is a surface called a **center surface** of S . When S is a sphere, two center surfaces degenerate to a point; if S is a surface of revolution, one of the center surfaces degenerates to the axis of revolution and the other is a certain surface of revolution. If S is general, each of the center surfaces is the locus of an edge of regression of the developable surface generated by normals of S along a line of curvature.

When a 1-parameter family of surfaces S_t is given by the equation $F(x_1, x_2, x_3, t)=0$, a surface E that does not belong to this family is called an **enveloping surface** of the family of surfaces $\{S_t\}$ if E is tangent to some S_t at each point of E , that is, if E and S_t have the same tangent plane. The equation of E is obtained by eliminating t from $F(x_1, x_2, x_3, t)=0$ and $(\partial F/\partial t)(x_1, x_2, x_3, t)=0$. In general, if we denote by $\varphi(x_1, x_2, x_3)=0$ the equation obtained by eliminating t from $F=0$ and $\partial F/\partial t=0$, then the surface defined by $\varphi=0$ is either the enveloping surface of $\{S_t\}$ or the locus of singular points of S_t . The intersection C_{t_0} of the enveloping surface E of $\{S_t\}$ and S_{t_0} is a curve defined by $F(x_1, x_2, x_3, t_0)=0$, $(\partial F/\partial t)(x_1, x_2, x_3, t_0)=0$. We call C_{t_0} a **characteristic curve** of $\{S_t\}$. Since $\{C_t\}$ is a family of curves on the enveloping surface E , there may exist an envelope F on E . In such a case, F is called the **line of regression** of $\{S_t\}$. The equation of F is obtained by eliminating t from $F=0$, $\partial F/\partial t=0$, and $\partial^2 F/\partial t^2=0$. In particular, the enveloping surface of a family of planes is a developable surface, and their characteristic curves are straight lines. Moreover, the line of

regression coincides with the line of regression of the tangent surface.

If there exists a diffeomorphism between two surfaces such that first fundamental forms at each pair of corresponding points are proportional, then the surfaces are said to be in a **conformal correspondence**. In particular, when the proportionality factor is a constant, they are said to be in a **similar** (or **homothetic**) **correspondence**. There exists a local conformal correspondence between any analytic surface and a plane. Namely, if we choose suitable parameters, we can reduce the first fundamental form of any analytic surface to the form $A(\xi, \eta)(d\xi^2 + d\eta^2)$. Such parameters are called **isothermal parameters**. From the existence of isothermal parameters we can see that there exists a local conformal correspondence between any two analytic surfaces. The assumption of analyticity in these theorems is not necessary [10]. If there exists a diffeomorphism between two surfaces under which geodesics are mapped to geodesics, then the surfaces are said to be in **geodesic correspondence**. A surface has a locally geodesic correspondence with a plane if and only if it is a surface of constant curvature. If two surfaces are in geodesic correspondence, then with respect to parameters with the same values at corresponding points, we have the relation

$$\overline{\left\{ \begin{matrix} \alpha \\ \beta_\gamma \end{matrix} \right\}} = \left\{ \begin{matrix} \alpha \\ \beta_\gamma \end{matrix} \right\} + \delta_\beta^\alpha A_\gamma + \delta_\gamma^\alpha A_\beta$$

for coefficients of connections of the two surfaces.

By the [†]Alexander-Pontryagin duality theorem, a submanifold M in E^3 that is homeomorphic to S^2 divides E^3 into two domains, and two points belonging to different domains cannot be connected by a broken segment unless the segment meets the surface. Such a manifold M is called a **closed surface**. One of the two domains consists of those points with bounded distance from a point belonging to the domain. Such a domain is called the interior of the closed surface M . If the set M^* consisting of M and its interior is convex in E^3 , the surface M is called a **closed convex surface** (or **ovaloid**).

The Gaussian curvature of an ovaloid cannot be negative at any point. A closed surface with $K > 0$ must be an ovaloid. Moreover, it is known that on any closed surface there exists at least one point where $K > 0$ (J. Hadamard). If there exists no umbilical point and K is strictly positive in a domain on a surface, then the two principal curvatures regarded as continuous functions on the domain cannot take their local maximum and local minimum values at the same point (D. Hilbert). A com-

pact, connected surface of class C^4 with constant Gaussian curvature is a sphere. A closed surface with $K > 0$ and $H = \text{constant}$ is a sphere (H. Liebmann).

A problem proposed by H. Hopf asks whether an orientable compact surface with constant mean curvature is a sphere. In connection with this problem, Hopf showed that a closed orientable surface of class C^3 of genus zero with constant mean curvature is a sphere. If there is a certain relation $W(k_1, k_2) = 0$ between the two principal curvatures k_1, k_2 ($k_1 \geq k_2$) of a surface, the surface is called a **Weingarten surface** (or **W-surface**). There are many interesting results for W -surfaces. As an extension of the convex surface, tight immersions have been studied (\rightarrow 365 Riemannian Submanifolds).

The Gaussian curvature K is invariant under isometries. Hence a sphere is transformed to a sphere by each isometry. This fact is sometimes described as the **rigidity** of a sphere. More generally, if two ovaloids are isometric, then they are congruent (**Cohn-Vossen's theorem**). It is known that if we remove a small circular disk from a sphere, then the remaining portion of the sphere is isometrically deformable. On the existence of closed geodesics on ovaloids, G. D. Birkhoff proved the following theorem: There exist at least three closed geodesics on any ovaloid of class C^3 . It is also known that there exist surfaces of revolution that are not spheres but whose geodesics are all closed (\rightarrow 178 Geodesics). On a hyperbolic non-Euclidean compact [†]space form of genus p ($p \geq 2$) there exists a geodesic whose points are everywhere dense in it (E. Hopf) (for the ergodicity of flows along geodesics on this surface \rightarrow 136 Ergodic Theory; also 126 Dynamical Systems).

J. Singular Points of a Surface

Suppose that a neighborhood of a point p_0 of a surface S in E^3 is given by a certain vector-valued function f of class C^r as $r = \tilde{r}(u, v)$. Then a point p_0 where two vectors $(\partial \tilde{f} / \partial u)_{p_0}, (\partial \tilde{f} / \partial v)_{p_0}$ are linearly independent is called a **regular point**. A point on S that is not regular is called a **singular point**. If for suitable parameters we have $(\partial \tilde{f} / \partial u)_{p_0} = 0$ but $(\partial \tilde{f} / \partial v)_{p_0}, (\partial^2 \tilde{f} / \partial u^2)_{p_0}, (\partial^2 \tilde{f} / \partial u \partial v)_{p_0}$ are linearly independent, then such a singular point is called a **semiregular point**. In general, shapes of neighborhoods of singular points are extremely complicated. However, we note the following: (i) by a small deformation of the function f (and its derivatives of orders at most r) we can reduce p_0 to a regular or semiregular point of the deformed surface; (ii) if p_0 is semiregular, we can choose

suitable parameters and curvilinear coordinates of class C^r in E^3 near p_0 so that the surface S in the neighborhood of the origin p_0 is expressed by the equations $x_1 = u^2$, $x_2 = v$, $x_3 = uv$ (H. Whitney's theorem [15]). (The higher-dimensional case has also been considered (Whitney [16]).)

112 (XII.15) Differential Operators

A. Definition

A mapping (or an operator) A of a function space F_1 to a function space F_2 is said to be a **differential operator** if the value $f(x)$ of the image $f = Au$ ($u \in F_1, f \in F_2$) at each point x is determined by the values at x of u and a finite number of its derivatives. If u and f are distributions, the definition applies with the derivative interpreted in the sense of distributions (\rightarrow 125 Distributions and Hyperfunctions). In this article we restrict ourselves to the case of linear differential operators and consider only those of the form

$$P(x, D) = \sum_{|\alpha| \leq m} a_\alpha(x) D^\alpha, \quad (1)$$

where α denotes n -tuples $(\alpha_1, \alpha_2, \dots, \alpha_n)$ of nonnegative integers, called **multi-indices**; $|\alpha|$ the **length** of α : $|\alpha| = \alpha_1 + \alpha_2 + \dots + \alpha_n$; and D^α the differential operator $D^\alpha = D_1^{\alpha_1} D_2^{\alpha_2} \dots D_n^{\alpha_n}$, with $D_j = (-i)\partial/\partial x_j$. The coefficient $(-i)$ is sometimes omitted. The coefficients $a_\alpha(x)$ are functions defined on an open set Ω in n -dimensional space. We call $P(x, D)$ an **ordinary differential operator** if the dimension n of Ω is 1 and a **partial differential operator** if $n \geq 2$. Ordinary differential operators and partial differential operators behave quite differently in many respects.

We set

$$P(x, \xi) = \sum_{|\alpha| \leq m} a_\alpha(x) \xi^\alpha, \quad \xi^\alpha = \xi_1^{\alpha_1} \dots \xi_n^{\alpha_n},$$

where $\xi = (\xi_1, \xi_2, \dots, \xi_n) \in \mathbf{R}^n$ or \mathbf{C}^n . The **order** of $P(x, D)$ is the greatest integer $|\alpha|$ for which $a_\alpha(x) \neq 0$. In expression (1) m is assumed to be equal to the order, and in that case

$$P_m(x, D) = \sum_{|\alpha|=m} a_\alpha(x) D^\alpha$$

is called the **principal part** of $P(x, D)$, and the corresponding polynomial $P_m(x, \xi)$ the **characteristic polynomial**.

Differential operators have been investigated for a long time in connection with the linear differential equations

$$P(x, D)u(x) = f(x), \quad x \in \Omega. \quad (2)$$

Except for ordinary differential operators, however, it is rather recently that the properties of such operators have been studied from the general viewpoint.

We denote a differential operator with constant coefficients by $P(D)$. In general, $P(x, D)$ is assumed to be a linear differential operator with coefficients that are C^∞ -functions. However, many of the results for C^∞ -coefficients also hold when the coefficients are sufficiently differentiable. (For \dagger function spaces $\mathcal{D}(\Omega)$, $\mathcal{D}'(\Omega)$, $\mathcal{E}(\Omega)$, $\mathcal{E}'(\Omega)$, $C(\Omega)$, $C^\infty(\Omega)$, $C_0^\infty(\Omega)$, $L_p(\Omega)$, $\mathcal{A}(\Omega)$, $\mathcal{B}(\Omega)$, etc., \rightarrow 125 Distributions and Hyperfunctions, 168 Function Spaces).

Differential operators are classified according to their properties. The most important are the elliptic, hyperbolic, and parabolic types. A differential operator $P(x, D)$ is said to be an **elliptic** operator if the characteristic polynomial $P_m(x, \xi)$ has no real zero except for $\xi = 0$ for each $x \in \Omega$. Typical examples are the Laplacian $\Delta = -(D_1^2 + \dots + D_n^2)$ and the Cauchy-Riemann operator $\partial/\partial\bar{z} = (1/2)(\partial/\partial x + i\partial/\partial y)$.

A differential operator is said to be **hyperbolic** if the associated Cauchy problem is well posed (\rightarrow 325 Partial Differential Equations of Hyperbolic Type). The d'Alembertian $D_1^2 - (D_2^2 + \dots + D_n^2)$ is an example. A differential operator of the form $\partial/\partial t + P(t, x, D_x)$ is called **parabolic** if $P(t, x, D_x)$ is strongly elliptic (\rightarrow Section G) in x . The heat operator $iD_{n+1} - \Delta$ is typical.

These three types of operators appear most often in applications, and if $n = 2$, then any operator of order 2 with real coefficients in $(\partial/\partial x_j)^2$ belongs to one of them at a generic point. In other cases, however, there are differential operators that do not belong to any of them.

B. Fundamental Solutions

If a differential operator $P(x, D)$ with $\mathcal{D}(\Omega)$ as its domain has a left inverse F that is expressed as an \dagger integral operator with \dagger kernel distribution (in $\mathcal{D}'_{x,y}$; \rightarrow 125 Distributions and Hyperfunctions F), then the kernel is said to be a **fundamental solution** (or **elementary solution**). F is usually a right inverse of the weak extension (\rightarrow Section F) of $P(x, D)$ and maps $\mathcal{D}(\Omega)$ into $\mathcal{E}(\Omega)$. The image is mapped to the original function by $P(x, D)$. Nevertheless, F is not a genuine right inverse, and hence the fundamental solution is not unique if it exists.

When $P(D)$ is a differential operator with constant coefficients, we call a distribution $E(x)$ a **fundamental solution** if it satisfies

$$P(D)E(x) = \delta(x), \quad (3)$$

where $\delta(x)$ is \dagger Dirac's distribution (δ function). If $E(x)$ is a fundamental solution in this sense, then $F(x, y) = E(x - y)$ is the kernel of a left inverse of $P(D)$ and is a fundamental solution in the sense of the preceding paragraph.

Every differential operator $P(D)$ with constant coefficients has a fundamental solution in the sense of (3) (**Ehrenpreis-Malgrange theorem**; see L. Hörmander [4] for a proof).

General operators $P(x, D)$ with variable coefficients do not necessarily have fundamental solutions. However, if $P(x, D)$ belongs to one of the classical types of operators (elliptic, hyperbolic, or parabolic), then it has a fundamental solution at least locally. (See F. John [8] for elliptic operators, J. Leray [11] for strongly hyperbolic operators, and S. Mizohata [12] and S. D. Eidel'man [9] for parabolic operators.) Leray has generalized John's method to strongly hyperbolic operators in an enormous work [13].

C. Ranges of Differential Operators

Let $P(D)$ be a differential operator with constant coefficients. Then it follows from the Ehrenpreis-Malgrange theorem that $P(D)\mathcal{D}'(\Omega) \supset \mathcal{D}(\Omega)$ holds for any open set Ω . However, there are differential operators $P(x, D)$ with variable coefficients such that for any Ω , $P(x, D)\mathcal{D}'(\Omega) \not\supset \mathcal{D}(\Omega)$. H. Lewy first devised such an example:

$$P(x, D) = -iD_1 + D_2 - 2(x_1 + ix_2)D_3.$$

Let $C_{2m-1}(x, D)$ be the homogeneous part of order $2m-1$ of the commutator

$$P(x, D)\overline{P(x, D)} - \overline{P(x, D)}P(x, D).$$

Then in order that $P(x, D)\mathcal{D}'(\Omega) \supset \mathcal{D}(\Omega)$, it is necessary that

$$P_m(x, \xi) = 0 \quad \text{imply} \quad C_{2m-1}(x, \xi) = 0$$

for all $x \in \Omega$, $\xi \in \mathbb{R}^n$ (**Hörmander's theorem** [4]).

When $P(x, D)$ is a differential operator that does not satisfy this condition (e.g., Lewy's operator), choose an $f(x) \in \mathcal{D}(\Omega)$ that is not in $P(x, D)\mathcal{D}'(\Omega)$. Then the differential equation (2) has no distribution solutions at all. P. Schapira extended this result to the case of \dagger hyperfunctions (also \rightarrow 274 Microlocal Analysis).

Concerning the ranges of differential operators $P(D)$ with constant coefficients, we have the following detailed results due to L. Ehrenpreis [28], B. Malgrange [14], and Hörmander [4].

An open set Ω is said to be ***P*-convex** for a differential operator $P(D)$ if for each compact set $K \subset \Omega$ there exists a compact set $K' \subset \Omega$ such that $\varphi \in C_0^\infty(\Omega)$ and $\text{supp } P(-D)\varphi \subset K$ imply $\text{supp } \varphi \subset K'$. Convex sets are *P*-convex for any $P(D)$. All open sets are *P*-convex if and only if $P(D)$ is an elliptic operator.

Theorem: The following conditions are equivalent: (i) Ω is *P*-convex; (ii) $P(D)\mathcal{D}'(\Omega) \supset \mathcal{E}(\Omega)$; (iii) $P(D)\mathcal{E}(\Omega) = \mathcal{E}(\Omega)$. Property (iii), the Mittag-Leffler theorem, and the solvability of †Cousin's first problem for the solutions of $P(D)u = 0$ are equivalent.

An open set Ω is said to be **strongly *P*-convex** if for each compact set $K \subset \Omega$ there exists a compact set K' such that $\mu \in \mathcal{E}'(\Omega)$ and $\text{supp } P(-D)\mu \subset K$ imply $\text{supp } \mu \subset K'$; and $\mu \in \mathcal{E}'(\Omega)$ and $\text{sing supp } P(-D)\mu \subset K$ imply $\text{sing supp } \mu \subset K'$; where the **singular support** of μ is the closure of the set of all points at which μ is not a C^∞ -function. Convex sets are strongly *P*-convex, and strongly *P*-convex sets are *P*-convex.

Theorem: Ω is strongly *P*-convex if and only if $P(D)\mathcal{D}'(\Omega) = \mathcal{D}'(\Omega)$.

R. Harvey has shown that every domain Ω is *P*-convex in the sense of hyperfunctions, i.e., the equation $P(D)u = f$ always has a hyperfunction solution u on Ω for any hyperfunction f on Ω . For the †real analytic functions $\mathcal{A}(\Omega)$, however, $P(D)\mathcal{A}(\Omega) = \mathcal{A}(\Omega)$ does not hold for convex open set Ω in general. Hörmander [15] gave a necessary and sufficient condition for $P(D)$ and Ω in order that this hold.

D. Hypoellipticity

A differential operator $P(x, D)$ is called **hypoelliptic** in Ω if for any distribution $u(x) \in \mathcal{D}'(\Omega)$, $Pu \in C^\infty(\Omega)$ implies $u \in C^\infty(\Omega)$. Further, a differential operator with real analytic coefficients $P(x, D)$ is called **analytically hypoelliptic** in Ω if P is hypoelliptic and if for any distribution $u(x) \in \mathcal{D}'(\Omega)$, $Pu \in \mathcal{A}(\Omega)$ implies $u(x) \in \mathcal{A}(\Omega)$.

There are two fundamental facts about such operators. Let P have constant coefficients; then $P(D)$ is hypoelliptic if and only if $P(\xi + i\eta) = 0$ and $|\xi + i\eta| \rightarrow \infty$ imply that $|\eta| \rightarrow \infty$ (**Hörmander's theorem** [4]). Furthermore, $P(D)$ is analytic hypoelliptic if and only if P is elliptic (**Petrovskii's theorem** [16]). The heat operator is not elliptic, but hypoelliptic. If $P(D)$ is elliptic, then actually any hyperfunction $u(x) \in \mathcal{B}(\Omega)$ such that $Pu \in \mathcal{A}(\Omega)$ is real analytic (R. Harvey, G. Bengel). On the other hand, if $P(D)$ is not elliptic, there is a hyperfunction solution u of $Pu = 0$ that is not a distribution.

Strictly speaking, the notion of the hypoellipticity for general differential operators was first formulated explicitly by L. Schwartz

[27]. Before that time, D. Hilbert, E. E. Levi and K. O. Friedrichs, and others investigated this problem for some elliptic operators, and the hypoellipticity was called **Weyl's lemma** (\rightarrow 323 Partial Differential Equations of Elliptic Type).

Similarly to the constant coefficient case the following two theorems are fundamental: Elliptic and parabolic operators $P(x, D)$ with C^∞ coefficients are hypoelliptic (Schwartz [27], Mizohata [12]). Elliptic operators $P(x, D)$ with real analytic coefficients are analytic hypoelliptic (I. G. Petrovskii [16], C. B. Morrey and L. Nirenberg). The latter holds also for hyperfunction solutions (M. Sato and Schapira). Moreover, the following result is known: If for each compact set K in an open set Ω , there exists a constant C such that $\|P^k u\|_K \leq C^{k+1}(mk)!$, then $u \in \mathcal{A}(\Omega)$, where $\|\cdot\|_K$ denotes the L_p -norm on K (H. Komatsu, T. Kotake, and M. S. Narasimhan).

However, as seen by the example $D_1 + ix_1^k D_2$ in \mathbf{R}^2 (k is even), the analytic hypoellipticity also holds for nonelliptic operators. Such an operator is called a subelliptic operator; subelliptic operators have been investigated by Hörmander, Yu. V. Egorov, F. Trèves, and others [19].

Hörmander has obtained a fairly complete result on the hypoellipticity of the operators of the form

$$L = \sum_{i=1}^r X_i^2 + X_0 + c(x),$$

where X_0, \dots, X_r are homogeneous first-order differential operators with real coefficients ([17]; O. A. Oleinik and E. V. Radkevich [18]). Hypoellipticity was investigated extensively after the introduction of pseudodifferential operators and Fourier integral operators (\rightarrow 345 Pseudodifferential Operators).

E. Differential Operators in Banach Spaces

We consider differential operators $P(x, D)$ defined on a domain Ω as operators in the function spaces $C(\Omega)$ or $L_p(\Omega)$. Differential operators of order $m \geq 1$ are always unbounded operators in the Banach space $X = C(\Omega)$ or $L_p(\Omega)$. Moreover, their domains of definition as operators in X are not generally determined uniquely by the expressions $P(x, D)$ as differential operators.

$P(x, D)$ is a linear operator that maps $C_0^\infty(\Omega)$ into X . This operator has a closed extension. The minimal closed extension P_0 is called the **minimal operator** of $P(x, D)$ in X . We have $u \in \mathcal{D}(P_0)$ and $P_0 u = f$ if and only if there exists a sequence $\varphi_n \in C_0^\infty(\Omega)$ such that $\varphi_n \rightarrow u$, $P(x, D)\varphi_n \rightarrow f$. On the other hand, the

closed linear operator P_1 whose domain is the set of all $u \in X$ such that $P(x, D)u \in X$ in the sense of distribution is called the **maximal operator** (or **weak extension**) of $P(x, D)$. We have $u \in \mathcal{D}(P_1)$ and $P_1 u = f$ if and only if $\langle u, {}^t P(x, D)\varphi \rangle = \langle f, \varphi \rangle$ for any $\varphi \in C_0^\infty(\Omega)$, where ${}^t P(x, D)$ is the **transposed operator**

$${}^t P(x, D)\varphi(x) = \sum_{|z| \leq m} (-D)^z (a_z(x)\varphi(x)).$$

Integration by parts shows that P_1 is an extension of P_0 and that when X is the t dual space of a space Y , the weak extension P_1 in X is the t dual of the minimal operator of ${}^t P(x, D)$ in Y . Let $X = L_p(\Omega)$ ($1 < p < \infty$), Ω be a bounded open set with smooth boundary, and $P(D)$ have constant coefficients. Then P_1 coincides with the smallest closed extension of the operator $P(D)$ having as its domain the set of all $u \in C^\infty(\Omega) \cap X$ such that $P(D)u \in X$. The latter closed extension is called the **strong extension**. The difference between the weak and the strong extension is not obvious in the variable coefficient case.

P_0 coincides with P_1 when Ω is the entire space and $P(x, D)$ is an elliptic operator whose coefficients are constants or close to constants (J. Peetre, *Medd. Lunds Univ. Mat. Sem.*, 16 (1959); T. Ikebe and T. Kato, *Arch. Rational Mech. Anal.*, 9 (1962)). In general, we have $P_0 \neq P_1$. Let $P(x, D)$ be an ordinary differential operator with bounded coefficients such that $|a_m(x)| \geq \delta > 0$ and Ω be the bounded interval (a, b) . Then the domain of P_1 coincides with the set of all $(m-1)$ -times continuously differentiable functions u such that the $(m-1)$ st derivative is absolutely continuous and $P(x, D)u \in X$, while the domain of P_0 is the set of all functions u which satisfy in addition the boundary conditions

$$\begin{aligned} u(a) &= u'(a) = \dots = u^{(m-1)}(a) \\ &= u(b) = \dots = u^{(m-1)}(b) = 0. \end{aligned}$$

(Moreover, $u^{(m)}(a) = u^{(m)}(b) = 0$ when $X = C(a, b)$.)

Let $G(P_0), G(P_1) (\subset X \times X)$ be the t graphs of P_0, P_1 . Then the quotient space $\mathcal{B} = G(P_1)/G(P_0)$ is called the **boundary space**, and an element of the dual \mathcal{B}' of \mathcal{B} , i.e., a continuous linear functional on $G(P_1)$ which vanishes on $G(P_0)$, is called a **boundary value** relative to $P(x, D)$. For the ordinary differential operators discussed above, the boundary space is the set of all linear combinations of $u^{(i)}(a)$ and $u^{(j)}(b)$. When $P(x, D)$ is an ordinary differential operator, we can explicitly determine the boundary values also in the case where the interval (a, b) is infinite, the coefficients $a_z(x)$ are not bounded, or $a_m(x) \rightarrow 0$ ($x \rightarrow a, b$); and we can show that \mathcal{B} is finite-dimensional. When $P(x, D)$ is a partial differential operator, \mathcal{B} is

generally of infinite dimension, and the concrete forms of the elements of \mathcal{B} and \mathcal{B}' are not known. However, we have some information by M. I. Vishik (*Amer. Math. Soc. Transl.*, (2) 24 (1963)) about the boundary values of elliptic operators of the second order. Combining this with the results by J.-L. Lions and E. Magenes (*J. Anal. Math.*, 11 (1963)), we can obtain information for elliptic operators of higher order.

F. Differential Operators with Boundary Conditions

A closed operator between the minimal operator P_0 and the maximal operator P_1 is determined by designating a closed subspace B of the boundary space \mathcal{B} . This operator is called the **operator with the boundary condition B** . Particularly important are boundary conditions expressed in the form

$$Q_i(x, D)u(x) = 0, \quad x \in \partial\Omega, \quad i = 1, \dots, k, \quad (4)$$

with differential operators $Q_i(x, D)$ ($i = 1, \dots, k$) defined on the boundary $\partial\Omega$ of Ω .

When $P(x, D)$ is an ordinary differential operator defined on a finite interval and the orders of Q_i are at most $m-1$ (or m), (4) always has a definite meaning. However, for partial differential operators, we need an interpretation of (4), i.e., (4) does not necessarily determine the subspace B of \mathcal{B} uniquely.

Let P_s be the smallest closed extension of $P(x, D)$ with $\{u \in C^\infty(\Omega) \cap X \mid Q_i(x, D)u(x) = 0, x \in \partial\Omega; P(x, D)u \in X\}$ as its domain. P_s is called the **strong extension** of the differential operator $P(x, D)$ with boundary condition (4).

On the other hand, when Ω, P , and Q_i satisfy suitable conditions, we can define the transposed differential operator ${}^t P(x, D)$ with the transposed boundary operators $R_j(x, D)$ ($j = 1, \dots, l$). Namely, there are differential operators $R_j(x, D)$ on the boundary such that a necessary and sufficient condition for $u \in C^\infty(\bar{\Omega})$ to satisfy (4) and $Pu(x) = f(x)$ is

$$\int_{\Omega} f(x)v(x)dx = \int_{\Omega} u(x){}^t P v(x)dx \quad (5)$$

for all $v(x) \in C^\infty(\bar{\Omega})$ with the boundary conditions $R_j v = 0, x \in \partial\Omega$. Then the operator P_w defined by $P_w u(x) = f(x)$ for the pairs $u(x), f(x) \in X$ satisfying (5) is called the **weak extension** of the differential operator $P(x, D)$ with boundary condition (4). As in the case of operators without boundary conditions, the weak extension is an extension of the strong extension, and generally is the dual of the strong extension in the dual space X' of the transposed differential operator with the transposed boundary condition.

Regularity up to the boundary. The fundamental problems for the differential operator $P(x, D)$ with the homogeneous boundary condition (4) are to determine, for both the strong and the weak extensions, the spaces of solutions of the homogeneous equations $Pu=0$ and their ranges. The problems mostly reduce to determining when the strong and the weak extensions coincide and, including this, also to the problem of regularity on the closed domain $\bar{\Omega}$ containing the boundary of the solutions u of the equation $P_w u = f$.

This problem was solved by Nirenberg for strongly elliptic operators in $L^2(\Omega)$ with the Dirichlet boundary condition

$$\partial^{j-1} u(x) / \partial n^{j-1} = 0, \quad j = 1, 2, \dots, m/2,$$

and generalized later by F. Browder, M. Schechter [20], S. Agmon, Lions, and others for elliptic operators in $L_p(\Omega)$ with a kind of coercive boundary condition (\rightarrow Section H).

Consequently, when Ω is bounded and smooth, P_w is equal to P_s for those operators. Write P for P_w . Then the space $N(P)$ of the solutions of $Pu=0$ is a subspace of finite dimension, and the range $R(P)$ is a closed subspace of finite codimension. In particular, it follows that the index of P , $\dim N(P) - \text{codim } R(P)$, is finite.

G. Strongly Elliptic Operators

A differential operator $P(x, D)$ is said to be **strongly elliptic** if its characteristic polynomial satisfies

$$\text{Re } P_m(x, \xi) \geq C |\xi|^m > 0, \quad \xi \neq 0.$$

Many of the elliptic operators, such as the Laplacian, that appear in applications are strongly elliptic. L. Gårding treated the boundary value problem with the Dirichlet condition (in the generalized sense) for strongly elliptic operators. His work initiated the general study of differential operators (\rightarrow 323 Partial Differential Equations of Elliptic Type). His theory is based on the following inequality, called **Gårding's inequality**:

$$\|\nabla^{m/2} u\|_{L_2}^2 \leq C \left(\text{Re} \int Pu \cdot \bar{u} dx + \|u\|_{L_2}^2 \right),$$

$$u \in C_0^\infty(\Omega).$$

H. Coercive Boundary Conditions

The boundary condition (4) is said to be **coercive** if

$$\|\nabla^m u\| \leq C(\|Pu\| + \|u\|) \quad (6)$$

holds for any $u \in C^\infty(\bar{\Omega})$ that satisfies (4). In

order that a differential operator P have a coercive boundary condition, it is necessary that it be a special type of elliptic operator. In this case, Agmon, N. Aronszajn, Schechter, and others found conditions under which (4) is coercive. Agmon, A. Douglis, and Nirenberg show that the inequality (6) holds in $L_p(\Omega)$ and in the normed spaces of Hölder continuous functions under a suitable condition. The classical boundary conditions $au + b\partial u/\partial n = 0$ ($a \geq 0, b \geq 0, a + b = 1$) are coercive for elliptic operators of the second order (\rightarrow 323 Partial Differential Equations of Elliptic Type). However, problems remain when the coefficients of $Q_j(x, D)$ are discontinuous. In order to have coincidence of the strong and weak extensions or regularity up to the boundary, it is necessary neither that P be elliptic nor that the boundary condition be coercive. But it is not known to what extent these conditions can be weakened. At present, major contributions are Hörmander's work (*Acta Math.*, 99 (1958)) dealing with operators with constant coefficients and flat boundaries, and works by J. J. Kohn [21], Nirenberg, and Hörmander concerning noncoercive boundary conditions. The latter works are connected with the theory of several complex variables, and have attracted much attention.

I. Self-Adjoint Extension

One of the fundamental problems in the case $X = L_2(\Omega)$ is whether the minimal operator P_0 has a self-adjoint extension. P_0 is symmetric if and only if $P(x, D)$ is **formally self-adjoint**: $P(x, D) = {}^t P(x, D)$. Under this condition the boundary space \mathcal{B} turns out to be the direct sum of two subspaces $\mathcal{B}_\pm = \{(x, P_1 x) \mid x \in \mathcal{D}(P_1), P_1 x = \pm ix\} + G(P_0)$. The numbers $n_\pm = \dim \mathcal{B}_\pm$ are called the **deficiency indices** of P_0 , and P_0 has a self-adjoint extension if and only if $n_+ = n_-$.

H. Weyl gave a method for computing n_\pm for the **Sturm-Liouville operators**:

$$P(x, D) = - \left(\frac{d}{dx} p(x) \frac{d}{dx} \right) + q(x), \quad x \in (a, b).$$

We say that a (resp. b) is of **limit circle type** if the solutions $u(x)$ of $P(x, D)u(x) + lu(x) = 0$ ($l \in \mathbb{C}$) always belong to L_2 in a neighborhood of a (resp. b) and of **limit point type** if a solution does not belong to L_2 . This classification does not depend on the choice of $l \in \mathbb{C}$. (1) If both a and b are of limit point type, then $n_+ = n_- = 0$ and hence P_0 is self-adjoint. (2) If a is of limit circle type and b is of limit point type, then $n_+ = n_- = 1$, and the self-adjoint extensions of P_0 are the operators P_α that are obtained from P_1 by assigning the boundary

condition

$$p(a)u'(a)\cos\alpha + u(a)\sin\alpha = 0.$$

The same is true when a and b are interchanged. (3) If both a and b are of limit circle type, then $n_+ = n_- = 2$, and we can impose two boundary conditions to obtain the self-adjoint extensions.

These results have been extended by K. Kodaira [23] and N. Dunford and J. Schwartz [3] to the case of ordinary differential operators of order m . There are formally self-adjoint operators that have no self-adjoint extensions. For example, the operator $-id/dx$ in $L_2(0, \infty)$ has deficiency indices $n_+ = 1 \neq n_- = 0$.

For partial differential operators, it is difficult to determine explicitly all self-adjoint extensions of a given formally self-adjoint operator because the boundary space is complicated. If the boundary condition (4) is formally self-adjoint and coercive, then it follows from the results of Schechter and others that the differential operator with boundary condition (4) is self-adjoint. Furthermore, conditions under which P_0 is self-adjoint or has a self-adjoint extension are known. The following theorem is often used as a condition of the latter type. If a \dagger symmetric operator defined on a dense subspace of a Hilbert space X is positive definite:

$$(Tx, x) \geq 0, \quad x \in \mathcal{D}(T),$$

then there is a positive definite self-adjoint extension \tilde{T} (Friedrichs's theorem). The self-adjoint extension obtained by this theorem is called the **Friedrichs extension**.

J. Generators of Semigroups

From the point of view of probability theory, W. Feller investigated the extensions of the Laplacian d^2/dx^2 and similar operators that are the generators of order-preserving semigroups. Recently various attempts have been made to generalize his results to the multi-dimensional case (\rightarrow 115 Diffusion Processes; 378 Semigroups of Operators and Evolution Equations).

P. D. Lax and A. N. Milgram proved that if $P(x, D)$ is a strongly elliptic operator, then $-P(x, D)$ with the Dirichlet condition in $L_2(\Omega)$ is the generator of a semigroup [1].

K. Boundary Value Problems

There are two methods of solving the inhomogeneous boundary value problem

$$P(x, D)u(x) = f(x), \quad x \in \Omega,$$

$$Q_i(x, D)u(x) = g_i(x), \quad x \in \partial\Omega, \quad i = 1, \dots, k.$$

In the first method, we take a function $v(x)$ that satisfies $Q_i(x, D)v(x) = g_i(x)$ and reduce the problem to the homogeneous one for $u_0 = u - v$. In the second method, we consider the pair $P(x, D)$ and $Q_i(x, D)$ as an operator that maps a function u to the pair of functions $(Pu, Q_i u)$ and investigate it directly. The latter method was adopted by Peetre and Hörmander [4].

L. Estimates in Weighted Spaces

J. F. Treves, Hörmander [4], and H. Kumano-go obtained estimates similar to (6) in L_p -spaces relative to the weighted measure $w_i(x)dx$ instead of the usual L_p -spaces, and applied them to the proof of the uniqueness of Cauchy problems for differential equations with variable coefficients (\rightarrow 321 Partial Differential Equations (Initial Value Problems)). Hörmander [22] applied similar estimates to the proof of the \dagger fundamental theorems of Stein manifolds.

M. Eigenfunction Expansions

When a self-adjoint operator P in the Hilbert space $L_2(\Omega)$ is a self-adjoint extension of a differential operator $P(x, D)$, the \dagger spectral decomposition of P is concretely expressed by the expansion of functions $u \in L_2(\Omega)$ into eigenfunctions of $P(x, D)$.

If Ω is bounded, $P(x, D)$ is an elliptic operator defined on a neighborhood of $\bar{\Omega}$, and the boundary condition is coercive, then the \dagger spectrum of P is composed solely of eigenvalues, and the eigenvectors of P are eigenfunctions of $P(x, D)$ in the classical sense and are of class C^∞ up to the boundary.

N. Asymptotic Distribution of Eigenvalues

If $P = -\Delta$, the number $v(\lambda)$ of eigenvalues less than λ satisfies the asymptotic relation

$$v(\lambda) \sim \frac{\lambda^{n/2} A}{2^{n-1} \pi^{n/2} n \Gamma(n/2)}, \quad \text{as } \lambda \rightarrow \infty$$

regardless of the shape of the domain and the boundary condition, where n is the dimension and A is the volume of Ω [2]. This was first proved by Weyl and extended by T. Carleman, Gårding, and others to the case of operators of higher order with variable coefficients (\rightarrow 323 Partial Differential Equations of Elliptic Type).

O. Weyl-Stone-Titchmarsh-Kodaira Theory

When Ω is unbounded or the coefficients of $P(x, D)$ have singularities near the boundary of Ω , the spectrum of P may have a continuous part.

Let $P(x, D)$ be an ordinary differential operator on an interval (a, b) . Then for each $\lambda \in \mathbb{C}$ the equation $(P(x, D) - \lambda)\varphi(x) = 0$ has m linearly independent solutions $\varphi_k(x, \lambda)$ ($k = 1, \dots, m$), and any solution is represented as a linear combination of them. Weyl and M. H. Stone obtained the spectral decomposition of P (of the second order) in the form

$$u(x) = \sum_{j,k=1}^m \int_{-\infty}^{\infty} \varphi_j(x, \lambda) d\rho_{jk}(\lambda) \times \int_a^b \overline{\varphi_k(y, \lambda)} u(y) dy,$$

$$Pu(x) = \sum_{j,k=1}^m \int_{-\infty}^{\infty} \lambda \varphi_j(x, \lambda) d\rho_{jk}(\lambda) \times \int_a^b \overline{\varphi_k(y, \lambda)} u(y) dy,$$

where the $\rho_{jk}(\lambda)$ are functions of bounded variation and their variations represent the spectral measure. This formula shows that linear combinations of the $\varphi_j(x, \lambda)$ form generalized eigenfunctions even when λ belongs to the continuous spectrum. Later, E. C. Titchmarsh and Kodaira gave a formula to obtain the density matrix $\rho_{jk}(\lambda)$ and completed the theory (Titchmarsh [6], Kodaira [23], Dunford and Schwartz [3]). This expansion theorem makes it possible to deduce in a unified manner expansion theorems for classical special functions, such as the † Fourier series expansion theorem, the expansions by † Hermite polynomials and † Laguerre polynomials, the † Fourier integral theorem, and various expansions in terms of † Bessel functions [6, 7].

The relation between the coefficients of the differential operator and the spectral distribution of P is important in applications and is the subject of many papers [3, 5, 6].

For example, let $P(x, D) = -d^2/dx^2 + q(x)$ and $\Omega = (-\infty, \infty)$. If $q(x) \rightarrow \infty$ as $|x| \rightarrow \infty$, then $P(x, D)$ is essentially self-adjoint, the spectrum is entirely composed of the point spectrum, and a detailed estimate of the j th eigenvalue λ_j is also known [6]. If $q(x)$ converges rapidly to 0 as $|x| \rightarrow \infty$, then $P(x, D)$ is essentially self-adjoint, and there is only a continuous spectrum for $\lambda > 0$ and eigenvalues for $\lambda < 0$ with at most 0 as accumulation point. If $q(x)$ is a periodic function of x , then $P(x, D)$ is again essentially self-adjoint, and the spectrum consists of a continuous spectrum decomposed in a sequence of nonoverlapping intervals. The converse problem of determining $q(x)$ when

the spectral measure is given has been studied by I. M. Gel'fand and B. M. Levitan (*Amer. Math. Soc. Transl.*, (2) 1 (1955); original in Russian, 1951).

P. Eigenfunction Expansion for Partial Differential Operators

The theory of eigenfunction expansion for partial differential operators with continuous spectra is not complete, as it is for ordinary differential operators. What causes difficulties is that the solutions of $(P(x, D) - \lambda)u = 0$, which should be the generalized eigenfunctions, form an infinite-dimensional space, and except for special cases it is impossible to introduce convenient parameters in it. Many proofs are known for a general result, saying that any self-adjoint elliptic operator has an eigenfunction expansion into generalized eigenfunctions of the form

$$u(x) = \int_{-\infty}^{\infty} \sum_{j=1}^{k(\lambda)} \varphi_j(x, \lambda) d\rho_j(\lambda) \int_{\Omega} \overline{\varphi_j(y, \lambda)} u(y) dy,$$

[10]. There are few operators, however, for which we know how to construct $\varphi_j(x, \lambda)$ and the measure $d\rho_j(\lambda)$. The Fourier transform gives the expansion for operators with constant coefficients defined on the whole space. By means of a generalized form of the Fourier transform, Ikebe gave an eigenfunction expansion for the Schrödinger operator $-\Delta + q(x)$ in \mathbb{R}^3 under the condition that $q(x) \in L_2$ and $O(|x|^{-2-\varepsilon})$ as $|x| \rightarrow \infty$ [24]. Y. Shizuta, Mizohata, Lax and R. S. Phillips, N. A. Shenk, Ikebe, D. K. Fadeev, and others proved the same results for similar operators defined on an exterior domain with a bounded set deleted from a higher-dimensional Euclidean space. These theories are closely related to the † scattering theory of the Schrödinger equation $(-id/dt - P)u = 0$ or the wave equation $(d^2/dt^2 + P)u = 0$ associated with those operators. Lax and Phillips have developed the latter scattering theory [26] (\rightarrow 375 Scattering Theory).

Many of the problems in † quantum mechanics reduce to finding the spectral distribution of self-adjoint partial differential operators.

Q. Expansion Theorems for Non-Self-Adjoint Operators

A kind of eigenfunction expansion theorem may hold for non-self-adjoint differential operators or for non-Hilbert spaces. (See papers by the Russian school for ordinary differential operators and those by Browder,

Agmon, and others for partial differential operators.)

R. Systems of Differential Operators

We have so far dealt with single differential operators that map functions u to functions f . A linear differential operator that maps a p -tuple (u_1, \dots, u_p) of functions to a q -tuple (f_1, \dots, f_q) of functions can be written as

$$f_i(x) = \sum_{j=1}^p P_{ij}(x, D)u_j(x), \quad i = 1, \dots, q,$$

where $P(x, D) = (P_{ij}(x, D))$ is a matrix of single differential operators. Such a matrix is called a **system of differential operators**. A system $P(x, D)$ is said to be **underdetermined** if $p > q$, **determined** if $p = q$, and **overdetermined** if $p < q$. Many propositions that hold for single operators hold for determined systems under appropriate conditions.

However, there is a fundamental difference between overdetermined (underdetermined) systems and determined systems, as is seen from the theory of several complex variables, which is the theory of a typical overdetermined system $\partial/\partial\bar{z} = (\partial/\partial\bar{z}_i)$. The theory is much more difficult for overdetermined (underdetermined) systems. The general theory of overdetermined and underdetermined systems with constant coefficients has been constructed by Ehrenpreis [28], Malgrange, V. Palamodov, and Hörmander [22] for C^∞ -functions and distributions. It has been extended by H. Komatsu to the case of hyperfunctions. T. Miwa has discussed the same problem for real analytic functions.

S. Symmetric Systems of the First Order

Determined systems of the first order are important in applications. Many problems in mathematical physics are formulated in terms of them. Also, single equations of higher order can be reduced to determined systems of the first order by regarding the derivatives as unknown functions. In some cases determined systems of the first order are easier to handle than single operators of higher order. In particular, a system of differential operators

$$P(x, D) = \sum A_i(x) \partial/\partial x_i + B(x)$$

is said to be a **symmetric positive system** if the matrices $A_i(x)$ and $B(x)$ satisfy the following conditions: $A_i^* = A_i$; $B + B^* + \sum \partial A_i/\partial x_i$ is positive semidefinite. Symmetric positive systems have been studied in detail by Friedrichs [25], Phillips, C. S. Morawetz, Lax, and others.

113 (III.17) Differential Rings

Let R be a \dagger commutative ring with a unity element 1. If a map δ of R into R is such that for any pair x, y of elements of R , (i) $\delta(x+y) = \delta x + \delta y$, and (ii) $\delta(xy) = \delta x \cdot y + x \cdot \delta y$, then δ is called a **derivation** (or **differentiation**) in R . A ring R provided with a finite number of mutually commutative differentiations in R is called a **differential ring**. In this article we consider only the case where R contains a subfield that has the unity element in common with R . In particular, if R is a field, we call it a **differential field**.

In the above definition of differential ring, it is not necessary to mention the \dagger characteristic of the subfield contained in R . However, to make it more effectively applicable in the case of nonzero characteristics, we may define **differential rings using higher differentiation** in place of the differentiation defined above. If a sequence $\delta = \{\delta_v\}$ of maps $\delta_0, \delta_1, \delta_2, \dots$ of R into R satisfies the following conditions (i)–(iv) for any pair x, y of elements of R and any pair λ, μ of nonnegative integers, then δ is called a

higher differentiation in R : (i) $\delta_\lambda(x+y) = \delta_\lambda x + \delta_\lambda y$; (ii) $\delta_\lambda(xy) = \sum \delta_\alpha x \cdot \delta_\beta y$ (the addition is performed over all pairs α, β of nonnegative integers that satisfy $\alpha + \beta = \lambda$); (iii) $\delta_\lambda(\delta_\mu x) = \binom{\lambda+\mu}{\lambda} \delta_{\lambda+\mu} x$; (iv) $\delta_0 x = x$. Two higher differentiations $\delta = \{\delta_v\}$ and $\delta' = \{\delta'_v\}$ are said to be commutative if and only if δ_λ and δ'_μ commute for all pairs λ, μ of nonnegative integers. Higher differentiations were introduced by H. Hasse (1935) for the study of the field of \dagger algebraic functions of one variable in the case of nonzero characteristics.

These two definitions of differential rings coincide if the characteristic of R is zero. For simplicity, we shall restrict ourselves to that case.

Let $\delta_1, \dots, \delta_m$ be the differentiations of the differential ring R . If x is an element of R , $\delta_1^{s_1} \delta_2^{s_2} \dots \delta_m^{s_m} x(s_1, s_2, \dots, s_m$ are nonnegative integers) is called a **derivative** of x . We call x constant if and only if $\delta_1 x = \dots = \delta_m x = 0$. An \dagger ideal α of R with $\delta_i \alpha \subset \alpha$ ($i = 1, 2, \dots, m$) is called a **differential ideal** of R . If it is a \dagger prime ideal (**semiprime ideal** (i.e., an ideal containing all those elements x that satisfy $x^g \in \alpha$ for some natural number g)), then α is called a **prime differential ideal** (**semiprime differential ideal**). A subring S of R with $\delta_i S \subset S$ can be regarded as a differential ring with respect to the differentiations $\delta_1, \dots, \delta_m$. We call S a **differential subring** of R and R a **differential extension ring** of S .

Let X_1, \dots, X_n be elements of a differential extension field of a differential field K with the differentiations $\delta_1, \dots, \delta_m$, and let $\delta_1^{s_1} \delta_2^{s_2} \dots \delta_m^{s_m} X_i$ ($s_1 \geq 0, \dots, s_m \geq 0, 1 \leq i \leq n$) be \dagger algebraically independent over K . The totality of their polynomials over K , which forms a differential ring, is called the **ring of differential polynomials** of the **differential variables** X_1, \dots, X_n over K , and is denoted by $K\{X_1, \dots, X_n\}$. Its elements are called **differential polynomials**. For this ring of differential polynomials we have an analog of \dagger Hilbert's basis theorem in the ring of ordinary polynomials, **Ritt's basis theorem**: If we are given any set \mathfrak{M} of differential polynomials of X_1, \dots, X_n over K , we can choose a finite number of differential polynomials P_1, \dots, P_r from \mathfrak{M} such that each element Q of \mathfrak{M} has an integral power Q^g equal to a linear combination of P_1, \dots, P_r and their derivatives, where the coefficients of the linear combination are elements of $K\{X_1, \dots, X_n\}$. This theorem implies that in the ring of differential polynomials, every semiprime differential ideal can be expressed as the intersection of a finite number of prime differential ideals; if this expression is \dagger irredundant, it is unique (\rightarrow 67 Commutative Rings).

The equation obtained by equating a dif-

ferential polynomial to zero is called an **algebraic differential equation**. Concerning these equations, we are able to use methods similar to those used in algebraic geometry in studying the usual algebraic equations. J. Ritt made interesting studies on solutions of algebraic differential equations by such methods, principally in the case when the ground field K consists of meromorphic functions.

Since that time, basic study of differential rings and fields has been fairly well organized and has developed into theories such as the following two:

(1) **Picard-Vessiot theory**. This is a classical theory of linear homogeneous differential equations originated by E. Picard and E. Vessiot; it resembles the Galois theory concerning algebraic equations. The Galois group in this case is a linear group, and its structure characterizes the solution of the differential equation. E. Kolchin introduced the general concept of the **Picard-Vessiot extension field** of a differential field and studied in detail the group of **differential automorphisms** (i.e., the group of all those automorphisms that commute with the differentiations and fix elements of the ground field), thus making the classical theory more precise and more general.

(2) **Galois theory of differential fields**. Generalizing the concept of the Picard-Vessiot extension, Kolchin introduced the notion of the **strongly normal extension field** and established the Galois theory for such extensions. In this theory, we see that the Galois group is an algebraic group relative to a universal domain over the field of constants of the ground field. Conversely, every algebraic group is the Galois group of a strongly normal extension field. We also see that a strongly normal extension can be decomposed, in a certain sense, into a Picard-Vessiot extension and an Abelian extension (i.e., an extension whose Galois group is an Abelian variety) (\rightarrow Kolchin [2–5], Okugawa [6]).

114 (IX.18) Differential Topology

A. General Remarks

Differential topology can be defined as the study of those properties of differentiable manifolds that are invariant under diffeomorphisms. The basic objects studied in this field are the topological, combinatorial, and differentiable structures of manifolds and the relationships among them. Some of the remarkable contributions, such as H. Whitney's embedding theorem [1], the triangulation theorems of J. H. C. Whitehead and S. S. Cairnes [2, 3], and Morse theory [4], were made in the 1930s. In the late 1950s, outstanding results were obtained by R. Thom, J. W. Milnor, S. Smale, M. Kervaire, and F. Hirzebruch, among others. Differential topology thus became a new, fascinating branch of mathematics.

B. Differentiable Structures

We assume that all manifolds are paracompact. Let M be a topological manifold. A C^r -equivalence class of atlases of class C^r ($1 \leq r \leq \infty$) on M is called a **C^r -structure** on M . Any C^r -structure on M contains an atlas of class C^∞ on M , and its C^∞ -equivalence class is uniquely determined (Whitney [1]). This C^∞ -structure is called a **differentiable structure** on M compatible with the given C^r -structure. Moreover, any C^∞ -structure admits a real analytic structure compatible with it in this sense (Whitney [1]). A C^∞ -manifold is also called a **smooth manifold**, and a differentiable structure a **smooth structure**. Let D_0, D_1 be differentiable structures on M . If two C^∞ -manifolds (M, D_0) and (M, D_1) are not diffeomorphic, we say that the differentiable structures D_0, D_1 are **distinct** (\rightarrow 105 Differentiable Manifolds). Milnor defined a certain invariant of differentiable structure using the Hirzebruch index theorem (\rightarrow 56 Characteristic Classes) and proved that there are several distinct differentiable structures on the 7-dimensional sphere S^7 (Milnor [5]). Milnor's

example of such structures was: Let $f_k: S^3 \rightarrow SO(4)$ be the mapping defined by $f_k(\sigma)\tau = \sigma^h \tau \sigma^j$, where k is an odd integer, h, j are integers determined by $h+j=1$, $h-j=k$, and σ, τ are \dagger quaternions of norm 1. Let M_k^7 be the total space of the S^3 -bundle over S^4 corresponding to the mapping f_k . This is an oriented closed manifold with the naturally defined differentiable structure. Moreover, for each k , M_k^7 is homeomorphic to the 7-dimensional sphere S^7 . But if k, l are odd and $k^2 \not\equiv l^2 \pmod{7}$, M_k^7 is not diffeomorphic to M_l^7 . Differentiable manifolds (such as M_k^7) that are homeomorphic, but not diffeomorphic, to the natural sphere are called **exotic spheres**. After the discovery made by Milnor, many topological manifolds other than the 7-dimensional sphere and possessing several distinct differentiable structures have been found (N. Shimada, I. Tamura). Moreover, topological manifolds admitting no differentiable structures have been constructed (M. Kervaire [6], Smale, Tamura [7], J. Eells and N. Kuiper, C. T. C. Wall [8]). On the other hand, manifolds of dimension ≤ 3 admit unique differentiable structures.

We can introduce a \dagger Riemannian metric on a C^∞ -manifold. Let M_1^k and M_2^n be C^∞ -manifolds (k -dimensional and n -dimensional, respectively) and $f: M_1^k \rightarrow M_2^n$ be an \dagger immersion. We fix a Riemannian metric on M_2^n . For each point p of M_1^k , let $N_p(f)$ be the linear space of all tangent vectors of M_2^n at $f(p)$ that are orthogonal to the \dagger tangent space of $f(U(p))$, where $U(p)$ is a small open neighborhood of p in M_1^k . Then $\{N_p(f) | p \in M_1^k\}$ forms an $(n-k)$ -dimensional \dagger vector bundle v_f over M_1^k , called the **normal bundle** of the immersion f . The equivalence class of v_f is independent of the choice of Riemannian metric on M_2^n . When f is an \dagger embedding, we denote the submanifold $f(M_1^k)$ by L^k . Let $N_\varepsilon(L^k)$ be the set of all points whose distances (with respect to the Riemannian metric) from L^k are $\leq \varepsilon$. If L^k is compact and ε is sufficiently small, $N_\varepsilon(L^k)$ is an n -dimensional submanifold of M_2^n with boundary and is uniquely determined independently of the choice of ε up to diffeomorphism. This submanifold is called a **tubular neighborhood** of L^k in M_2^n and is denoted by $N(L^k)$. The interior of $N(L^k)$ is called an **open tubular neighborhood**. The total space $E(v_f)$ of the normal bundle v_f of the embedding f is diffeomorphic to the open tubular neighborhood of L^k in M_2^n .

C. C^r -Triangulation and the Smoothing Problem

Let (K, f) be a \dagger triangulation of the C^r -manifold M^n ($1 \leq r \leq \infty$) ($f: |K| \rightarrow M^n$) satisfying

the following conditions: (i) For any closed n -simplex σ of K , $f|_{\sigma}: \sigma \rightarrow M^n$ is a C^r -mapping; (ii) for any point p of σ , the \dagger Jacobian matrix of $f|_{\sigma}$ has rank n at p . Then we say that (K, f) is a **C^r -triangulation** of the C^r -manifold M^n , and the C^r -structure of M^n is **compatible** with the triangulation (K, f) . Concerning C^r -triangulations of C^r -manifolds, we have the following results (S. Cairns [2], J. H. C. Whitehead [3]): (i) any C^r -manifold ($1 \leq r \leq \infty$) has a C^r -triangulation, and any C^r -triangulation of the boundary can be extended to the whole manifold; (ii) for a C^r -triangulation (K, f) of a C^r -manifold M^n , the triangulated space $(K, f; M^n)$ is a \dagger combinatorial manifold; (iii) for two C^r -triangulations (K_1, f_1) and (K_2, f_2) of a C^r -manifold M^n , the triangulated spaces $(K_1, f_1; M^n)$ and $(K_2, f_2; M^n)$ are combinatorially equivalent.

Conversely, for a combinatorial manifold $(K, f; M^n)$, a differentiable structure on M that is compatible with the triangulation (K, f) is called a **smoothing** of M . The question of whether a smoothing of a combinatorial manifold exists is called the **smoothing problem**. We have some criteria for its solvability. One is expressed in terms of transverse fields, and another in terms of \dagger microbundles (\rightarrow 147 Fiber Bundles P). We also have the following method using the theory of \dagger obstruction (J. Munkres [9]; M. W. Hirsch and B. Mazur [10]). Let Γ_k be the group of oriented differentiable structures on the \dagger combinatorial k -sphere (an exact definition of this group is given in Section I). Let K^i be the i - \dagger skeleton of a combinatorial n -manifold $(K, f; M^n)$ and α a smoothing of a neighborhood U of $f(K^i)$ in M^n . Then there exists an obstruction cocycle $C_\alpha \in Z^{i+1}(K, \Gamma_i)$ satisfying the following conditions: (i) if $C_\alpha(\sigma^{i+1}) = 0$ for an $(i+1)$ -simplex σ^{i+1} of K , the smoothing α can be extended over a neighborhood of $f(K^i \cup \sigma^{i+1})$, and vice versa; (ii) if there exists another smoothing α' of a neighborhood of $f(K^i)$ that coincides with the smoothing α of a neighborhood of $f(K^{i-1})$, then $C_{\alpha'} - C_\alpha$ is a \dagger coboundary; conversely, for any $(i+1)$ -coboundary b with coefficients in Γ_i , there exists a smoothing α' of a neighborhood of $f(K^i)$ such that $b = C_{\alpha'} - C_\alpha$. Using this method we can prove that for $n \leq 7$ all combinatorial manifolds of dimension n are smoothable.

D. Embedding and Immersion Theorems

In the following, M^n and X^m are C^∞ -manifolds of dimensions n and m , respectively. Two \dagger immersions $f_0, f_1: M^n \rightarrow X^m$ are said to be **regularly homotopic** if there exists a \dagger homotopy $f_t: M^n \rightarrow X^m$, $0 \leq t \leq 1$, such that f_t is an immer-

sion for each t and the induced mapping (\dagger differential of f_t) $df_t: T(M^n) \rightarrow T(X^m)$ on the tangent spaces naturally gives rise to a continuous mapping over $T(M^n) \times I$. Two \dagger embeddings are **isotopic** if they are regularly homotopic and the homotopy f_t is an embedding for each t . Given M^n and X^m , a fundamental problem of embedding (immersion) theory is to classify the embeddings (immersions) of M^n in X^m according to their isotopy (regular homotopy) classes. Whitney proved that a continuous mapping $f: M^n \rightarrow X^m$ can be approximated by an immersion if $m \geq 2n$ and by an embedding if $m \geq 2n + 1$ [1]. The following results are also due to Whitney [1]: Any two immersions of M^n in X^m that are homotopic are regularly homotopic if $m \geq 2n + 2$, and any two embeddings of M^n in X^m that are homotopic are isotopic if $m \geq 2n + 3$. The range $m \geq 2n + 3$ is called the **stable range** of embeddings.

In [11, 12] (1944) Whitney improved his classical theorems and showed that M^n can always be immersed in \mathbf{R}^{2n-1} for $n > 1$ and M^n can always be embedded in \mathbf{R}^{2n} . The methods used in his proof have played an important role in the subsequent development. Classification of immersions of the n -sphere S^n in \mathbf{R}^m was determined by Smale [13]. Let $p: T(M^n) \rightarrow M^n$ and $p': T(X^m) \rightarrow X^m$ be the projections of the tangent bundles of M^n and X^m , respectively. A mapping $\varphi: T(M^n) \rightarrow T(X^m)$ is a **linear fiber mapping (linear fiber map)** if, for each $x \in M^n$, $\varphi(p^{-1}(x))$ is contained in a fiber of $T(X^m)$ and $\varphi|_{p^{-1}(x)}$ is a linear mapping of rank n . A **linear homotopy** $\varphi_t: T(M^n) \rightarrow T(X^m)$ ($0 \leq t \leq 1$) is a homotopy such that each φ_t is a linear fiber mapping. The following theorem of Hirsch [14] is fundamental to immersion theory: Assume $n < m$. If $\varphi: T(M^n) \rightarrow T(X^m)$ is a linear fiber mapping, the mapping $\bar{\varphi}: M^n \rightarrow X^m$ induced by φ can be approximated by an immersion $f: M^n \rightarrow X^m$ such that df and φ are linearly homotopic. Two immersions $f, g: M^n \rightarrow X^m$ are regularly homotopic if and only if df and dg are linearly homotopic. If M^n is immersible in \mathbf{R}^{m+r} , where $m > n$ with r linearly independent fields of \dagger normal vectors, then M^n is immersible in \mathbf{R}^m . In particular, if M^n is a π -manifold (\rightarrow Section I), M^n is immersible in \mathbf{R}^{n+1} .

Let $\mathcal{E}(M^n)$ be the set of isomorphism classes of real \dagger vector bundles over M^n , and consider $\theta: \mathcal{E}(M^n) \rightarrow KO(M^n)$ (\rightarrow 237 K-Theory). An element $\xi \in KO(M^n)$ is said to be **positive** if ξ is in the image of θ . If $\xi_0 \in \tilde{KO}(M^n)$, the **geometric dimension** of ξ_0 , written $g(\xi_0)$, is the least integer k such that $\xi_0 + k$ is positive. Then Hirsch's theorem [14] can be expressed as follows: M^n is immersible in \mathbf{R}^{n+k} ($k > 0$) if and only if $g(n - \tau(M^n)) \leq k$, where $\tau(M^n)$ is the tangent bundle of M^n .

A. Haefliger [15] obtained the following important result: Let M^n be compact and $\dagger(k-1)$ -connected, and let X^m be k -connected. Then any continuous mapping of M^n in X^m is homotopic to an embedding if $2k < n$, $m \geq 2n - k + 1$, and any two homotopic embeddings of M^n in X^m are isotopic if $2k < n + 1$, $m \geq 2n - k + 2$. Thus if $m > 3(n+1)/2$, any two embeddings of S^n in \mathbf{R}^m are isotopic. The range $m > 3(n+1)/2$ is called the **metastable range**. Haefliger further classified the embeddings of S^{4n-1} in \mathbf{R}^{6n} and showed the existence of embeddings of S^{4n-1} in \mathbf{R}^{6n} that are not isotopic to the natural one. More complete results for the classification of embeddings of \dagger homotopy n -spheres in S^m were obtained by J. Levine [16]. Furthermore, Levine proved the following unknotting theorem in higher-dimensional knot theory [16]: Let $f: S^{n-2} \rightarrow S^n$ be a C^∞ -embedding for $n \geq 6$; then $f(S^{n-2})$ is unknotted if and only if $S^n - f(S^{n-2})$ is homotopy equivalent to S^1 (\rightarrow 235 Knot Theory G; also 65 Combinatorial Manifolds D).

We list some results about embeddings and immersions. If M^n is noncompact, M^n can always be embedded in \mathbf{R}^{2n-1} ; if M^n is a noncompact π -manifold, M^n can always be immersed in \mathbf{R}^n ; if M^n is compact and orientable and $n > 4$, M^n can always be embedded in \mathbf{R}^{2n-1} .

E. Nonembedding and Nonimmersion Theorems

We denote the \dagger total Stiefel-Whitney class of M^n by $w(M^n)$ and the \dagger total Pontryagin class of M^n by $p(M^n)$ (\rightarrow 56 Characteristic Classes). Then $(w(M^n))^{-1} (\in H^*(M^n; \mathbf{Z}_2))$ and $(p(M^n))^{-1} (\in H^*(M^n; \mathbf{Z}))$ can be written as $\bar{w}(M^n) = \sum \bar{w}_i(M^n)$ ($\bar{w}_i \in H^i(M^n; \mathbf{Z}_2)$) and $\bar{p}(M^n) = \sum \bar{p}_i(M^n)$ ($\bar{p}_i \in H^{4i}(M^n; \mathbf{Z})$). Then the property of characteristic classes for the \dagger Whitney sum implies the following theorem: If M^n can be immersed in \mathbf{R}^{n+k} , then $\bar{w}_i(M^n) = 0$ for $i > k$ and $\bar{p}_i(M^n) = 0$ for $i > [k/2]$. Furthermore, if M^n can be embedded in \mathbf{R}^{n+k} , then $\bar{w}_k(M^n) = 0$. As an application, these results yield the nonembedding (nonimmersion) theorem for projective spaces (\rightarrow Appendix A, Table 6.VII). Sharper theorems were obtained subsequently. In particular, Atiyah proved the following: Let λ^i ($i = 0, 1, \dots$) be \dagger exterior power operations (\rightarrow 237 K-Theory), and let γ^i be the operations defined by the formal power series $\sum_{i=0}^{\infty} \gamma^i t^i = (\sum_{i=0}^{\infty} \lambda^i t^i)(1-t)^{-1}$. Then $\gamma^i(n - \tau(M^n)) = 0$ for $i > k$ ($i \geq k$) if M^n can be immersed (embedded) in \mathbf{R}^{n+k} . Furthermore, we have an interesting result for the differentiable case. For any positive integer q , there exists a differentiable

manifold M^n such that M^n is immersible in \mathbf{R}^k but not embeddable in \mathbf{R}^{k+q} .

F. Handlebodies

Let W be a C^∞ -manifold with boundary ∂W . Then the boundary ∂W has a neighborhood U that is homeomorphic to $\partial W \times \mathbf{R}_+$, where $\mathbf{R}_+ = [0, \infty)$. Let W_1, W_2 be C^∞ -manifolds with boundaries and $f: \partial W_1 \rightarrow \partial W_2$ be a diffeomorphism. Then the quotient space M of $W_1 \cup W_2$ obtained by identifying points corresponding under f has a natural differentiable structure. This construction of the C^∞ -manifold M from the C^∞ -manifolds W_1, W_2 is called **pastings together the boundaries**.

Now we consider the topological product $W_1 \times W_2$ of manifolds W_1, W_2 with boundaries $\partial W_1, \partial W_2$. $W_1 \times W_2 - \partial W_1 \times \partial W_2$ has a natural atlas of class C^∞ . By introducing a suitable atlas of class C^∞ in a neighborhood of $\partial W_1 \times \partial W_2$ in $W_1 \times W_2$, we obtain a C^∞ -manifold with boundary homeomorphic to $W_1 \times W_2$. More generally, let M be an n -manifold with boundary, let N be a finite union of submanifolds of dimension $\leq n-2$ in ∂M , and suppose that M has a corner along N . Extension of the C^∞ -structure of $M-N$ over M as in this paragraph is called **straightening the angle**.

Let D^n be the oriented unit n -disk in the n -dimensional Euclidean space \mathbf{R}^n , M_1^n and M_2^n be oriented compact C^∞ -manifolds, and $f_i: D^n \rightarrow M_i^n$ ($i=1, 2$) be C^∞ -embeddings, f_1 \dagger orientation-preserving and f_2 \dagger orientation-reversing. Then, pasting together the boundaries of $M_1^n - \text{Int } f_1(D^n)$ and $M_2^n - \text{Int } f_2(D^n)$ by the mapping $f_2 \circ f_1^{-1}$, we obtain an oriented C^∞ -manifold, called the **connected sum** of M_1^n and M_2^n and denoted by $M_1^n \# M_2^n$. The connected sum $M_1^n \# M_2^n$ has the orientation induced from those of M_1^n and M_2^n , and its differentiable structure is uniquely determined independently of the mappings f_i . Let S^n be the natural n -dimensional sphere. Then we have $M^n \# S^n \approx M^n$ (here \approx means diffeomorphic), $(M_1 \# M_2) \# M_3 \approx M_1 \# (M_2 \# M_3)$, $M_1 \# M_2 \approx M_2 \# M_1$.

Let M^n be a manifold with boundary and $f: (\partial D^s \times D^{n-s}) \rightarrow \partial M^n$ be a C^∞ -embedding. Then we call the quotient space $X(M^n; f; s)$ of $M^n \cup (D^s \times D^{n-s})$ obtained by the identification of corresponding points under f the **manifold with a handle attached by f** . Also, we call the construction of $X(M^n; f; s)$ from M^n **attaching a handle** and call $D^s \times D^{n-s}$ an s -**handle**. After straightening the angle, $X(M^n; f; s)$ is considered naturally a C^∞ -manifold with boundary. Let $f_i: \partial D_i^s \times D_i^{n-s} \rightarrow \partial M^n$ ($i=1, \dots, k$) be embeddings whose images are mutually disjoint. Then similarly, using embeddings f_1, \dots, f_k , we can define a C^∞ -manifold with handles $X(M^n;$

$f_1, \dots, f_k; s)$. In particular, $X(X(\dots(X(X(D^n; f_1; s_1); f_2; s_2) \dots); f_j; s_j))$ is called a **handlebody**.

Let M^{n-1} be an oriented $(n-1)$ -manifold and $f: \partial D^s \times D^{n-s} \rightarrow (M^{n-1} - \partial M^{n-1})$ an orientation-preserving C^∞ -embedding. Then, by straightening the angle, the quotient space of $(M^{n-1} - \text{Int } f(\partial D^s \times D^{n-s})) \cup (D^s \times \partial D^{n-s})$ obtained by the identification of points corresponding under f is a C^∞ -manifold $\chi(M^{n-1}; f)$. We say this manifold is obtained by a **spherical modification** (or **surgery**) of type $(s, n-s)$ from M^{n-1} . The manifold $\chi(M^{n-1}; f)$ has a natural orientation, and $\partial \chi(M^{n-1}; f) = \partial M^{n-1}$. The process of spherical modification has the following relation to that of attaching a handle: Let W be an n -dimensional manifold and $f: \partial D^s \times D^{n-s} \rightarrow \partial W$ an embedding. Then $\partial X(W; f; s) = \chi(\partial W; f)$. When $W = M^{n-1} \times [0, 1]$ and $f: \partial D^s \times D^{n-s} \rightarrow M \times \{1\}$, $\partial X(W; f; s) = \chi(M \times \{1\}; f) \cup M \times \{0\}$, and therefore M is cobordant (\rightarrow Section H) to $\chi(M; f)$. Conversely, let M_1 be cobordant to M_2 . Then we can obtain M_2 from M_1 by a finite sequence of spherical modifications (A. Wallace [17], Milnor). Let M^n be an n -dimensional C^∞ -manifold and $f: M^n \rightarrow \mathbf{R}^1$ be a C^∞ -function. If f satisfies the following conditions, then it is called a **nice function**: (i) All \dagger critical points of f are \dagger nondegenerate; (ii) for any critical point p of f , the \dagger index (\rightarrow 279 Morse Theory) of f at p is equal to $f(p)$. We have the following theorems.

1. Let M be a compact C^∞ -manifold. Then there exists a nice function on M (M. Morse, Smale [18], Wallace [17]).

2. Let M be a compact C^∞ -manifold and $f: M \rightarrow \mathbf{R}^1$ a C^∞ -function all of whose critical points are nondegenerate. Suppose that the number of critical points on $f^{-1}[-\varepsilon, \varepsilon]$ is k and that they are all contained in $f^{-1}(0)$. Suppose further that the indices of these critical points are all equal to s . Then $f^{-1}(-\infty, \varepsilon]$ is diffeomorphic to the manifold with handles $X(f^{-1}(-\infty, -\varepsilon]; f_1, \dots, f_k; s)$ (Morse, Thom, Smale [18]).

3. \dagger Generalized Poincaré conjecture. Let M^n be an n -dimensional \dagger homotopy sphere of class C^∞ ($n \geq 5$). Then M^n can be obtained by pasting together the boundaries of two n -disks. Consequently, M^n is homeomorphic to the n -dimensional sphere S^n (Smale [18], H. Yamaguchi [19]).

4. Let M^n be a \dagger contractible compact n -dimensional manifold ($n > 5$), with ∂M connected and simply connected. Then M^n is diffeomorphic to the n -disk D^n (Smale [18]).

5. Let M_1^n, M_2^n be oriented, compact, simply connected n -dimensional manifolds ($n > 4$). If M_1 is h -cobordant (\rightarrow Section I) to M_2 , then M_1 is diffeomorphic to M_2 (**h -cobordism theorem**; Smale [20]).

6. If $M_1^n \times \mathbf{R}^k$ is diffeomorphic to $M_2^n \times \mathbf{R}^k$, we say that M_1^n is k -**equivalent** to M_2^n . Let M_1, M_2 be compact n -dimensional manifolds of the same \dagger homotopy type. Then M_1 is k -equivalent to M_2 if and only if for a \dagger homotopy equivalence $f: M_1 \rightarrow M_2$, $\tau(M_1) \oplus \varepsilon_k$ is equivalent to $f^*\tau(M_2) \oplus \varepsilon_k$, where $\tau(M_i)$ is the \dagger tangent bundle of M_i and ε_k the \dagger trivial vector bundle of dimension k (Mazur).

7. In some special cases the classification of manifolds by diffeomorphism is completely determined. (i) The classification of simply connected 5-dimensional manifolds M with vanishing second \dagger Stiefel-Whitney class $w_2(M)$ is determined by $H_2(M)$. (ii) A 2-connected compact 6-dimensional manifold is diffeomorphic to either S^6 or the connected sum of a finite number of copies of $S^3 \times S^3$ (Smale [20]). Besides these, the classifications of $(n-1)$ -connected $2n$ -dimensional manifolds (Wall [8]) and $(n-1)$ -connected $(2n+1)$ -dimensional manifolds (Tamura [21], Wall [22]) have been obtained.

G. Thom Complexes

Let ξ be a real n -dimensional vector bundle over a paracompact space X , A_ξ be the total space of the associated bundle of ξ with fiber the closed n -disk D^n , and \dot{A}_ξ be the total space of the associated bundle of ξ with fiber the $(n-1)$ -sphere ∂D^n . Then the quotient space $X_\xi = A_\xi / \dot{A}_\xi$, obtained from A_ξ by contracting \dot{A}_ξ to a point, is called the **Thom space** of the vector bundle ξ . If X is a \dagger CW-complex, then the Thom space X_ξ of ξ has the homotopy type of a CW-complex and is called a **Thom complex**. The Thom space X_ξ has the canonical base point p_ξ corresponding to \dot{A}_ξ .

For a coefficient group G , denote by G_ξ the \dagger local system of coefficient groups with stalk G associated with the \dagger orientation sheaf of an \mathbf{R}^n -bundle ξ . Then we have the **Thom-Gysin isomorphism**:

$$H^q(X; G_\xi) \cong H^{n+q}(X_\xi, p_\xi; G),$$

$$H_q(X; G_\xi) \cong H_{n+q}(X_\xi, p_\xi; G).$$

Let G be a closed subgroup of the orthogonal group $O(n)$ and BG be the base space of the universal n -dimensional vector bundle γ_G with structure group G . Then we can take a connected CW-complex as BG . We denote the Thom complex of the vector bundle γ_G by MG and call it the **Thom complex associated with** (G, n) . The Thom complex associated with (G, n) is $(n-1)$ - \dagger connected. If G is connected, then we have $\pi_n(MG) \cong \mathbf{Z}$, $\pi_n(MO(n)) \cong \mathbf{Z}_2$, $H^n(MG; \mathbf{Z}) \cong \mathbf{Z}$, and $H^n(MO(n); \mathbf{Z}_2) \cong \mathbf{Z}_2$ (\mathbf{Z}_2 stands for the quotient group $\mathbf{Z}/2\mathbf{Z}$). The generator U of $H^n(MG; \mathbf{Z})$ is called the **fundamental (cohomology) class of the Thom complex** MG . For a general Thom space X_ξ , we can also define the fundamental class of X_ξ using the Thom-Gysin isomorphism.

mental (cohomology) class of the Thom complex MG . For a general Thom space X_ξ , we can also define the fundamental class of X_ξ using the Thom-Gysin isomorphism.

A C^∞ -submanifold W^p of a compact manifold V^n is a \dagger support of a \dagger singular cycle and represents a homology class $z \in H_p(V^n; G)$ ($G = \mathbf{Z}_2$ or \mathbf{Z}). In this case we say that the homology class z of V^n is **realizable** by a submanifold. A homology class $z \in H_{n-k}(V^n; G)$ is realizable by a submanifold if and only if there exists a mapping $f: V^n \rightarrow MO(k)$ (or $MSO(k)$) such that $f^*(U)$ is the dual cohomology class of z (Thom [23]).

The homotopy group $\pi_{n+k}(MO(n))$ (resp. $\pi_{n+k}(MSO(n))$) ($n > k$) is determined only by k for any n up to isomorphism. It is called the k -dimensional **stable homotopy group of the Thom spectrum** $MO = \{MO(n)\}$ ($MSO = \{MSO(n)\}$) and is denoted by $\pi_k(MO)$ ($\pi_k(MSO)$). For the \dagger unitary group $U(n)$ and the \dagger symplectic group $Sp(n)$, we define Thom complexes $MU(n)$ and $MSp(n)$ as the Thom complexes associated with $(U(n), 2n)$ and $(Sp(n), 4n)$ by the canonical inclusions $U(n) \subset O(2n)$ and $Sp(n) \subset O(4n)$, respectively. The k -dimensional stable homotopy groups $\pi_k(MU) = \lim \pi_{2n+k}(MU(n))$, $\pi_k(MSp) = \lim \pi_{4n+k}(MSp(n))$ of Thom spectra $MU = \{\dots, MU(n), SMU(n), MU(n+1), \dots\}$, $MSp = \{\dots, MSp(n), SMSp(n), S^2MSp(n), S^3MSp(n), MSp(n+1), \dots\}$ can be defined similarly to the case of $\pi_k(MO)$, where $SMU(n)$ denotes the \dagger reduced suspension of $MU(n)$. The stable homotopy groups of Thom spectra are calculated in connection with the cohomology groups utilizing the Thom-Gysin isomorphism (\rightarrow 202 Homotopy Theory T) (Thom [23], Milnor [24]).

H. Cobordism

Cobordism theory is a theory of classification of differentiable manifolds initiated by L. S. Pontryagin and V. A. Rokhlin, who called it **intrinsic homology**. The theory was brought to maturity by Thom [23]. Its fundamental problem is to determine whether a given compact manifold is the boundary of another manifold. Corresponding cobordism theories for combinatorial and topological manifolds are being developed (Wall, R. Williamson).

We consider only compact C^∞ -manifolds that are not necessarily connected. Let \mathfrak{D} be the set of all diffeomorphism classes of C^∞ -manifolds, and let \mathfrak{D}_0 be the set of all orientation-preserving diffeomorphism classes of oriented C^∞ -manifolds. For an oriented manifold V , we write $-V$ for the manifold with reversed orientation.

For two compact k -manifolds $V, W \in \mathfrak{D}_0$, we say that V is **cobordant** to W if there exists a compact $(k+1)$ -manifold $X \in \mathfrak{D}_0$ such that $\partial X = V \cup (-W)$. In this definition, considering \mathfrak{D} instead of \mathfrak{D}_0 , we say that V is **cobordant** to $W \bmod 2$. The equivalence class of V^k with respect to the cobordism relation (the cobordism relation mod 2) is called an **oriented (unoriented) cobordism class** and is denoted by $[V^k] ([V^k]_2)$. The set of all oriented (unoriented) cobordism classes $[V^k] ([V^k]_2)$ of k -manifolds forms an Abelian group $\Omega_k (\mathfrak{R}_k)$ by the natural addition $[V^k] + [W^k] = [V^k \cup W^k] ([V^k]_2 + [W^k]_2 = [V^k \cup W^k]_2)$. This is called the k -dimensional **oriented (unoriented) cobordism group**. Define the product $[V^k] \times [W^l] = [V^k \times W^l] ([V^k]_2 \times [W^l]_2 = [V^k \times W^l]_2)$. Then the direct sum $\Omega = \sum \Omega_k (\mathfrak{R} = \sum \mathfrak{R}_k)$ forms an anticommutative (commutative) \dagger graded algebra, which is called the **cobordism ring** or **Thom algebra**. We have the following theorems.

1. Ω_k, \mathfrak{R}_k are isomorphic to the stable homotopy groups $\pi_k(MSO), \pi_k(MO)$ of the Thom spectra MSO, MO , respectively (**Thom's fundamental theorem**) [23].

2. For a natural number k not of the form $2^i - 1$, there exists a compact manifold $P(k)$, and \mathfrak{R} is a polynomial ring over \mathbb{Z}_2 with generators $\{[P(k)]_2 | k \neq 2^i - 1\}$. $\Omega \otimes \mathbb{Q}$ (\mathbb{Q} is the field of rational numbers) is a polynomial ring over \mathbb{Q} with generators $\{[PC^{2m}] | m \geq 1\}$, where PC^{2m} is the complex $2m$ -dimensional projective space (Thom [23]). Moreover, Milnor [24] proved that the p -component of Ω_k is zero for an odd prime p . Wall proved that the 2-component of Ω_k contains no element of order 4, using a certain exact sequence which contains the natural homomorphism $\Omega_k \rightarrow \mathfrak{R}_k$ [25].

3. Let T be the ideal of Ω consisting of all torsion elements in Ω . Then Ω/T is a polynomial ring over \mathbb{Z} with generators $\{[Y_{4k}] | k \geq 1\}$, where we can take for Y_{4k} a complex $2k$ -dimensional nonsingular algebraic variety (Milnor).

\dagger Characteristic numbers are invariants of cobordism classes. Combining the results stated in 2, we have the following theorem:

4. Let V, W be manifolds. V is cobordant to $W \bmod 2$ if and only if they have the same corresponding \dagger Stiefel-Whitney numbers. Let V, W be oriented manifolds. V is cobordant to W if and only if they have the same corresponding Stiefel-Whitney numbers and \dagger Pontryagin numbers. The \dagger index of an oriented $4k$ -dimensional compact manifold is a cobordism class invariant and can be expressed as a linear combination with rational coefficients of \dagger Pontryagin numbers (\rightarrow 56 Characteristic Classes).

A manifold whose \dagger stable tangent bundle

has a complex structure is called a **stably** (or **weakly**) **almost complex manifold**. Let V, W be $2n$ -dimensional compact stably almost complex manifolds ($n \geq 1$). We say that V is **C-equivalent** to W if they have the same \dagger Chern numbers. The set of all C-equivalence classes $[V]_C$ forms the **complex cobordism group** \mathfrak{U}_n as in the (real) case of cobordism groups (the existence of the inverse of an element is not trivial). Introducing multiplication into the direct sum $\mathfrak{U}_* = \sum \mathfrak{U}_n$ by the product of manifolds, we obtain the **complex cobordism ring**. We have $\mathfrak{U}_n \cong \pi_{2n}(MU)$ and \mathfrak{U}_* is a polynomial ring over \mathbb{Z} with generators $\{[Y'_{2k}]_C | k \geq 1\}$, where we can take for Y'_{2k} a complex k -dimensional nonsingular algebraic variety (Milnor [24]).

1. h -Cobordism Groups of Homotopy Spheres

A manifold M is said to be **parallelizable** if its tangent bundle $\tau(M)$ is trivial, and **almost parallelizable** if there exists a finite number of points x_i in M such that $M - \bigcup \{x_i\}$ is parallelizable. A manifold M is called **stably parallelizable** (or **s-parallelizable**) if the \dagger Whitney sum $\tau \oplus \varepsilon_1$ of its tangent bundle $\tau(M)$ and the trivial line bundle ε_1 is trivial. A manifold M^n is called a π -**manifold** if M^n has a trivial normal bundle when it is embedded into a Euclidean space \mathbb{R}^N ($N > 2n$). A manifold M^n is a π -manifold if and only if M^n is s-parallelizable. The concepts defined in this paragraph are related by inclusions as follows: parallelizable \subsetneq s-parallelizable \subsetneq almost parallelizable. For a connected manifold with boundary, these three concepts are equivalent. \dagger Group manifolds are parallelizable. An n -dimensional manifold homeomorphic to the n -dimensional sphere is parallelizable if and only if $n = 1, 3, 7$ (Milnor [26]). Suppose that we are given an $(n-1)$ -dimensional sphere S^{n-1} (n even). We can consider the problem of determining the maximal number r such that there exists a tangent r -frame field over S^{n-1} . J. F. Adams solved this problem using \dagger K-theory (\rightarrow 237 K-Theory) as follows: Let $n = (2a+1)2^b$, $b = c+4d$, where a, b, c, d are integers and $0 \leq c \leq 3$. Put $\rho(n) = 2^c + 8d$. Then $r = \rho(n) - 1$. On the other hand, homotopy spheres are π -manifolds [27].

Let V_1, V_2 be oriented compact manifolds. Then we say that V_1 is **h -cobordant** to V_2 if there exists an oriented manifold W with boundary $\partial W = V_1 \cup (-V_2)$ such that V_i ($i = 1, 2$) is a deformation retract of W . The set of all h -cobordism classes of oriented homotopy n -spheres forms an Abelian group θ_n with connected sum as addition. This is called the (**h -cobordism**) **group of homotopy n -spheres**. We

denote by $\theta_n(\partial\pi)$ the subgroup of homotopy n -spheres that are boundaries of π -manifolds. Kervaire and Milnor gave certain exact sequences that contain the groups θ_n , the stable homotopy groups G_n of spheres, and the stable homotopy groups $\pi_n(SO)$. They clarified relations among these groups and proved that $\theta_n(\partial\pi) = 0$ for n even, $\theta_n(\partial\pi) = \text{finite group}$ for n odd $\neq 3$, $\theta_n/\theta_n(\partial\pi) \subset \text{Coker } J_n$, etc. [27], where $J_n: \pi_n(SO) \rightarrow G_n$ is the *J -homomorphism. From these results it follows that the θ_n ($n \neq 3$) are finite Abelian groups, $\theta_n = 0$ for $n < 7$, $\neq 3$, $\theta_7 \cong \mathbb{Z}_{28}$, etc. (\rightarrow Appendix A, Table 6.I).

By pasting together the boundaries of two n -disks D_1^n and D_2^n , we obtain an oriented manifold which is considered as a smoothing of the combinatorial n -sphere. The set of all orientation-preserving diffeomorphism classes of smoothings of the combinatorial n -sphere forms an Abelian group Γ_n with connected sum as addition. This is called the **group of oriented differentiable structures on the combinatorial sphere**. By the generalized Poincaré conjecture and the h -cobordism theorem, we obtain $\Gamma_n = \theta_n$ ($n \neq 3, 4$). Furthermore, $\Gamma_3 = 0$ and $\Gamma_4 = 0$ (J. Cerf [28]). The group Γ_n can also be defined as follows: Let $\text{Diff}^+ D^n$, $\text{Diff}^+ S^{n-1}$ be the **groups of orientation-preserving diffeomorphisms** of D^n , S^{n-1} , respectively, where multiplication is defined by composition. Let $r: \text{Diff}^+ D^n \rightarrow \text{Diff}^+ S^{n-1}$ be the homomorphism induced by the restriction $D^n \rightarrow S^{n-1}$. Then the image of r is a normal subgroup, and $\Gamma_n = \text{Diff}^+ S^{n-1}/r(\text{Diff}^+ D^n)$.

J. Surgery Theory

A process of modifying a manifold into another by a sequence of spherical modifications is called **surgery** on the manifold (\rightarrow Section F). The technique of surgery proved to be a powerful tool for the development of differential topology in the 1960s. Kervaire and Milnor exploited this technique in their study of homotopy spheres [27]. W. Browder [29] and S. P. Novikov [30] used surgery to construct differentiable manifolds with the same homotopy type as that of a given Poincaré complex in dimension greater than 4.

To explain the main points of surgery theory, we introduce some terminology. A pair of finite *CW complexes (X, Y) is called a **Poincaré pair of formal dimension n** if there exists a class $\mu \in H_n(X, Y; \mathbb{Z})$ called the **fundamental class** such that the \cap -product $\mu \cap: H^q(X; \mathbb{Z}) \rightarrow H_{n-q}(X, Y; \mathbb{Z})$ is an isomorphism for each q . When $Y = \emptyset$, X is called a **Poincaré complex**. Let M be an n -dimensional smooth manifold. Consider an embedding g of M into a Euclidean space \mathbb{R}^{n+k} , where k is

large enough (i.e., $k \geq n+2$). Then the isomorphism class of the *normal bundle of g is independent of the choice of embedding, and it depends only on M . Any representative of the isomorphism class is called the **normal k -vector bundle** of M and is denoted by ν_M^k . Let (X, Y) be a Poincaré pair of formal dimension n , and let ξ be a real k -vector bundle over X . A **normal mapping (normal map)** (f, b) consists of a degree 1 mapping $f: (M, \partial M) \rightarrow (X, Y)$ and a *bundle mapping $b: \nu_M^k \rightarrow \xi$ which covers f .

A normal mapping $(f, b): (M, \partial M) \rightarrow (X, Y)$ is **normally cobordant** to a normal mapping $(f', b'): (M', \partial M') \rightarrow (X, Y)$ if $\partial M = \partial M'$ and there exist a smooth $(n+1)$ -manifold W and a mapping $F: W \rightarrow X$ such that $\partial W = M \cup (-M') \cup \partial M \times I$, F is covered by a bundle mapping $B: \nu_W^k \rightarrow \xi$, and $(F, B)|_{(M, \partial M)} = (f, b)$, $(F, B)|_{(M', \partial M')} = (f', b')$.

The fundamental theorem of surgery theory is formulated as follows: Let (X, Y) be a Poincaré pair of formal dimension n . Suppose that X is simply connected and $n \geq 5$. Let $(f, b): (M, \partial M) \rightarrow (X, Y)$ be a normal mapping that restricts to a homotopy equivalence on the boundary $f|_{\partial M}: \partial M \rightarrow Y$. Then (f, b) is normally cobordant to a normal mapping $(f', b'): (M', \partial M') \rightarrow (X, Y)$ with $f': M' \rightarrow X$ a homotopy equivalence if and only if a well-defined obstruction $\sigma(f, b)$ vanishes. $\sigma(f, b)$ is called the **surgery obstruction**. When n is odd, $\sigma(f, b)$ always vanishes. When $n \equiv 0 \pmod{4}$, $\sigma(f, b)$ is an integer. If $Y = \emptyset$, it is given by $(I(M) - I(X))/8$, where $I(\quad)$ denotes the *index of the manifold or of the Poincaré complex. If $n \equiv 2 \pmod{4}$, $\sigma(f, b)$ is an integer mod 2, called the **Arf-Kervaire invariant**. For a thorough development of simply connected surgery \rightarrow [31].

In the PL or even in the topological categories, surgery theory can be developed similarly (Browder and Hirsch, R. C. Kirby and L. C. Siebenmann [32]).

In his study of Hauptvermutung for simply connected manifolds, D. Sullivan reformulated surgery in terms of the "surgery exact sequences" involving the classifying spaces G/PL or G/O . (These spaces are "homotopy theoretic fibers" of $BPL \rightarrow BG$ or $BO \rightarrow BG$ respectively.) In the special case where X is a closed simply connected PL n -manifold, the surgery exact sequence can be formulated as follows ($n \geq 5$):

$$0 \rightarrow hT(X) \xrightarrow{\eta} [X, G/PL] \xrightarrow{\theta} \begin{cases} \mathbb{Z} & (n \equiv 0 \pmod{4}), \\ \mathbb{Z}_2 & (n \equiv 2 \pmod{4}), \\ 0 & (n \text{ odd}). \end{cases}$$

The set $hT(X)$ is the totality of equivalence classes of pairs (M, f) , where M is a closed PL n -manifold and f is a homotopy equivalence $M \rightarrow X$. Two such pairs (M', f') and (M'', f'') are defined to be equivalent if there exists a PL

homeomorphism $h: M' \rightarrow M''$ such that $f'' \circ h$ is homotopic to f' . The set of homotopy classes $[X, G/PL]$ of mappings $X \rightarrow G/PL$ is appropriately identified with the set of all normal cobordism classes of normal mappings with target X or with the set of all PL reductions of the **Spivak normal fiber space** of X as a Poincaré complex [31]. The mapping η can be defined naturally, and the mapping θ corresponds to the assignment of the surgery obstruction. The image $\eta(M, f) \in [X, G/PL]$ is sometimes called the **normal invariant** of (M, f) . Sullivan reduced the classification problem of manifolds within a given homotopy type to a homotopy theoretic problem of the classifying spaces G/PL , G/O [33] (also \rightarrow [31, 34]).

In the latter half of the 1960s, surgery theory was extended by Wall to cover all compact non-simply connected manifolds which are not necessarily orientable. He introduced a certain Abelian group $L_n(\pi; w)$, now called the **Wall group**, which functorially depends on the fundamental group $\pi = \pi_1(X)$, with the orientation character $w: \pi_1(X) \rightarrow \mathbb{Z}_2$, and which is of period 4 with respect to the formal dimension n of X . In Wall's theory, the surgery obstruction $\sigma(f, b)$ takes its value in this group. The group structure of Wall groups has been calculated in many cases. Sullivan's exact sequences are extended to the non-simply connected cases [34]. Making use of the extended exact sequences, Wall and W. C. Hsiang and J. L. Shaneson classified homotopy tori. The result played an important role in the work of Kirby and Siebenmann on the π -annulus conjecture and stable homeomorphisms which led to the solution of π -Hauptvermutung and triangulation problems on topological manifolds in 1969 (\rightarrow 65 Combinatorial Manifolds). Surgery theory has many applications to other geometric problems. Among them are finding missing boundaries for open manifolds, equivariant surgery, homology surgery [35], and surgery on codimension two submanifolds [36, 37].

K. 4-Dimensional Manifolds

The results in differential topology discussed above are mainly concerned with manifolds of dimension ≥ 5 . For 4-manifolds, however, because of their peculiar nature which is not observed in other dimensions, many fundamental problems had remained unsolved until M. H. Freedman's epoch-making paper [54] appeared in 1982. His paper, together with S. K. Donaldson's theorem [55] which was published a little later, was a breakthrough in the theory of 4-manifolds.

It was Rokhlin who first discovered a strange property of 4-manifolds [38]. **Rokhlin's theorem** states: Let M be a closed oriented smooth 4-manifold. If M is almost parallelizable (or equivalently, if M is a spin 4-manifold), then the index of M is divisible by 16. Milnor and Kervaire gave an alternative proof of this theorem from the differential-topological point of view [39]. Freedman and Kirby and Y. Matsumoto gave geometric or elementary proofs.

Until 1981, Rokhlin's theorem had been a constant source of many curious phenomena in 4-dimensional topology. The list contains, for example: (1) the class $(4m+2, 4n+2) \in H_2(S^2 \times S^2) \cong \mathbb{Z} \oplus \mathbb{Z}$ cannot be represented by a smoothly embedded 2-sphere in $S^2 \times S^2$ (Kervaire and Milnor). This result was improved by W.-C. Hsiang and R. H. Szczarba, A. G. Tristram, and Rokhlin. (2) The h -cobordism theorem fails to hold in 4 or 3 dimensions (T. Matsumoto, Siebenmann [40]). (3) There exists a closed smooth 4-manifold M that is homotopy equivalent to the real projective space $\mathbb{R}P^4$, but $M \not\cong \mathbb{R}P^4$ (Cappell and Shaneson). (4) There exists an open 4-manifold W^4 properly homotopy equivalent to $S^3 \times \mathbb{R}$ but distinct (Freedman).

Closed, connected, simply connected 4-manifolds M and N are homotopy equivalent if and only if the intersection forms defined on the 2-dimensional (co)homology groups are equivalent as inner product spaces over \mathbb{Z} [41]. Wall [42] proved that if closed simply connected smooth 4-manifolds M and N are homotopy equivalent, then they are h -cobordant. Moreover, if M and N are h -cobordant, then there exists an integer $k \geq 0$ such that $M \# k(S^2 \times S^2)$ is diffeomorphic to $N \# k(S^2 \times S^2)$.

About 1973, using a certain infinite repetition process, A. Casson constructed a family of noncompact smooth 4-manifolds which are properly homotopy equivalent to the open 2-handle $D^2 \times \mathbb{R}^2$. A 4-manifold belonging to the family is called a **Casson handle**. He observed that if all the Casson handles are diffeomorphic to $D^2 \times \mathbb{R}^2$, then theories analogous to surgery and the h -cobordism theorem in higher dimensions can also be developed in dimension 4.

In his 1982 paper [54], Freedman proved that each Casson handle is homeomorphic to $D^2 \times \mathbb{R}^2$. (It was proved later that Casson handles are not, in general, diffeomorphic to $D^2 \times \mathbb{R}^2$.) This result and the proper h -cobordism theorem, also due to Freedman, proved many fundamental results on the topological structure of 4-manifolds: (1) If closed simply connected smooth 4-manifolds M , N are h -cobordant, they are homeomorphic. In

particular, a 4-dimensional homotopy 4-sphere is homeomorphic to the 4-sphere S^4 . (Proof of the 4-dimensional Poincaré conjecture.) (2) A topological 4-manifold properly homotopy equivalent to \mathbf{R}^4 is homeomorphic to \mathbf{R}^4 . (3) Given a nonsingular symmetric bilinear form ω over \mathbf{Z} , there exists a closed, connected, simply connected topological 4-manifold whose intersection form is equivalent to ω . (Therefore Rokhlin's theorem cannot be extended to topological 4-manifolds. From this, it follows that there exist simply connected topological 4-manifolds which are nonsmoothable or even nontriangulable.) (4) The homeomorphism class of a closed connected simply connected 4-manifold is determined by the intersection form and the Kirby-Siebenmann class. (This statement is an improved one by F. Quinn [56].)

Donaldson [55] revealed a sharp contrast existing between smooth and topological 4-manifolds. Donaldson's theorem states: If the intersection form of a closed, connected, simply connected smooth 4-manifold is positive definite, then the form is equivalent to the standard one $\langle 1 \rangle \oplus \langle 1 \rangle \oplus \dots \oplus \langle 1 \rangle$. This theorem, together with Casson's theory and Freedman's result (2) stated above, implies that there exists an exotic differential structure on a 4-dimensional Euclidean space \mathbf{R}^4 . Moreover, as an application of Donaldson's theorem, the problem of representing a 2-dimensional homology class of $S^2 \times S^2$ by a smoothly embedded 2-sphere was completely solved (K. Kuga [57]): the class $(p, q) \in H_2(S^2 \times S^2)$ is represented by a smoothly embedded S^2 if and only if $|p| \leq 1$ or $|q| \leq 1$.

Many problems concerning differential structures on 4-manifolds remain unsolved. It is not known whether an exotic smooth 4-sphere exists.

Among other results, the proof of the 4-dimensional annulus conjecture by Quinn [56] is remarkable.

L. Miscellaneous Results

The Browder-Livesay invariant. Let Σ^n be a homotopy n -sphere, T an **involution** on Σ^n , that is, a smooth mapping $T: \Sigma^n \rightarrow \Sigma^n$ with $T \circ T = \text{id}_{\Sigma^n}$. Assume that T is free from fixed points. The involution T is said to **desuspend** if there exists a homotopy $(n-1)$ -sphere Σ' smoothly embedded in Σ^n which is invariant under the action of T . Browder and G. R. Livesay defined an obstruction $\sigma(T)$ in the group $0(n: \text{even}), \mathbf{Z} (n \equiv 3 \pmod{4}), \mathbf{Z}_2 (n \equiv 1 \pmod{4})$ such that $\sigma(T) = 0$ if and only if T desuspends (provided that $n \geq 6$) [43]. The invariant $\sigma(T)$ is now called the **Browder-**

Livesay invariant. The technique used there was equivariant surgery under the action of T .

De Rham homotopy theory. A new approach to topology of manifolds was invented by Sullivan [44], who considered the exterior algebra of differential forms (with polynomial coefficients) on a simplicial complex. Through the construction of the **minimal model** for the algebra of differential forms, he recovers the rational homotopy type of the complex under some reasonable condition on the fundamental group. Following upon the classical de Rham theorem which recovers the (real) cohomology algebra from the algebra of differential forms, this approach is called the **de Rham homotopy theory**. This method has proved to be useful for the explicit calculation of the algebraic topological invariants of $^*\text{Kähler}$ manifolds, $^*\text{loop}$ spaces, cross-section spaces, $^*\text{algebraic}$ varieties, etc.

Kirby calculus. Kirby [45] initiated a link-theoretic approach to 3- and 4-manifolds. Let L be a link in S^3 . Suppose that each component of L is given a **framing**, which means a trivialization of a tubular neighborhood. Such a link is called a **framed link**. A framing of a component is determined by the $^*\text{linking}$ number between the component and its replacement along the framing. By attaching 2-handles to the 4-disk D^4 along a framed link in $S^3 = \partial D^4$, we obtain a handlebody; here we denote it by W_L . It is known that each closed connected oriented 3-manifold is obtained as the boundary of such a handlebody (W. B. R. Lickorish, Wallace). Kirby proved that for framed links L and L' , the boundaries ∂W_L and $\partial W_{L'}$ belong to the same orientation-preserving diffeomorphism class if and only if L is transformed into L' by a sequence of the following two kinds of elementary operations: (i) adding or deleting a trivial knot (separated from L) with framing ± 1 , (ii) band summation of components corresponding to "handle sliding." Kirby's approach is called **Kirby calculus** on framed links. For applications \rightarrow [45, 53].

115 (XVII.8) Diffusion Processes

A. General Remarks

Let $(\Omega, \mathfrak{B}, P)$ be a * probability space. A * Markov process $\{X_t\}_{0 \leq t < \infty}$ on a * topological space S with * continuous time parameter t is called a **diffusion process** if the * sample function $X_t(\omega)$ is continuous in t with probability 1 until a random time $\zeta(\omega)$, called the * terminal time. After the terminal time, $X_t(\omega)$ stays at the terminal point ∂ . Such a process is said to be **1-dimensional** or **multidimensional** according as S is an interval or a manifold (possibly with boundary) with dimension ≥ 2 . Brownian motion is a typical diffusion process (\rightarrow 45 Brownian Motion).

To give conditions for a Markov process to be a diffusion process, let us assume that S is a * complete metric space with metric ρ . Let $\{X_t\}$ be a Markov process on S with time parameter t ranging over a finite interval $[t_1, t_2]$ and satisfying

$$\sup P(s, x, t, S - U_\varepsilon(x)) = O(h) \quad (h \downarrow 0) \quad (1)$$

for every $\varepsilon > 0$, where $U_\varepsilon(x)$ is the ε -neighbor-

hood of x and sup is taken over all $x \in S$, and $s, t \in [t_1, t_2]$ such that $0 < t - s < h$. Then $\{X_t\}$ is a diffusion process if and only if

$$\int_{t_1}^{t_2} P(\rho(X_t, X_{t+h}) > \varepsilon) dt = o(h) \quad (h \downarrow 0)$$

for every $\varepsilon > 0$ [5]. This includes the following result due to E. B. Dynkin (1952) and J. R. Kinney (1953) as a special case: If in (1) we can replace $O(h)$ with $o(h)$, then $\{X_t\}$ will be a diffusion process. Specifically, when $\{X_t\}$ is a 1-dimensional * strong Markov process, the latter condition is also necessary for the process to be a diffusion process.

Diffusion processes are intimately related to a certain class of * partial differential equations. Let S be the real line. Assume that the * transition probability $P(s, x, t, E)$ ($s < t$) of the process $\{X_t\}_{0 \leq t < \infty}$ satisfies

$$1 - P(s, x, s + h, (x - \varepsilon, x + \varepsilon)) = o(h) \quad (h \downarrow 0) \quad (2a)$$

for every $\varepsilon > 0$ and that the following limits exist:

$$\lim_{h \rightarrow 0+} \frac{1}{h} \int_{x-\varepsilon}^{x+\varepsilon} (y-x)^2 P(s, x, s+h, dy) = 2a(s, x) > 0, \quad (2b)$$

$$\lim_{h \rightarrow 0+} \frac{1}{h} \int_{x-\varepsilon}^{x+\varepsilon} (y-x) P(s, x, s+h, dy) = b(s, x), \quad (2c)$$

$$\lim_{h \rightarrow 0+} \frac{1}{h} (P(s, x, s+h, S) - 1) = c(s, x) \leq 0. \quad (2d)$$

Assume further that the transition probability is * absolutely continuous with respect to Lebesgue measure: $P(s, x, t, dy) = p(s, x, t, y) dy$. Then under some suitable additional conditions, $p(s, x, t, y)$ satisfies

$$\frac{\partial p}{\partial s} = -a(s, x) \frac{\partial^2 p}{\partial x^2} - b(s, x) \frac{\partial p}{\partial x} - c(s, x)p, \quad (3)$$

and

$$\frac{\partial p}{\partial t} = \frac{\partial^2}{\partial y^2} (a(t, y)p) - \frac{\partial}{\partial y} (b(t, y)p) + c(t, y)p, \quad (4)$$

where δ is the * Dirac delta function. The coefficient c vanishes if $\{X_t\}$ is * conservative. Equations (3) and (4) are called **Kolmogorov's backward equation** and **forward equation**, respectively. They are also called the **Fokker-Planck partial differential equations**.

A. N. Kolmogorov [1] derived equations (3) and (4) in 1931, and W. Feller proved that (3) (or (4)) has a unique solution under certain regularity conditions on the coefficients a , b , and c , and that the solution $p(s, x, t, y)$ is non-

negative, has an integral with respect to y that does not exceed 1, and satisfies the †Chapman-Kolmogorov equation

$$\int p(s, x, t, y) p(t, y, u, z) dy = p(s, x, u, z)$$

for every $0 < s < t < u$. Hence $p(s, x, t, y)$ determines a †Markov process analytically. However, rigorous proof establishing the sufficiency of condition (2) for the Markov process $\{X_t\}$ to be a diffusion process did not appear until the 1950s.

In the †temporally homogeneous case, $p(s, x, s+h, y)$ does not depend on s and can be written as $p(h, x, y)$. Then $a(s, x)$, $b(s, x)$, and $c(s, x)$ are also independent of s , and $p(t, x, y)$ satisfies

$$\frac{\partial p}{\partial t} = a(x) \frac{\partial^2 p}{\partial x^2} + b(x) \frac{\partial p}{\partial x} + c(x)p,$$

$$p(0+, x, y) = \delta(x - y). \quad (5)$$

Feller made an intensive study of this case and completely solved the problem of existence and uniqueness of the solution of (5) assuming that $p(t, x, y)$ is nonnegative and that its integral with respect to y does not exceed 1 [7]. In particular, when t varies in $[0, +\infty)$ and S is an interval $[r_1, r_2]$, Feller used the Hille-Yosida theory of †semigroups of operators to determine the conditions that should be satisfied by r_1 and r_2 in order that the differential equation (5) (with the initial condition and his additional assumptions) yield one and only one solution. Feller also introduced the notion of generalized differential operators, which expresses the differential operator in the right-hand side of (5) in the most general form [8]. The probabilistic meaning of his results was clarified by Dynkin, H. P. McKean, K. Itô, D. B. Ray, and others, and all 1-dimensional diffusion processes with the †strong Markov property have now been completely determined.

Since not much research on temporally nonhomogeneous diffusion processes has been done so far, we restrict our explanation to temporally homogeneous ones. Let $\mathfrak{M} = (X_t, W, P_x | x \in S)$ be a Markov process, where S is a †state space, W is the †path space consisting of all paths $w: [0, +\infty) \rightarrow S \cup \{\partial\}$ which are continuous in t for $0 \leq t < \zeta(w)$ ($w(t) = \partial$ for $t \geq \zeta(w)$ while $w(t) \in S$ for $0 \leq t < \zeta(w)$), and P_x is a probability measure on W under the condition that the process starts from x at $t = 0$ (\rightarrow 261 Markov Processes). We can actually identify W with the †basic space Ω and set $X_t(w) = w(t)$ for $w \in \Omega$. Assume that \mathfrak{M} has the †strong Markov property. It follows from †Dynkin's formula for †infinitesimal generators (\rightarrow 261 Markov Processes) that the infinitesimal generator \mathfrak{G} of a diffusion process has the local property stating that if u and v belong to the domain of \mathfrak{G} and coincide in a neighborhood of x_0 , then $\mathfrak{G}u(x_0) = \mathfrak{G}v(x_0)$.

B. 1-Dimensional Diffusion Processes

Let S be a straight line. A point $x \in S$ is called a **right singular point** if $X_t(w) \geq x$ for all $t \in [0, \zeta(w))$ with P_x -probability 1. A **left singular point** is defined analogously, with \geq replaced by \leq . A right and left singular point is called a **trap**, while a right singular point which is not left singular is called a **right shunt** (a **left shunt** is defined analogously). A point is called a **regular point** if it is neither right nor left singular.

The set of all regular points is open. Let (r_1, r_2) be a connected component of this open set. One of the most important results concerning this situation is the proof of the existence of a strictly increasing function $s(x)$ defined on (r_1, r_2) and two measures m and k on (r_1, r_2) such that the infinitesimal generator \mathfrak{G} of \mathfrak{M} is represented as

$$\mathfrak{G}u(x) = \frac{u^+(dx) - u(x)k(dx)}{m(dx)}, \quad (6)$$

where $u^+(dx)$ is the measure $du^+(x)$ induced by the †right derivative $u^+(x)$ of $u(x)$ with respect to $s(x)$ (i.e., $u^+(x) = \lim_{\Delta x \rightarrow +0} \{u(x + \Delta x) - u(x)\} / \{s(x + \Delta x) - s(x)\}$). Equation (6) gives a generalization of second-order †differential operator $au'' + bu' + cu$ ($a > 0, c \leq 0$) [12]. Here m is positive for nonempty open sets, both m and k are finite for compact sets in (r_1, r_2) , and s, m , and k are unique in the following sense: If there are two sets of values of s_i, m_i , and k_i ($i = 1, 2$), then $s_2(x) = cs_1(x) + \text{constant}$, $m_2(dx) = c^{-1}m_1(dx)$, and $k_2(dx) = c^{-1}k_1(dx)$ for some positive constant c . We call s, m , and k , respectively, the **canonical scale**, **canonical measure** (or **speed measure**), and **killing measure** for \mathfrak{M} . They determine the behavior of $X_t(w)$ belonging to \mathfrak{M} inside the interval (r_1, r_2) . Conversely, given any such set of s, m , and k , we can find a 1-dimensional diffusion process \mathfrak{M} such that s, m , and k are, respectively, the canonical scale, canonical measure, and killing measure of \mathfrak{M} . If $X_t(w)$ is nonvanishing in (r_1, r_2) with probability 1, the killing measure k is identically zero, and the canonical scale s satisfies the equation

$$P_x(\sigma_{x_2} < \sigma_{x_1}) = \frac{s(x) - s(x_1)}{s(x_2) - s(x_1)}$$

for $x_1 < x < x_2$, where σ_y is the †hitting time of the point y .

The motion $X_t(w)$ belonging to the process \mathfrak{M} and contained in (r_1, r_2) can be constructed

from the Brownian motion by means of a topological transformation of the state space (interval) based on s , a †time change based on m , and a †killing based on k . More precisely, we first transform the interval (r_1, r_2) by $x \rightarrow s(x)$ into the interval $(s(r_1 + 0), s(r_2 - 0))$ so that the diffusion process on this new interval has a canonical scale coincident with x . The speed and killing measures are transformed accordingly. We can, therefore, assume that the canonical scale is x . Let us consider the case $(r_1, r_2) = (-\infty, +\infty)$ for simplicity. Let $t(t, x)$ be the †local time of Brownian motion at x (\rightarrow 45 Brownian Motion). Next, we apply the †time change to the Brownian motion by means of the †additive functional

$$\varphi(t) = \int_{-\infty}^{+\infty} t(t, x) m(dx),$$

and finally †kill the latter process by means of the †multiplicative functional

$$\alpha(t) = \exp\left(-\int_{-\infty}^{+\infty} t(\varphi^{-1}(t), x) k(dx)\right).$$

Thus we obtain the process \mathfrak{M} in $(-\infty, \infty)$. In particular, if $m(dx) = a(x)^{-1} dx$ and $k(dx) = |c(x)| dx$, we have

$$\varphi(t) = \int_0^t a(X_\tau)^{-1} d\tau,$$

$$\alpha(t) = \exp\left(\int_0^t c(X_{\varphi^{-1}(\tau)}) d\tau\right),$$

and $\mathfrak{G}u = au'' + cu$.

At a shunt the infinitesimal generator \mathfrak{G} has a form that is a generalization of the first-order differential operator $bu' + cu$ ($c \leq 0$), with $b > 0$ or $b < 0$ according as it is a right shunt or a left shunt. At a trap we have $\mathfrak{G}u(x) = -u(x)/E_x(\zeta)$.

When S is an interval with endpoints r_1 and r_2 and all interior points are regular, the left endpoint r_1 is classified into the following 4 types, according to the behavior of \mathfrak{M} near r_1 : Take an arbitrary fixed point $r \in (r_1, r_2)$, and set $n(dx) = m(dx) + k(dx)$ and

$$\alpha = \int_{(r_1, r)} (s(r) - s(x)) n(dx),$$

$$\beta = \int_{(r_1, r)} n((x, r)) s(dx).$$

Then r_1 is a **regular boundary** if $\alpha < \infty$, $\beta < \infty$; an **entrance boundary** if $\alpha < \infty$, $\beta = \infty$; an **exit boundary** if $\alpha = \infty$, $\beta < \infty$; and a **natural boundary** if $\alpha = \infty$, $\beta = \infty$. This classification is independent of the choice of r . A similar classification of r_2 can be established. $X_t(w)$ approaches r_1 in finite time with positive or null probability according as β is finite or infinite. If $\alpha = \infty$, it never happens that $X_t(w)$

starts from r_1 and reaches the interior of the interval S even if $r_1 \in S$, whereas if $\alpha < \infty$ we can construct (adjoining r_1 to S if necessary) a diffusion process that enters the interior from r_1 and whose motion in the interior coincides with that of $X_t(w)$.

If r_1 is a regular boundary for \mathfrak{M} and $r_1 \in S$, then there are various possibilities for the behavior of $X_t(w)$ at r_1 . They are expressed by the boundary conditions satisfied by the functions u belonging to the domain of the infinitesimal generator \mathfrak{G} . The condition is in general of the form

$$\gamma u(r_1) + \delta \mathfrak{G}u(r_1) + \mu u^+(r_1) = 0,$$

where γ , δ , and μ are constants, $\gamma, \delta \leq 0$, $\mu \geq 0$, and $|\delta| + \mu > 0$. If $\gamma = \delta = 0$, then r_1 is said to be a **reflecting barrier**. If r_1 is regular for \mathfrak{M} and does not belong to S , then $X_t(w)$ vanishes exactly as $X_t(w)$ reaches r_1 , and r_1 is called an **absorbing barrier**. This case corresponds to the boundary condition $u(r_1) = 0$. Whatever the boundary condition may be, \mathfrak{M} is constructed from the Brownian motion with reflecting barrier by topological transformation of the state space, time change, and killing. Here if $\gamma \neq 0$, then killing may occur at r_1 ; if $\delta \neq 0$, the set of visiting times of r_1 has positive Lebesgue measure; and if $\mu \neq 0$, the trace of the motion may go beyond the point r_1 and reach the interior points of S [2, 7–9].

If we weaken the assumption of continuity of paths and admit jumps from r_1 , the general boundary condition becomes

$$\gamma u(r_1) + \delta \mathfrak{G}u(r_1) + \mu u^+(r_1) + \int_{(r_1, r_2]} (u(x) - u(r_1)) v(dx) = 0,$$

where v is a measure with respect to which $\min(1, s(x) - s(r_1 + 0))$ is integrable.

When $S = (r_1, r_2)$, the transition probability is absolutely continuous with respect to the canonical measure, the density $p(t, x, y)$ has an †eigenfunction expansion

$$p(t, x, y) = \int_{-\infty}^0 e^{\lambda t} e(d\lambda; x, y),$$

and $p(t, x, y)$ is positive, jointly continuous in 3 variables, and symmetric in x and y . A similar result is also known when S is half-open or closed [9].

If \mathfrak{M} is †recurrent, i.e., $P_x(\sigma_y < +\infty) = 1$ for every x and y in S , then there exists a unique (up to a multiplicative constant) †invariant measure for S that is finite for all closed intervals in the interior of S . If \mathfrak{M} is conservative and all the interior points of S are regular, then the canonical measure is an invariant measure, provided that the endpoints are either entrance, natural, or regular reflecting.

C. Multidimensional Diffusion Processes

Let the state space S be a domain or the closure of a domain in the n -dimensional Euclidean space \mathbf{R}^n . Consider a temporally homogeneous diffusion process $\{X_t\}_{0 \leq t < \infty}$ on S . Under suitable regularity conditions the infinitesimal generator \mathfrak{G} coincides, for sufficiently smooth functions u in its domain, with the following \dagger elliptic partial differential operator A :

$$A = \sum_{i,j=1}^n a^{ij}(x) \frac{\partial^2}{\partial x^i \partial x^j} + \sum_{i=1}^n b^i(x) \frac{\partial}{\partial x^i} + c(x), \quad c \leq 0; \quad (7)$$

where S has a boundary, u satisfies a boundary condition of the form

$$\sum_{i,j=1}^n \alpha^{ij}(x) \frac{\partial^2 u(x)}{\partial x^i \partial x^j} + \sum_{i=1}^{n-1} \beta^i(x) \frac{\partial u(x)}{\partial x^i} + \gamma(x)u(x) + \delta(x)Au(x) + \mu(x) \frac{\partial u(x)}{\partial n} = 0, \quad (8)$$

where, for simplicity, we assume that S is the closed half-space defined by $x^n \geq 0$, (α^{ij}) is a symmetric nonnegative definite matrix, $\gamma \leq 0$, $\delta \leq 0$, $\mu \geq 0$, and $\partial/\partial n$ is the inward-directed \dagger conormal derivative associated with a^{ij} . This boundary condition was discovered by A. D. Venttsel' [13]. Conversely, given an operator A such as (7) and a boundary condition (8) (if S has a boundary), the existence and uniqueness of the corresponding diffusion process are known for several special cases. If $S = \mathbf{R}^n$ and A has continuous coefficients, there exists at least one diffusion process corresponding to A [14–16].

A probabilistic approach to constructing diffusion processes corresponding to the operator A with $c=0$ is given by Itô's method of \dagger stochastic differential equations (\rightarrow 406 Stochastic Differential Equations E). A somewhat different approach was introduced by D. W. Stroock and S. R. S. Varadhan [20] under the name of **martingale problems** (\rightarrow 261 Markov Processes C). Let $W^n = C([0, \infty) \rightarrow \mathbf{R}^n)$ be the space of all continuous functions $w: [0, \infty) \rightarrow \mathbf{R}^n$ endowed with compact uniform topology and $\mathfrak{B}(W^n)$ be the topological σ -field. Given $x \in \mathbf{R}^n$, a **solution to the martingale problem** for the operator A with $c=0$ starting from x is a probability measure P_x on $(W^n, \mathfrak{B}(W^n))$ satisfying $P_x(w(0)=x) = 1$ such that $f(w(t)) - \int_0^t Af(w(s))ds$ is a P_x -martingale for all $f \in C_0^\infty(\mathbf{R}^n)$, where $C_0^\infty(\mathbf{R}^n)$ denotes the set of all C^∞ -functions on \mathbf{R}^n having compact support. If $a = (a^{ij})$ is uniformly positive definite, bounded, and continuous and if $b = (b^i)$ is bounded and Borel measurable, the martingale problem for the operator A with $c=0$ is **well posed**, i.e., for each $x \in \mathbf{R}^n$, there is exactly

one solution starting from x . (For further information related to the theory of martingale problems \rightarrow [15, 20].)

Suppose next that S is the closure of a bounded domain with a sufficiently smooth boundary and A is given with sufficiently smooth coefficients. If the boundary condition is $\gamma u + \mu \partial u / \partial n = 0$, $\mu \neq 0$, then there exists a unique diffusion process on S corresponding to this situation. Moreover, if $\gamma = 0$, then the process is said to have a **reflecting barrier**. S. Watanabe [22] gave a probabilistic condition which characterizes the reflecting diffusion processes in the normal direction among all reflecting diffusion processes in oblique directions. Suppose that a general boundary condition (8) is given. We write the left-hand side of (8) as Lu . Write $u = Hf$ for the solution of $Au = 0$ with boundary value f . Under some natural additional conditions, T. Ueno proved that if $LH \dagger$ generates a Markov process on the boundary, then there exists a diffusion process for A with boundary condition (8) [21]. If $\{X_t\}$ has a reflecting barrier, the Markov process on the boundary is, conversely, obtained from $\{X_t\}$ through time change by a nonnegative continuous \dagger additive functional which increases only when the value of X_t is on the boundary. Stochastic differential equations are also used in constructing diffusion processes with boundary condition (8) [19] (\rightarrow 406 Stochastic Differential Equations). An elegant method for constructing diffusion processes with boundary condition (8) has been introduced by Watanabe [22]. It consists of piecing together excursions from the boundary to the boundary. In this construction, the stochastic integrals for \dagger Poisson point processes play an important role. There are various other results on multidimensional diffusion processes with general boundary conditions which cannot be covered by the method mentioned above (\rightarrow [23] and M. Motoo, *Proc. Intern. Symp. Stochastic Differential Equations, Kyoto, 1976*).

When we have a diffusion process on S with infinitesimal generator of the form A , we can obtain a probabilistic expression for the solutions of various partial differential equations involving A . Let σ be the hitting time of the boundary of S . Then $Hf(x)$ can be expressed as $E_x(f(X_{\sigma-0}))$. The solution of $Au = -f$ with boundary value 0 is given by $u(x) = E_x(\int_0^\sigma f(X_t)dt)$, while the solution $u(t, x)$ of $\partial u / \partial t = Au$ with boundary value 0 and initial value $u(0, x) = f$ is $E_x(f(X_t); t < \sigma)$. The first case gives the solution of a \dagger Dirichlet problem; and in this case, the condition for a boundary point to be \dagger regular relative to the Dirichlet problem can also be expressed probabilistically (\rightarrow 45 Brownian Motion, 261 Markov

Processes). Furthermore, if $f(X_t)$ is replaced by $f(X_t)\exp(\int_0^t k(X_s)ds)$ in the expressions for $u(x)$ and $u(t, x)$, A is replaced by $A + k$ (M. Kac [24]). When $k \leq 0$, this replacement gives rise to a killing of the process (\rightarrow 261 Markov Processes E).

By using the theory of \dagger Dirichlet forms we can investigate a general class of \dagger symmetric multidimensional diffusion processes which are not in the framework of the classical diffusion processes, i.e., diffusion processes whose infinitesimal generators are not necessarily differential operators (M. Fukushima, *Dirichlet Forms and Markov Processes*, 1980)).

D. Diffusion Processes on Manifolds

Let M be a \dagger connected \dagger oriented $\dagger\sigma$ -compact C^∞ \dagger manifold of dimension n . Let \hat{M} be M or $M \cup \{\partial\}$ (= the one-point \dagger compactification of M) according as M is \dagger compact or non-compact. Suppose that we are given a system of C^∞ \dagger vector fields A_0, A_1, \dots, A_r on M . We consider the following stochastic differential equation on M :

$$dX_t = \sum_{k=1}^r A_k(X_t) \circ dw^k(t) + A_0(X_t)dt \quad (9)$$

(\rightarrow 406 Stochastic Differential Equations), where $w(t) = (w^1(t), w^2(t), \dots, w^r(t))$ denotes an r -dimensional Brownian motion and the first term of the right-hand side is understood in the sense of the \dagger Stratonovich stochastic differential. Let $X(t, x, w)$ be the solution of (9) with $X_0 = x \in M$ defined on the r -dimensional Wiener space (W_0^r, P^w) (\rightarrow 406 Stochastic Differential Equations) and P_x be the probability law on $\hat{W}(M)$ of $(X(t, x, w))_{t \geq 0}$, where $\hat{W}(M)$ is the space of all continuous mappings $w: [0, \infty) \rightarrow \hat{M}$ with ∂ as a trap. Then $\{P_x | x \in M\}$ defines a diffusion process \mathfrak{M} on M which is generated by the second-order differential operator $\sum_{k=1}^r A_k^2/2 + A_0$, i.e., a diffusion process \mathfrak{M} with the infinitesimal generator \mathfrak{G} such that

$$\mathfrak{G}f(x) = \frac{1}{2} \sum_{k=1}^r A_k^2 f(x) + A_0 f(x) \quad \text{for } f \in C_0^\infty(M),$$

where $C_0^\infty(M)$ denotes the space of all C^∞ -functions on M with compact support. By appealing to the analytical theory of partial differential equations we can discuss regularity properties of the transition probability of \mathfrak{M} ([15]; L. Hörmander, *Acta Math.*, 119 (1967)). Recently, P. Malliavin [25] also suggested a probabilistic method for proving elliptic regularity results (see also [19]).

We now assume that all linear sums of A_0, A_1, \dots, A_r are \dagger complete. Then the terminal

time of \mathfrak{M} is infinite a.s. Let $W(M)$ be the space of all continuous mappings $w: [0, \infty) \rightarrow M$ endowed with compact uniform topology, and set $W_x(M) = \{w | w \in W(M), w(0) = x\}$. We describe the \dagger topological support $\mathcal{S}(P_x)$ of the probability P_x on $W_x(M)$, i.e., the smallest closed subset of $W_x(M)$ that carries the measure P_x . Let \mathcal{S} be the set of all piecewise constant mappings $u: [0, \infty) \rightarrow \mathbf{R}^r$. For a given $u = (u^1(t), u^2(t), \dots, u^r(t))$ of \mathcal{S} , we consider a system of ordinary differential equations

$$\frac{d}{dt} \varphi(t) = A_0(\varphi(t)) + \sum_{k=1}^r A_k(\varphi(t))u^k(t), \quad (10)$$

i.e., for every C^∞ -function f on M with compact support,

$$\frac{d}{dt} f(\varphi(t)) = A_0 f(\varphi(t)) + \sum_{k=1}^r (A_k f)(\varphi(t))u^k(t).$$

Then for every $u \in \mathcal{S}$ and $x \in M$, we obtain a curve $\varphi = \varphi(x, u) = (\varphi_t(x, u))$ on M by solving (10) with $\varphi(0) = x$. Set $\mathcal{S}^x = \{\varphi(x, u) | u \in \mathcal{S}\}$. Then we have

$$\mathcal{S}(P_x) = \overline{\mathcal{S}^x} \quad \text{for every } x \in M.$$

Let \mathcal{L} be the \dagger Lie algebra generated by A_1, A_2, \dots, A_r , and set $\mathcal{L}(x) = \{V_x | V \in \mathcal{L}\}$. If $\dim \mathcal{L}(x) = n$ for every $x \in M$, then $\mathcal{S}(P_x) = W_x(M)$ for every $x \in M$. For further information \rightarrow Stroock and Varadhan (*Proc. 6th Berkeley Symp. Math. Statist. Prob.* III, 1972) and H. Kunita (*Proc. Int. Symp. Stochastic Differential Equations, Kyoto*, 1976).

Let A be a smooth \dagger nondegenerate second-order \dagger elliptic differential operator on M which is expressed in local coordinates as

$$A = \frac{1}{2} \sum_{i,j=1}^n a^{ij}(x) \frac{\partial^2}{\partial x^i \partial x^j} + \sum_{i=1}^n \bar{b}^i(x) \frac{\partial}{\partial x^i},$$

where $(a^{ij}(x))$ is symmetric and \dagger strictly positive definite. Then there exist a \dagger Riemannian metric g and a C^∞ \dagger vector field b on M such that

$$A = \frac{1}{2} \Delta_M + b, \quad (11)$$

where Δ_M is the \dagger Laplace-Beltrami operator on the \dagger Riemannian manifold (M, g) . We now construct the diffusion process generated by the operator A , introducing a stochastic differential equation on the \dagger bundle $O(M)$ of the \dagger orthonormal frames. There exists an \dagger affine connection ∇ \dagger compatible with the Riemannian metric g such that for every C^∞ -function f on M ,

$$\frac{1}{2} \sum_{k=1}^n L_k^2(f \circ \pi)(r) = \left(\frac{1}{2} \Delta_M + b \right) (f)(\pi(r)),$$

$$r \in O(M),$$

where (L_1, L_2, \dots, L_n) is the system of \dagger canonical horizontal vector fields (\dagger basic vector fields) on $O(M)$ corresponding to the affine connection ∇ and $\pi: O(M) \rightarrow M$ is the natural projection [19]. We now consider the following stochastic differential equation on $O(M)$:

$$dr_t = \sum_{k=1}^n L_k(r_t) \circ dw^k(t). \quad (12)$$

Let $r(t, r, w)$ be the solution of (12) with $r_0 = r \in O(M)$ defined on the n -dimensional Wiener space (W_0^n, P^W) . Now a stochastic curve $X(t, r, w)$ on M is defined by $X(t, r, w) = \pi(r(t, r, w))$. Set $X(t, r, w) = \partial$ for $t \geq \zeta$, where ζ is the \dagger explosion time of $r(t, r, w)$. Then the probability law of $(X(t, r, w))_{t \geq 0}$ on $\hat{W}(M)$ depends only on $x = \pi(r)$, and it defines a diffusion process \mathfrak{M} on M which is generated by the operator A of (11). (For details \rightarrow [19, 26].) When $A = \Delta_M/2$, i.e., $b = 0$ in (11), the diffusion process \mathfrak{M} is called the \dagger Brownian motion on the Riemannian manifold M (\rightarrow 45 Brownian Motion).

Next consider the case when (L_1, L_2, \dots, L_n) in (12) is a system of canonical horizontal vector fields corresponding to the \dagger Riemannian connection, and let b be a C^∞ -vector field on M . Let \tilde{b} be the scalization of b , i.e., $\tilde{b} = (\tilde{b}^1, \tilde{b}^2, \dots, \tilde{b}^n)$, $\tilde{b}^i(r) = \sum_{j=1}^n b^j(x) f_j^i$, and $(f_j^i) = (e_j^i)^{-1}$ for $r = (x, e_1, e_2, \dots, e_n) \in O(M)$, where $b = \sum_{i=1}^n b^i \partial / \partial x^i$ and $e_i = \sum_{j=1}^n e_j^i \partial / \partial x^j$ in local coordinates. Suppose that $\tilde{b}^i(r)$ is bounded on $O(M)$ for $i = 1, 2, \dots, n$. Then

$$M(t) = \exp \left[\sum_{i=1}^n \int_0^t \tilde{b}^i(r_s) dw^i(s) - \frac{1}{2} \sum_{i=1}^n \int_0^t (\tilde{b}^i(r_s))^2 ds \right]$$

is an \dagger exponential martingale. The diffusion process generated by the operator $\Delta_M/2 + b$ is obtained from the Brownian motion on M constructed above by the \dagger transformation of drift, i.e., the transformation by the \dagger multiplicative functional $M(t)$ (\rightarrow 261 Markov Processes). (G. Maruyama (*Nat. Sci. Rep. Ochanomizu Univ.*, 15 (1954)) studied this for 1-dimensional processes, I. V. Girsanov [27] and M. Motoo (*Ann. Inst. Statist. Math.*, 12 (1960–1961)) for multidimensional cases.)

Consider a diffusion process $\mathfrak{M} = \{P_x | x \in M\}$ on M generated by the operator A of (11). Let ω_b be the \dagger differential 1-form defined from the vector field b by

$$\omega_b(V)_x = g_x(b_x, V_x)$$

for every $x \in M$ and every C^∞ -vector field V on M . Then \mathfrak{M} is symmetrizable if and only if ω_b is \dagger exact, i.e., if there exists a function F on M such that $\omega_b = dF$. The \dagger invariant measures

are then of the form $\text{const.} \times \exp[2F(x)]m(dx)$, where $m(dx)$ is the \dagger Riemannian volume (E. Nelson, *Duke Math. J.*, 25 (1958); Kolmogorov, *Math. Ann.*, 113 (1937)). The diffusion process \mathfrak{M} is said to be **locally symmetrizable** if for every \dagger simply connected domain $D \subset M$ there exists a Borel measure $\nu^D(dx)$ on D such that

$$\int_D T_t^D f(x) g(x) \nu^D(dx) = \int_D f(x) T_t^D g(x) \nu^D(dx)$$

for all bounded continuous functions f and g , where

$$T_t^D f(x) = \int_{\hat{W}(M)} f(w(t)) I_{\{t | \tau_D(w) > t\}} P_x(dw),$$

$$\tau_D(w) = \inf \{t | w(t) \notin D\}.$$

Then \mathfrak{M} is locally symmetrizable if and only if ω_b is \dagger closed, i.e., $d\omega_b = 0$. R. Z. Khas'minskiĭ [28] proved a pair of useful tests for explosions of diffusion processes on $M = \mathbf{R}^n$, similar to Feller's test for $n = 1$ mentioned in Section B (\rightarrow [18]). In case of a general manifold we can investigate the possibility of explosions for \mathfrak{M} by appealing to the comparison theorems for \dagger curvatures in the theory of differential geometry [19, 29]; S. T. Yau, *J. Math. Pures Appl.*, 57 (1978)). The diffusion process \mathfrak{M} on M is said to be \dagger recurrent if $P_x[X_t \in U \text{ for some } t > 0] = 1$ for any open subset U of M ; otherwise it is called \dagger transient. It is well known that an n -dimensional Brownian motion on \mathbf{R}^n is recurrent if $n \leq 2$ and transient if $n \geq 3$ [9]. There also are some results for the criterion which determines whether \mathfrak{M} is recurrent or transient ([19, 28]; A. Friedman, *Stochastic Differential Equations and Applications* I, II, 1975, and K. Ichihara, *Publ. Res. Inst. Math. Sci.*, 14 (1978)). Explicit formulas for the transition probability of the Brownian motion on a hyperbolic space are given in [29]. For information related to the asymptotic behavior of diffusion processes as $t \downarrow 0$ we refer the reader to Varadhan (*Comm. Pure Appl. Math.*, 20 (1967)) and S. A. Molchanov (*Russian Math. Surveys*, 30 (1975)).

Diffusion approximations for suitably normalized random sequences have been studied extensively beginning with the work of A. J. Khinchin [30]. The theory of \dagger limiting distributions of sums of \dagger independent (or weakly dependent) random variables is among the best-known examples (\rightarrow 250 Limit Theorems in Probability Theory). For information related to the theory of diffusion approximations, see Yu. V. Prokhorov (*Theory of Prob. Appl.*, 1 (1956)), A. V. Skorokhod [16], and Stroock, Varadhan, and G. Papanicolaou (*Proc. 1976 Duke Turbulence Conference*). Recently, many interesting examples of multidimensional diffusion processes have also been

introduced to describe probabilistic models in physics, biology, etc. (e.g., R. L. Stratonovich, *Topics in the Theory of Random Noise* I, II, 1963; J. F. Crow and M. Kimura, *An Introduction to Population Genetics Theory*, 1970; and K. Sato, *Proc. Int. Symp. Stochastic Differential Equations*, Kyoto, 1976).

In general, if a diffusion process $\{X_t\}$ is given on a noncompact space S and X_t has no limit points in S as $t \uparrow \zeta$, then some natural compactification should be induced by $\{X_t\}$. The notion of a * Martin boundary for Markov processes is introduced in this connection.

116 (XX.2) Dimensional Analysis

The system of units for physical quantities is derived from a certain set of **fundamental units**. If the fundamental units are denoted by θ, φ, ψ , etc., any other unit α (called a **derived unit**) can always be expressed in the form $\alpha = c\theta^l\varphi^m\psi^n \dots$ (c, l, m, n, \dots are constants), by definition or by physical laws. The exponents l, m, n, \dots are called the **dimensions** of α , and the content of the previous statement is expressed as $[\alpha] = [\theta^l\varphi^m\psi^n \dots]$, which is called the **dimensional formula**. The usual practice is to take as fundamental units length, time, mass, temperature, and energy, which are denoted by L, T, M, θ , and H , respectively. **Dimensional analysis** investigates the relation between physical quantities by use of the π theorem and the law of similitude given below.

A. The π Theorem

If a relationship $f(\alpha, \beta, \dots) = 0$ holds among n physical quantities α, β, \dots independently of the choice of fundamental units, the equation $f(\alpha, \beta, \dots) = 0$ can always be transformed into $F(\pi_1, \pi_2, \dots) = 0$, where the π_i are $n - m$ dimensionless quantities (m is the number of fundamental units) of the form $\pi_i = \alpha^{a_i}\beta^{b_i} \dots$. If we choose the π_i so that $\pi_1 = \alpha\beta^{-r_1}\gamma^{-z_1} \dots$ and π_2, π_3 , etc. do not contain α , then $f = 0$ implies $\alpha = \beta^{r_1}\gamma^{z_1} \dots \Phi(\pi_2, \pi_3, \dots)$, which clearly shows the manner in which the quantity α is related to other quantities β, γ, \dots .

B. The Law of Similitude

In general, if two physical systems of the same kind have the same values of the π_i , then the physical states of the systems are similar. If we are given a family of mutually similar systems, it is sufficient to observe a particular one among them (a "model") in order to estimate physical values attached to any one of the given systems.

Consider, for example, the case of the drag D acting on geometrically similar bodies placed in the flow of a viscous incompressible fluid. If v is the velocity, l the representative length of the body, ρ the density of the fluid, and μ the viscosity (which has the dimensional formula $ML^{-1}T^{-1}$), then the π theorem gives $D/\rho v^2 l^2 = f(\rho v l / \mu)$. Hence the drag coefficient as given by the left-hand side can be obtained by the experiments performed on a geometrically similar model. The dimensionless quantity $R = \rho v l / \mu$ ($v = \mu / \rho$) is called the **Reynolds number**. If the wave resistance due to gravity

as well as the effect of compressibility are taken into account, gravitational acceleration g and sound velocity a must be included, so that we have $D/\rho v^2 l^2 = f(vl/v, v^2/lg, v/a, C_1, C_2, \dots)$, where C_1, C_2, \dots are other dimensionless quantities depending on the physical properties of the fluid. $Fr = v^2/lg$ is called the **Froude number**, and $M = v/a$ the **Mach number**.

Next, consider the case of heat transfer between a solid surface and a flowing fluid. Let the area of the solid surface be denoted by S , the heat transferred per unit time by Q (HT^{-1}), the thermal conductivity of the fluid by k ($HL^{-1}T^{-1}\theta^{-1}$), the specific heat by C ($HM^{-1}\theta^{-1}$), the two representative temperatures by T_0 and T_1 , and the representative length by l , where expressions in parentheses represent dimensional formulas. Then we have, as dimensionless quantities, the **Nusselt number** $Nu = Q/(kS(T_1 - T_0)/l)$, the **Prandtl number** $Pr = \nu/\kappa$ ($\kappa = k/\rho c$), the **Grashoff number** $Gr = d^3 g(T_1 - T_0)/\nu^2 T_0$, and R , so that from the π theorem we have the relation $Nu = f(R, Pr, Gr, C_1, C_2, \dots)$. Furthermore, $Pe = \nu l / \kappa = Pr R$ is called the **Péclet number**.

117 (II.21) Dimension Theory

A. Introduction

Toward the end of the 19th century, G. Cantor discovered that there exists a one-to-one correspondence between the set of points on a line segment and the set of points on a square; and also, G. Peano discovered the existence of a †continuous mapping from the segment onto the square. Soon, the progress of the theory of

point-set topology led to the consideration of sets which are more complicated than familiar sets, such as polygons and polyhedra. Thus it became necessary to give a precise definition to dimension, a concept which had previously been used only vaguely. In 1913, L. E. J. Brouwer [9] gave a definition of dimension based on an idea of H. Poincaré. In 1922, the foundations of dimension theory for separable metric spaces were established by K. Menger [11] and P. Uryson [10]. Subsequently, P. S. Aleksandrov and W. Hurewicz contributed much to the development of the theory. The foundations of dimension theory for general metric spaces were established independently by M. Katětov and K. Morita. More general theory for \dagger normal spaces has also been investigated; the same results as in metric spaces, however, do not always hold.

B. Definition of Dimension

Let X be a normal space. If any finite open \dagger covering of X has an open covering of \dagger order $\leq n + 1$ as its refinement (\rightarrow 425 Topological Spaces R) (i.e., if for any open sets G_i ($i = 1, \dots, s$) such that $X = G_1 \cup \dots \cup G_s$, there exist open sets H_i ($i = 1, \dots, s$) such that $H_i \subset G_i$, $X = H_1 \cup \dots \cup H_s$ and any $n + 2$ of the H_i have no point in common), then we write $\dim X \leq n$. If $\dim X \leq n$ but $\dim X \leq n - 1$ does not hold, then we define X to be n -dimensional and write $\dim X = n$. We call $\dim X$ the **covering dimension**, (or **Lebesgue dimension**) of X . The idea behind this definition is due to H. Lebesgue.

There are other definitions of *dimension* that are given inductively. Let us define $\text{Ind } X = -1$ if X is empty. If for any pair consisting of a closed set F and an open set G with $F \subset G$ in X there exists an open set V such that $F \subset V \subset G$ and $\text{Ind}(\bar{V} - V) \leq n - 1$, then we define $\text{Ind } X \leq n$. Next, we define $\text{ind } \emptyset = -1$. For any point p of X and any neighborhood G of p , suppose that there exists an open neighborhood V of p such that $V \subset G$ and $\text{ind}(\bar{V} - V) = n - 1$. Then we define $\text{ind } X \leq n$. As before, we set $\text{Ind } X = n$ ($\text{ind } X = n$) if $\text{Ind } X \leq n$ ($\text{ind } X \leq n$) but $\text{Ind } X \leq n - 1$ ($\text{ind } X \leq n - 1$) does not hold. (The definition of $\text{ind } X$ is due to Menger.) We call $\text{Ind } X$ ($\text{ind } X$) the **large inductive dimension** of X (the **small inductive dimension** of X).

If $\dim X \leq n$ does not hold for any n , then X is called **infinite-dimensional**, written $\dim X = \infty$; we define $\text{Ind } X = \infty$ and $\text{ind } X = \infty$ similarly. These dimensions are invariant under \dagger homeomorphisms.

The set of irrational points in a Euclidean

space, the \dagger Cantor discontinuum, and \dagger Baire zero-dimensional spaces are all 0-dimensional. The set of rational points in a separable \dagger Hilbert space is 1-dimensional.

C. Dimension of Metric Spaces

The following theorems hold for the dimension of metric spaces (M. Katětov, *Czechoslovak Math. J.*, 2 (1952); K. Morita, *Math. Ann.*, 128 (1954)). Let X and Y be metric spaces. The equality $\dim X = \text{Ind } X$ holds. If $Y \subset X$, then $\dim Y \leq \dim X$. If X is a union of a countable number of closed sets F_i ($i = 1, 2, \dots$), then $\dim X = \max(\dim F_i)$ (**sum theorem for dimension**). The inequality $\dim(X \cup Y) \leq \dim X + \dim Y + 1$ holds. If $\dim X = n$, then X is a union of $n + 1$ 0-dimensional subsets (**decomposition theorem for dimension**). We have $\dim(X \times Y) \leq \dim X + \dim Y$, where $X \neq \emptyset$ (**product theorem for dimension**).

Each of the following is a necessary and sufficient condition for $\dim X \leq n$: (i) There exists a subspace A of a Baire zero-dimensional space B (τ) and a continuous closed mapping f of A onto X such that $f^{-1}(x)$ consists of at most $n + 1$ points for each point x of X (K. Morita, *Sci. Rep. Tokyo Kyoiku Daigaku*, 5 (1955)); (ii) there exists a metric of X which gives the same topology on X such that for any positive number ε , any point x of X , and any $n + 2$ points x_i ($i = 1, \dots, n + 2$) at a distance less than ε from the $(\varepsilon/2)$ -neighborhood of x , there are at least two points x_i and x_j ($i \neq j$) with distance $< \varepsilon$ (J. Nagata, *Fund. Math.*, 45 (1958)).

Hurewicz's problem asked whether the equality $\dim X = n + m$ ($m > 0$) implies the existence of an m -dimensional space A and a mapping f of A onto X having property (i). It was solved affirmatively for separable metric spaces by J. H. Roberts and for general metric spaces by K. Nagami (*Japan. J. Math.*, 30 (1960)).

If X is the union of a countable number of closed \dagger strongly paracompact subspaces, in particular if X is separable, then $\text{Ind } X = \text{ind } X$ [1, 2]. However, it was shown by P. Roy (*Bull. Amer. Math. Soc.*, 68 (1962)) that this equality does not hold in general.

D. Euclidean Spaces and Dimension

The n -dimensional \dagger Euclidean space \mathbf{R}^n is exactly n -dimensional in the sense mentioned above; thus this concept of dimension agrees with our intuition. The proof of $\dim \mathbf{R}^n \geq n$ comes from **Lebesgue's theorem**: If each member of a finite closed covering of an n -cube has

sufficiently small diameter, then the order of the covering is not less than $n + 1$. (The proof of $\dim \mathbf{R}^n \leq n$ is easy.) Let X be a subset of \mathbf{R}^n and f a homeomorphism from X onto a subset $f(X)$ of \mathbf{R}^n . If x is an interior point of X , then $f(x)$ is an interior point of $f(X)$. Also, if an open set A of \mathbf{R}^n is homeomorphic to a subset B of \mathbf{R}^n , then B is open in \mathbf{R}^n (**Brouwer's theorem on the invariance of domain** [8]).

This theorem holds for any manifold but not for general separable metric spaces. By the theorem of invariance of domain it can be shown that \mathbf{R}^m and \mathbf{R}^n , $m \neq n$, are not homeomorphic (**theorem on invariance of dimension of Euclidean spaces**). Any n -dimensional separable metric space is embedded in a Euclidean space \mathbf{R}^{2n+1} , or, more precisely, in the subset of \mathbf{R}^{2n+1} consisting of all points x of which at most n coordinates are rational (**Menger-Nöbeling embedding theorem**, G. Nöbeling, *Math. Ann.*, 104 (1930)). Thus, from the topological point of view, any finite-dimensional separable metric space can be identified with a subset of a Euclidean space. Moreover, it is known that any n -dimensional separable metric space is homeomorphic to a subset of some n -dimensional compact metric space.

If F is a bounded closed subset of \mathbf{R}^m , then $\dim F \leq n$ if and only if for any positive number ε , there exists a continuous mapping f from F into an n -dimensional polyhedron in \mathbf{R}^m such that the distance between x and $f(x)$ is less than ε for each point x of F .

E. Dimension of Normal Spaces

Let X be a normal space. Then $\text{Ind } X \geq \dim X$ and $\text{Ind } X \geq \text{ind } X$, but the equalities do not necessarily hold here. The following theorems were obtained by E. Čech, Aleksandrov, C. H. Dowker, E. Hemmingsen, and Morita [1]. If $\dim X \leq n$, then any locally finite open covering of X has an open covering of order $\leq n + 1$ as its refinement; if A is an ${}^{\dagger}F_{\sigma}$ subset of X or A is strongly paracompact, then $\dim A \leq \dim X$; if X has a ${}^{\dagger}\sigma$ -locally finite closed covering $\{F_{\alpha}\}$, then $\dim X = \max(\dim F_{\alpha})$.

In order that $\dim X \leq n$, it is necessary and sufficient that any continuous mapping from a closed subset of X into an n -sphere S^n can be extended continuously to X . If X and Y are † paracompact and X is † locally compact, or if $X \times Y$ is strongly paracompact, then $\dim(X \times Y) \leq \dim X + \dim Y$, where $X \neq \emptyset$; if X is a † CW complex, then the equality holds [14]. M. L. Wage (*Proc. Nat. Acad. Sci. US*, 75 (1978)) proved under the continuum hypothesis (CH) that $\dim(X \times Y) \leq \dim X + \dim Y$

does not hold in general even if $X \times Y$ is locally compact and normal, and $\dim X = \dim Y = 0$; T. Przymusiński (*Proc. Amer. Math. Soc.*, 76 (1979)) noted that CH can be avoided by a modification of Wage's construction. Katětov (*Časopis Pěst. Mat. Fys.*, 75 (1950)) proved that $\dim X$ is determined by the ring $C^*(X)$ of bounded real-valued continuous functions on X .

F. Homological Dimension

Aleksandrov contributed much to the development of dimension theory in introducing the concept of homological dimension (*Math. Ann.*, 106 (1932)). The **homological dimension** of a compact Hausdorff space X with respect to an Abelian group G is the largest integer n such that the n -dimensional † Čech homology group $\check{H}_n(X, A; G)$ is nonzero for some closed subset A of X . The **cohomological dimension** $D(X; G)$ is defined similarly by using the † Čech cohomology group $\check{H}^n(X, A; G)$. If $\dim X < \infty$, then $\dim X = D(X; \mathbf{Z})$ (\mathbf{Z} is the additive group of integers). The cohomological dimension of X with respect to an arbitrary Abelian group is determined by the cohomological dimension with respect to some specified groups, and the cohomological dimension of the product space $X \times Y$ is expressed in terms of those of X and Y (M. F. Bokshtein, [5]). A compact Hausdorff space X has the property that $\dim(X \times Y) = \dim X + \dim Y$ for any compact Hausdorff space Y if and only if $\dim X = D(X; \mathbf{Q}(p))$, where $\mathbf{Q}(p)$ is the additive group of rationals mod 1 of the form m/p^s for any prime number p (V. Boltyanskiĭ, [5]); this result holds also when X is paracompact (Y. Kodama, *J. Math. Soc. Japan*, 18 (1966)).

G. Dimension and Measure

Let X be a separable metric space. Then $\dim X \leq n$ if and only if X is homeomorphic to a subset of a Euclidean space \mathbf{R}^{2n+1} whose $(n+1)$ -dimensional † Hausdorff measure is 0 (E. Szpilrajn, *Fund. Math.*, 28 (1937); also — [1, 2]). The infimum of $\alpha \geq 0$ such that the Hausdorff measure $\Lambda_{\alpha}(X)$ of dimension α vanishes is called the **Hausdorff dimension** of X .

H. Dimension Type (Fréchet's Definition)

In analogy to the theory of † cardinal numbers in set theory, M. Fréchet (1909) defined the dimension type of topological spaces as fol-

lows: Two spaces X and Y are said to have the same **dimension type** if X is homeomorphic to a subset of Y and Y is homeomorphic to a subset of X .

I. Infinite-Dimensional Spaces

If X is a metric space with $0 < \dim X < \infty$, then for each positive integer m with $m \leq \dim X$, X contains a (closed) subset S with $\dim S = m$. Tumarkin asked the following question: For an infinite-dimensional compact metric space X and for each positive integer m , does X contain a closed subset S with $\dim S = m$? D. Henderson (*Amer. J. Math.*, 89 (1967)) answered this question in the negative. Furthermore, J. Walsh (*Bull. Amer. Math. Soc.*, 84 (1978)) constructed an infinite-dimensional compact metric space X such that if S is an arbitrary subset of X with $\dim S > 0$ then $\dim S = \infty$.

118 (V.9) Diophantine Equations

A. General Remarks

A **Diophantine equation** is an [†]algebraic equation whose coefficients lie in the ring \mathbf{Z} of rational integers and whose solutions are sought in that ring. The name comes from Diophantus, an Alexandrian mathematician of the third century A.D., who proposed many Diophantine problems; but such equations have a very long history, extending back to ancient Egypt, Babylonia, and Greece. As early as the sixth century B.C., Pythagoras is said to have partially solved the equation $x^2 + y^2 = z^2$ by $x = 2n + 1$, $y = 2n^2 + 2n$, $z = y + 1$. A general solution is given by the Pythagorean numbers $x = m^2 - n^2$, $y = 2mn$, $z = m^2 + n^2$.

[†]Fermat's problem also concerns a Diophantine equation.

Systematic studies of Diophantine equations over \mathbf{Z} have been made for the linear equation $\sum_{i=1}^n a_i x_i = a$ ($a_i, a \in \mathbf{Z}$) and for the quadratic equation $ax^2 + bxy + cy^2 = k$ ($a, b, c, k \in \mathbf{Z}$) in two unknowns. The latter forms a principal topic of C. F. Gauss's *Disquisitiones arithmeticae* and can be regarded as a starting point of modern algebraic number theory. The special quadratic equation $t^2 - Du^2 = \pm 4$ ($D \in \mathbf{Z}$) is called **Pell's equation**. If $D < 0$, then Pell's equation has only a finite number of solutions. If $D > 0$, then all solutions t_n, u_n of Pell's equation are given by $\pm((t_1 + u_1\sqrt{D})/2)^n = (t_n + u_n\sqrt{D})/2$, provided that the pair t_1, u_1 is a solution with the smallest $t_1 + u_1\sqrt{D} > 1$ [15]. Using continued fractions (\rightarrow 83 Continued Fractions), we can determine t_1, u_1 explicitly. A general quadratic Diophantine equation $ax^2 + bxy + cy^2 = k$ with two unknowns can be solved completely if we use solutions of Pell's equation; this is an application of the arithmetic of quadratic fields (\rightarrow 347 Quadratic Fields) [1]. On quadratic Diophantine equations of several unknowns, there are deep studies by C. L. Siegel (\rightarrow 348 Quadratic Forms).

Diophantine problems consist of giving criteria for the existence of solutions of algebraic equations in rings and fields and eventually determining the number of such solutions. The fundamental ring of interest is \mathbf{Z} and the fundamental field of interest is \mathbf{Q} . One discovers rapidly, however, that to have all the technical maneuverability necessary for handling general problems, one must consider rings and fields of finite type over \mathbf{Z} and \mathbf{Q} . Furthermore, one is led to consider finite fields and local fields when one deals with a localization of the problems under consideration.

Techniques from various fields of mathematics, e.g., algebraic number theory, algebraic geometry, analysis, Diophantine approximation, etc., have been successfully applied to solve Diophantine problems. However, much remains unsolved today. Yu. V. Matiyasevich (1970) showed that Hilbert's tenth problem is unsolvable; there is no general method of telling whether a Diophantine equation has a solution. This theorem in a sense indicates the complexity of Diophantine problems. For many centuries, no other topic has engaged the attentions of so many mathematicians, both professional and amateur, or resulted in so many published papers. For these miscellaneous results — Dickson [1] and Mordell [2].

B. Equations over Finite Fields

Let k be a finite field of characteristic p consisting of q ($= p^f$) elements. **Chevalley's theorem:** Let f be a \dagger form of degree d in n variables with coefficients in k such that $d < n$. Then $f=0$ has a nontrivial solution in k . A generalization is **Warning's theorem:** Let f_1, \dots, f_t be polynomials with coefficients in k in n variables of degrees d_1, \dots, d_t , respectively, and suppose that $d = d_1 + \dots + d_t < n$. Then the number N of common zeros of f_1, \dots, f_t satisfies $N \equiv 0 \pmod{p}$. **Warning's second theorem** asserts that if $N > 0$ then $N \geq q^{n-d}$. Warning's theorem was also improved by J. Ax (1964) to the effect that $N \equiv 0 \pmod{q^b}$ for any integer $b < n/d$ [3]. For equations over finite fields, counting the number of solutions is important. Let $f(x, y)$ be an \dagger absolutely irreducible polynomial in x and y over k . Let N denote the number of zeros in k of $f(x, y)$. A. Weil proved $|N - q| \leq 2g\sqrt{q} + c(d)$, where g is the genus of the curve $f(x, y) = 0$ and $c(d)$ is a constant depending on d . Weil's proof requires the use of deep results from algebraic geometry. This theorem is equivalent to the \dagger Riemann hypothesis for algebraic curves over finite fields [4]. Later, using Stepanov's method, W. M. Schmidt and E. Bombieri (1973) independently gave new proofs which do not depend on algebraic geometry [3]. P. Deligne [5] proved a far-reaching generalization of Weil's theorem to \dagger nonsingular absolutely irreducible equations in n variables. He showed $|N - q^{n-1}| = O(q^{(n-1)/2})$. This is a part of the \dagger Weil conjecture for zeta functions of algebraic varieties over finite fields (\rightarrow Section E; 450 Zeta Functions Q). Schmidt obtained in an elementary manner a weaker estimate $|N - q^{n-1}| = O(q^{n-3/2})$ but without the assumption of nonsingularity (\rightarrow Section F).

C. Equations over Local Fields

A method of solving problems in number theory by use of embeddings of the ground field into its \dagger completions is called a local method. Such methods have important consequences when applied to Diophantine equations. Let f be a polynomial in n variables with rational integer coefficients. The congruence $f \equiv 0 \pmod{p^k}$ is solvable for all $k \geq 1$ if and only if $f = 0$ is solvable in $\dagger p$ -adic integers. This is an easy consequence of the compactness of the ring of p -adic integers. We can solve $f = 0$ in p -adic integers provided that we can solve an infinite sequence of congruences. It is generally difficult to tell when we may limit our consideration to only a finite number of these. In this respect, the following lemma is most useful. **Hensel's lemma:** Let $f(x_1, \dots, x_n)$ be a polynomial whose coefficients are p -adic integers. Let $\gamma_1, \dots, \gamma_n$ be p -adic integers such that for some i ($1 \leq i \leq n$) and an integer $\delta \geq 0$, we have $f(\gamma_1, \dots, \gamma_n) \equiv 0 \pmod{p^{2\delta+1}}$ and $\partial f / \partial x_i(\gamma_1, \dots, \gamma_n) \equiv 0 \pmod{p^\delta}$, $\not\equiv 0 \pmod{p^{\delta+1}}$. Then there exist p -adic integers $\theta_1, \dots, \theta_n$, such that $f(\theta_1, \dots, \theta_n) = 0$ and $\theta_i \equiv \gamma_i \pmod{p^{\delta+1}}$ for $i = 1, \dots, n$. The case $\delta = 0$ is often useful; it implies that a nonsingular solution mod p can be extended to a p -adic solution. Generalization to simultaneous equations is also known [6]. Skolem's method is sometimes useful when we investigate certain types of equations over \dagger local fields. This method is based on some simple properties of local analytic manifolds over local fields [7]. If a quadratic form has zeros in each local field, then it has a rational zero (\dagger Minkowski-Hasse theorem). When a theorem of this type holds, we say that the \dagger Hasse principle holds (\rightarrow 348 Quadratic Forms). For forms of higher degree, the Hasse principle no longer holds even if the forms are absolutely irreducible and nonsingular. Counterexamples were first found for cubic (E. S. Selmer, 1951) and quintic (M. Fujiwara, 1972) forms. Asymptotic formulas in Waring's problem (\rightarrow 4 Additive Number Theory E) can be regarded as an analytic form of the Hasse principle. As to the quantitative formulation of the Hasse principle, there are deep results of Siegel for quadratic forms and their generalization by T. Tamagawa. R. Brauer (1945) showed that forms in sufficiently many variables represent zero in all p -adic fields. Forms of odd degree represent zero in the field of rational numbers if the number of variables is sufficiently large compared with the degree (B. J. Birch, 1957). Let f be a polynomial with p -adic integer coefficients and c_m ($m \geq 0$) be the number of solutions to the congruence $f \equiv 0 \pmod{p^m}$. The series $\varphi(t) = \sum_{m=0}^{\infty} c_m t^m$ is called the Poincaré series of f .

Diophantine Equations

J. Igusa (1975) proved, by using his theory of asymptotic expansions together with Hiro-naka's †resolution theorem, that $\varphi(t)$ is a rational function of t [8].

D. Integral Solutions of Some Diophantine Equations

In this section we are concerned with those equations for which some "theory" exists. For isolated results \rightarrow [1, 2].

(1) Binary Forms. Thue's theorem (1908): If $f(x) = \sum_{v=0}^n a_v x^v$ ($a_v \in \mathbb{Z}, n > 2$) has distinct roots, then the number of rational integral solutions of $\sum_{v=0}^n a_v x^v y^{n-v} = a$ ($\mathbb{Z} \ni a \neq 0$) is finite. This theorem is a direct consequence of Thue's theorem on Diophantine approximation, which says that there are only a finite number of rational numbers p/q ($p, q \in \mathbb{Z}, q > 0$) with $|\alpha - p/q| < 1/q^{(n/2)+1}$ for a given algebraic number α of degree n ($n > 2$) [9, p. 122]. K. F. Roth proved that $(n/2) + 1$ in this formula can be replaced by $2 + \varepsilon$ (ε is an arbitrary positive number independent of n) (*Mathematika*, 2 (1955), 1–20). **Roth's theorem** was generalized to some cases of number fields and function fields (\rightarrow 182 Geometry of Numbers) and is applied to Diophantine equations [9, 10]. A. Baker (1968), using a completely different method, has given explicit upper bounds for the solutions of Thue's equations, thus enabling one to compute effectively all the solutions. More precisely, if f in Thue's equation is irreducible over the rationals, then every integer solution (x, y) of the equation satisfies $\max(|x|, |y|) < \exp((nH)^{(10n)^5} + (\log a)^{2n+2})$, where H is the †height of f . The proof of this remarkable theorem is based on his deep result concerning the lower bound for the linear forms in the logarithm of algebraic numbers (*Mathematica*, 13 (1966); 14 (1967)). Baker's method has been applied to elliptic, hyperelliptic, and other curves (Baker, H. Stark, J. Coates, V. G. Sprindzhuk, etc.).

(2) Higher-Degree Forms. A natural generalization of binary forms is a **norm form**. Let K be an algebraic number field of degree $t \geq 3$ and $\alpha_1, \dots, \alpha_n$ be elements of K . Then the norm $N(\alpha_1 x_1 + \dots + \alpha_n x_n) = \prod_{i=1}^t (\alpha_1^{(i)} x_1 + \dots + \alpha_n^{(i)} x_n)$, where $\alpha^{(i)}$ denotes a conjugate of α , is a form of degree t with rational coefficients. It is easy to see that every form which has rational coefficients and is irreducible over \mathbb{Q} but which is a product of linear forms with algebraic coefficients is a constant multiple of a norm form [7]. A module M in an algebraic number field K is called **degenerate** if M has a submodule N such that, for some $\alpha \in K$, αN is a full module

in some subfield K' of K , where K' is neither \mathbb{Q} nor an imaginary quadratic field. The most basic in the theory of norm forms is (W. M.) **Schmidt's theorem**: Let $\alpha_1, \dots, \alpha_n$ be linearly independent over \mathbb{Q} and suppose that the module generated by $\alpha_1, \dots, \alpha_n$ is nondegenerate; then $N(\alpha_1 x_1 + \dots + \alpha_n x_n) = c$ ($c \in \mathbb{Q}$) has only finitely many solutions in integers x_1, \dots, x_n . (*Math. Ann.*, 191 (1971)). The proof is based on his remarkable result on †simultaneous approximation which generalizes Roth's theorem (\rightarrow 182 Geometry of Numbers G). There are investigations on special norm forms (T. Skolem, N. I. Fel'dman, K. Ramanathan, K. Györy, M. Fujiwara, etc.). For general forms of higher degree, not much is yet known except for the additive forms (\rightarrow 4 Additive Number Theory E). H. Davenport [11] proved that if $f(x)$ is a cubic form with rational integer coefficients in n variables, then $f(x) = 0$ has a nontrivial integral solution, provided that $n \geq 16$. This theorem was proved by means of an exquisite application of the †circle method together with some geometry of numbers. A well-known conjecture is that $n \geq 10$ instead of $n \geq 16$. It is known that over local fields, any cubic form in 10 variables has a nontrivial zero. There are various results of this type for simultaneous additive, quadratic, and cubic forms (Davenport, D. Lewis, R. Cook, Schmidt, etc.) [17]. A satisfactory theory of forms of higher degree, like that of quadratic forms, is not yet known but is quite desirable. In this vein, Igusa has obtained some new results of considerable interest, e.g., a †Poisson summation formula for higher-degree forms, using his theory of asymptotic expansions [8].

(3) Algebraic Curves. The fundamental result is **Siegel's theorem** (1929): Assume that the equations $f_i(X_1, \dots, X_n) = 0$ ($1 \leq i \leq m$) determine an algebraic curve with a positive †genus in an †affine space of dimension n . Then the number of rational integral solutions of $f_i(X_1, \dots, X_n) = 0$ ($1 \leq i \leq m$) is finite. This theorem was generalized by S. Lang in the following form: Let K be a finitely generated field over \mathbb{Q} and I a subring of K that is finitely generated over \mathbb{Z} . Furthermore, let C be a nonsingular projective algebraic curve with a positive genus defined over K , and let φ be a rational function on C defined over K . Then there are only a finite number of points P on C with $\varphi(P) \in I$ [10]. The proof of this theorem is based on a generalization of Roth's theorem in the above sense and on the weak Mordell-Weil theorem (\rightarrow Section C). A. Robinson and P. Roquette gave another approach to Siegel's theorem from the standpoint of nonstandard arithmetic (*J. Number Theory* 7 (1975)). On the other hand, a necessary condition for the exis-

tence of infinitely many solutions of $f(X, Y) = 0$ with rational integral coefficients was given by C. Runge (*J. Reine Angew. Math.*, 100 (1887)).

(4) Elliptic Curves. An elliptic curve E is an \dagger Abelian variety of dimension 1, or what is the same, an irreducible nonsingular \dagger projective algebraic curve of \dagger genus 1 furnished with a point O as origin. The \dagger Riemann-Roch theorem defines a group law on the set of \dagger divisor classes of E . Actually, if P, P' are points of E , then there exists a unique point P'' such that $(P) + (P') \sim (P'') + (O)$, where \sim means linear equivalence, i.e., the left-hand side minus the right-hand side is the divisor of a rational function on the curve. The group law on E is then defined by $P + P' = P''$. If the characteristic $\neq 2$ or 3, using the Riemann-Roch theorem one finds that the curve E can be defined by a Weierstrass equation $y^2 = x^3 + ax + b$ with a, b in the ground field over which the curve is defined. Conversely, any homogeneous nonsingular cubic equation has genus 1 and defines an elliptic curve in the projective plane once the origin has been selected. If both the curve and the origin are defined over a field k , then the group law is also defined over k , and it becomes a 1-dimensional Abelian variety defined over k . If the ground field k is the field of complex numbers, the group law is the same as that given by the \dagger addition theorem of the \dagger Weierstrass \wp -function with invariants $g_2 = -4a$ and $g_3 = -4b$ through the parametrization $x = \wp(u)$, $y = \frac{1}{2}\wp'(u)$. Much of the Diophantine theorems on elliptic curves are generalized to Abelian varieties. Here we shall deal mainly with elliptic curves defined by Weierstrass equations over \mathbf{Q} . Extension to algebraic number fields usually causes no trouble. For more general elliptic curves \rightarrow [19]. The Lutz-Mattuck theorem (\rightarrow Section E) obviously implies that the points of finite order in E_k ($k = \mathbf{Q}_p$) form a finite group. This torsion group is computable. In case a and b are in \mathbf{Z} then any point of finite order in E_0 has coordinates (x, y) in \mathbf{Z} and, if $y \neq 0$, $y^2 \mid 4a^3 + 27b^2$ (Lutz-Nagell). The **WC group** (Weil-Châtelet group) of E over k is the birational class of principal homogeneous spaces over k . The extent of validity of the Hasse principle for elliptic curves can be measured by the **Tate-Shafarevich group**, which is defined as the set of elements of the WC group that are everywhere locally trivial. This group is conjectured to be a finite group. For other results and interesting conjectures \rightarrow [12–14]. The number of integral points on elliptic curves is finite according to Siegel's theorem on algebraic curves. Explicit bounds for the size of these points have been given for several types of

elliptic curves by using Baker's method. For example, if $f(x, y)$ is an absolutely irreducible polynomial with coefficients in \mathbf{Z} such that the curve $f = 0$ has genus 1, then $\max(|x|, |y|) < \exp \exp \exp((2H)^m)$, where $m = 10^{d^{10}}$, $d = \deg f$, and H is the height of f (Baker and Coates, 1970. The method of proof was to reduce it to the Weierstrass equation case, which had been treated earlier by Baker, with a better bound.) By the \dagger Mordell-Weil theorem (\rightarrow Section E), $A_{\mathbf{Q}} \cong \mathbf{Z}^r \times$ finite torsion group. Here r is called the **rank** of E over \mathbf{Q} . There is a rather doubtful conjecture to the effect that the rank r is bounded. The rank r is conjectured to be equal to the order of the zero of $L(s, E)$ at $s = 1$ (**Birch-Swinnerton-Dyer conjecture**). Much numerical and theoretical evidence supports this famous conjecture [13].

E. Rational Points of Algebraic Varieties

Let V be an \dagger abstract algebraic variety defined over a field k , and let P be a point of V . Then P is called a **rational point** over k of V if the coordinates of the \dagger representative P_α contained in an \dagger affine open set V_α of V are in k (\rightarrow 16 Algebraic Varieties D). This definition is independent of the choice of the representative P_α . In particular, if V is a \dagger projective variety, the point P given by the \dagger homogeneous coordinates (x_0, x_1, \dots, x_n) is rational if and only if $x_i/x_p \in k$ ($0 \leq i \leq n$, $x_p \neq 0$). In the following we state main results concerning rational points of algebraic varieties, especially results concerning \dagger Abelian varieties, restricting k to be either an \dagger algebraic number field of finite degree, a \dagger p-adic number field, or a \dagger finite field.

Mordell-Weil Theorem. Let A be an Abelian variety of dimension n defined over an algebraic number field k of finite degree. Then the group A_k of all k -rational points on A is finitely generated. This theorem was proved by L. J. Mordell (1922) for the case of $n = 1$ and by Weil (1928) for the general case [10]. The assertion that A_k/mA_k is a finite group for any rational integer m is called the **weak Mordell-Weil theorem**; this theorem is basic in the proof of the Mordell-Weil theorem and is used in the proof of Siegel's theorem, too. A generalization of the Mordell-Weil theorem is obtained when k is a field (of arbitrary characteristic) finitely generated over the \dagger prime field [10].

If A is defined over a finite algebraic number field k , we have the following conjectures of Birch, Swinnerton-Dyer, and Tate on the rank of A_k . Let \mathfrak{p} be a prime ideal of k at which A has a good \dagger reduction, and denote by $A_{\mathfrak{p}}$ the reduced variety. Let $\pi_{\mathfrak{p}}^{(1)}, \dots, \pi_{\mathfrak{p}}^{(2n)}$ be the eigen-

values of the $N(p)$ th power endomorphism of A_p with respect to an l -adic representation, where $N(p)$ denotes the norm of p (\rightarrow 3 Abelian Varieties E, N), and put $L_p(s, A) = \prod_{i=1}^{2n} (1 - \pi_p^{(i)} N(p)^{-s})^{-1}$. The L -function of A defined by $L(s, A) = \prod' L_p(s, A)$, where the product ranges over all good primes, is the principal part of the zeta function of A (\rightarrow 450 Zeta Functions S). Birch and Swinnerton-Dyer conjectured that if $k = \mathbf{Q}$ and A is of dimension 1, then there exists a constant $C \neq 0$ such that $L(s, A) \sim C(s-1)^g$ as $s \rightarrow 1$. Tate generalized this conjecture to any A and k . Moreover, the constant C , appropriately modified by factors corresponding to the bad primes and the infinite primes, is thought to be expressible in terms of certain arithmetic invariants of A [13].

Lutz-Mattuck Theorem. The group of rational points of an Abelian variety A of dimension n over a p -adic number field k contains a subgroup of finite index isomorphic to the direct sum of n copies of the p -adic integers in k (E. Lutz, *J. Reine Angew. Math.*, 177 (1937); A. Mattuck, *Ann. Math.*, 62 (1955)).

Mordell's Conjecture. In his 1922 paper, in which the above theorem on the set of rational fields on 1-dimensional Abelian varieties (i.e., on elliptic curves) was established, Mordell stated the conjecture: Any algebraic curve of genus $g \geq 2$ defined over \mathbf{Q} has only a finite number of rational points. The same can be conjectured for such curves defined over any algebraic number field k of finite degree. This had remained as a conjecture until 1983. In 1961 I. R. Shafarevich conjectured: Let k be any algebraic number field of finite degree, S a finite set of finite prime spots of k , and g any natural number ≥ 2 . Then there are, up to k -isomorphism, only a finite number of non-singular algebraic curves of genus g defined over k having good reduction at every finite prime spot outside S .

In 1973, A. N. Parshin showed that Mordell's conjecture followed from this conjecture, which was finally proved in 1983 by G. Faltings [7]. Mordell's conjecture was thus settled in the affirmative. Analogs of these conjectures on algebraic function fields over finite fields are easier than the original ones and had been proved in the 1960s for Mordell's conjecture by Yu. I. Manin, H. Grauert, and M. Miwa, and for Shafarevich's conjecture by S. Alakelov, A. N. Parshin, and L. Szpiro.

F. C_i -Fields

Let F be a field, and let $i \geq 0$, $d \geq 1$ be integers. Let f be a homogeneous polynomial of n variables of degree d with coefficients

in F . If the equation $f=0$ has a solution $(x_1, \dots, x_n) \neq (0, \dots, 0)$ in F for any f with $n > d^i$, then F is called a $C_i(d)$ -field. If F is a $C_i(d)$ -field for any $d \geq 1$, then F is called a C_i -field. In order for F to be a C_0 -field, it is necessary and sufficient that F be an $\bar{\mathbf{A}}$ -algebraically closed field. A C_1 -field is sometimes called a **quasi-algebraically closed field**. There exists no non-commutative algebra over a C_1 -field F . A finite field is C_1 (C. Chevalley (1936)). If F_0 is algebraically closed, then $F = F_0(X)$ (rational function field of one variable) is a C_1 -field (**Tsen's theorem**). A homogeneous polynomial f of $n = d^i$ variables of degree d with coefficients in F such that $f=0$ has no solution in F except $(0, \dots, 0)$ is called a **normic form** of order i in F . If a C_i -field F_0 has at least one normic form of order i , then (i) $F_0(X_1, \dots, X_k)$ is a C_{i+k} -field; and (ii) an extension of F_0 of finite degree is a C_i -field. A complete field F with respect to an $\bar{\mathbf{A}}$ -exponential valuation is a C_1 -field whenever its residue field F_0 is algebraically closed. The field F of power series of one variable over a finite field F_0 is a C_2 -field (Lang). E. Artin conjectured that a p -adic field \mathbf{Q}_p is a C_2 -field. It was proved by H. Hasse (1923) that \mathbf{Q}_p is a $C_2(2)$ -field and by D. Lewis (1952) that \mathbf{Q}_p is a $C_2(3)$ -field. However, G. Terjanian (1966) [17] gave a counterexample to Artin's conjecture; that is, he gave a quartic form of 18 variables with coefficients in \mathbf{Q}_2 having only trivial zero in \mathbf{Q}_2 . Ax and S. Kochen (1965) [18] proved that for any integer $d \geq 1$ there exists an integer $p_0(d)$ such that \mathbf{Q}_p is a $C_2(d)$ -field for $p > p_0(d)$ (\rightarrow 276 Model Theory E).

119 (XXI.20) Dirichlet, Peter Gustav Lejeune

Peter Gustav Lejeune Dirichlet (February 13, 1805–May 5, 1859) was born of a French family in Düren, Germany. From 1822 to 1827 he was in Paris, where he became a friend of J.-B. Fourier. In 1827, he was appointed lecturer at the University of Breslau; in 1829, lecturer at the University of Berlin; and in 1839, professor at the University of Berlin. In 1855, he was invited to succeed C. F. Gauss at the University of Göttingen, where he spent his last four years as a professor.

His works cover many aspects of mathematics; however, those on number theory, analysis, and potential theory are the most famous. He greatly admired Gauss and is said to have kept Gauss's *Disquisitiones arithmeticae* at his side even when traveling.

In number theory, he created the Dirichlet series and proved that a sequence in arithmetic progression contains infinitely many prime numbers, provided that the first term and the common difference are relatively prime. Also, using his “drawer principle,” which states that if there are $n + 1$ objects in n drawers then at least one drawer contains at least 2 objects, he clarified the structure of unit groups of algebraic

120 A Dirichlet Problem

braic number fields. In potential theory he dealt with the Dirichlet problem concerning the existence of harmonic functions. He also gave Dirichlet's condition for the convergence of trigonometric series.

120 (X.30) Dirichlet Problem

A. The Classical Dirichlet Problem

Let D be a bounded or unbounded domain in \mathbf{R}^n ($n \geq 2$) with compact boundary S . The classical **Dirichlet problem** is the problem of finding a harmonic function in D that assumes the values of a prescribed continuous function on S . This problem is also called the first boundary value problem (\rightarrow 193 Harmonic Functions and Subharmonic Functions). In this article f always stands for a boundary function given on S . The problem is called an **interior problem** if D is bounded and an **exterior problem** if D is unbounded. In an exterior problem, it is further required that when an inversion with center at an exterior point P_0 of D is performed on D and a Kelvin transformation is performed on the solution in D (when the solution exists), the function thus obtained on the inverted image of D be harmonic at P_0 ($n \geq 3$). When $n = 2$, the solution in D , which is already regarded as a function on the inverted image of D , is required to be harmonic at P_0 . Thus an interior problem can be transformed to an exterior problem, and vice versa. We now explain the history of the classical problem.

Let D be a bounded domain with boundary S in \mathbf{R}^3 . G. Green (1828) asserted that if S is sufficiently smooth,

$$u(P) = -\frac{1}{4\pi} \int_S f(Q) \frac{\partial G(P, Q)}{\partial n_Q} d\sigma(Q) \quad (1)$$

is the solution for the Dirichlet problem, where f is prescribed on S , $G(P, Q)$ is Green's function with the pole at Q in D , n_Q is the outward-drawn normal to S at Q , and $d\sigma$ is the surface

face element on S . He took for granted the existence of Green's function from physical consideration of the problem. Thus his discussion was not quite rigorous. This defect was corrected by A. M. Lyapunov (1898) under a certain condition on S . Denote by u_m the Newtonian potential of a measure with density $m \geq 0$ on S . Assume that a continuous function f on S and a positive constant a are given. In 1840, C. F. Gauss investigated the existence of a density $m_f \geq 0$ on S of total mass a which satisfies $\int_S (u_{m_f} - 2f)m_f d\sigma = \min_m \int_S (u_m - 2f)m d\sigma$, where the total mass of m is equal to a . He asserted also that $u_{m_f} - f$ is equal to a constant b on S . If $f \equiv 0$, then u_{m_0} must be equal to a positive constant c on S , and hence $u_{m_f} - bc^{-1}u_{m_0}$ must be a solution of the exterior problem for the boundary function f on S . However, his discussion was incomplete because we cannot always ensure the existence of a density that gives a measure minimizing the integral. Moreover, even in the case where D is a ball, there exists a continuous function $f \geq 0$ on S such that there is no Newtonian potential that is equal to f on S up to a constant (M. Ohtsuka, 1961). Gauss (1840), W. Thomson (Lord Kelvin) (1847), and G. L. Dirichlet solved the Dirichlet problem by making use of the so-called **Dirichlet principle**, which is explained in detail in Section F. After K. Weierstrass (1870) pointed out that there is a case where no minimizing function exists, D. Hilbert (1899) gave a rigorous proof of the Dirichlet principle under a certain condition. Meanwhile, C. G. Neumann (1870) solved the Dirichlet problem rigorously for the first time, although he assumed that D is a convex domain with a smooth boundary. First, he considered the potential $W_1 = (1/2\pi) \cdot \int_S f(\partial r^{-1}/\partial n) d\sigma$ of a double layer in D ; then he formed the potential $W_2 = (1/2\pi) \cdot \int_S f_1(\partial r^{-1}/\partial n) d\sigma$ of a double layer with the values f_1 of W_1 on S and defined W_3, W_4, \dots similarly. The series $W_1 - W_2 + W_3 - W_4 + \dots$ plus a suitable constant gives a solution to the exterior Dirichlet problem for the boundary function f . In 1887, H. Poincaré also used (1) to solve the Dirichlet problem. He obtained Green's function with the pole at O in a bounded domain D in the following manner: Let D' be the image of D by an inversion with center O , S_0 be a spherical surface surrounding the boundary $\partial D'$ of D' , and μ be a uniform measure on S_0 such that the potential of μ is equal to 1 inside S_0 . By "sweeping out μ to $\partial D'$ ", the solution in D' of the exterior problem for the boundary function 1 is obtained. A ^{*}Kelvin transformation of this solution yields the solution h in D of the interior problem for the boundary function $1/OP$. Now $1/OP - h(P)$ is Green's function in D . In 1899

Poincaré used another method (without utilizing (1)) to solve the Dirichlet problem [8]. He observed that it is sufficient to consider the case where f is equal to the restriction to S of a polynomial g and that g is expressed in D as the sum of the Newtonian potential of a signed measure τ with density $-\Delta g/(4\pi)$ and a function that is harmonic in D and continuous on $D \cup S$. If it is possible to sweep out τ to ∂D , then the solution is obtained. He showed that this is in fact the case if at every point P of S there exists a cone that is disjoint from D and has its vertex at P . This condition is called **Poincaré's condition**. In 1900, I. Fredholm discussed the Dirichlet problem by reducing it to a problem of integral equations. A domain D is called a **Dirichlet domain** if the (classical) Dirichlet problem is always solvable in D . H. Lebesgue (1912) showed that a solution is obtained by the method of iterative averaging in every Dirichlet domain.

B. The Dirichlet Problem in a General Domain

It has been believed that the classical Dirichlet problem is always solvable in every domain until S. Zaremba observed in 1909 that the problem is not always solvable for a punctured ball. In 1913, Lebesgue gave a decisive example in which the domain is homeomorphic to a ball and bounded by a surface sufficiently smooth except at one point. Thus the central interest shifted to finding a harmonic function in D that depends only on a continuous function f given on ∂D and coincides with the classical solution when D is a Dirichlet domain. Extend f to a continuous function in the whole space, and denote it by f_0 . Approximate D by an increasing sequence $\{D_n\}$ of Dirichlet domains, and denote by u_n the solution in D_n of the Dirichlet problem for the boundary function f_0 . N. Wiener proved in 1924 that u_n converges to a harmonic function that is independent of the choice of the extension of f and $\{D_n\}$. The problem of deciding where on ∂D the general solution assumes the given boundary values is treated in Section D. O. D. Kellogg (1928) found a general method that includes Poincaré's method of sweeping out, Schwarz's alternating method, and the result of Wiener. Both Poincaré's method of sweeping out and Lebesgue's method of iterative averaging yield Wiener's general solution.

C. Perron's Method

We explain O. Perron's method (1923) by considering the improved method of M. Brelot [1]. For simplicity we assume that the domain

D is bounded in \mathbf{R}^3 . Let U be the family of subharmonic functions u bounded above and satisfying $\limsup_{P \rightarrow M} u(P) \leq f(M)$ for any boundary point M . Define $H_f(P)$ as $\sup_u u(P)$, where u runs through U , if this family is not empty; otherwise, set $H_f \equiv -\infty$. Call H_f a **hypofunction**. Define \bar{H}_f by $-\bar{H}_f$ and call it a **hyperfunction**. If $H_f = \bar{H}_f$, the common function is denoted by H_f ; if $H_f(P) < \infty$, then H_f is harmonic. This is called a **Perron-Brelot solution** (**Perron-Wiener-Brelot solution** or simply **PWB solution**). The method of defining H_f is called **Perron's method** (the Perron-Brelot method or the Perron-Wiener-Brelot method).

Wiener showed in 1923 that the †Daniell-Stone integral can be regarded as a general solution if a †Daniell-Stone integrable function f is given on the boundary of a Dirichlet domain; in 1925, he showed that the same is true for a general domain (not necessarily Dirichlet). He showed also that his solution coincides with the Perron-Brelot solution H_f if f is continuous. Unfortunately, however, from a wrong example he concluded that $H_f \neq \bar{H}_f$ can hold even for a simple discontinuous f , and so he lost interest in Perron's method. Brelot (1939) corrected Wiener's erroneous conclusion and proved that the Daniell upper and lower integrals are equal to \bar{H}_f and H_f , respectively. To any continuous f there corresponds an H_f , and there exists a †Radon measure μ_P satisfying $H_f(P) = \int f d\mu_P$. This measure is called a **harmonic measure** or harmonic measure function. Brelot showed that $H_f = \bar{H}_f$ if and only if f is μ_P -integrable for one (or every) P . In particular, if D is a Dirichlet domain and E is a closed set on the boundary ∂D , then the harmonic measure function $\mu_P(E)$ takes the value 1 at an inner point (in the space ∂D) of E and vanishes on $\partial D - E$. We note that μ_P is equal to the measure obtained by sweeping out the unit mass at P to ∂D .

D. Regular Boundary Points

If $H_f(P) \rightarrow f(M)$ as $P \rightarrow M \in \partial D$ for any continuous function f on ∂D , then M is called **regular**. The regularity of a point is a local property. A boundary point that is not regular is called **irregular**. The regularity of M is equivalent to the convergence of μ_P as $P \rightarrow M$ to the unit mass at M with respect to the †vague topology. There are many sufficient conditions and necessary conditions for a boundary point to be regular. The existence of a **barrier** is a qualitative condition that is necessary and sufficient for a boundary point to be regular. It was used by Poincaré and so named and used effectively by Lebesgue. A barrier is a continuous superharmonic func-

tion in D that assumes the boundary value 0 at M and has a positive lower bound outside every ball with center at M . A positive superharmonic function defined in the intersection of D and a neighborhood of M and taking the boundary value 0 can be used as a barrier. A necessary and sufficient condition for a boundary point M to be regular is the existence of a Green's function in D assuming the value 0 at M . This condition was given by G. Bouligand (1925), and it follows from the existence of a barrier. Another necessary and sufficient condition of a quantitative nature was obtained by Wiener. It is equivalent to the requirement that the complement of D is not †thin at M (\rightarrow 338 Potential Theory G). Kellogg conjectured that the set of irregular boundary points is of capacity zero and verified this in \mathbf{R}^2 (1928). The conjecture was proved first by G. C. Evans (1933) in \mathbf{R}^3 , and different proofs were given by F. Vasilescu (1935) and O. Frostman (1935). The conjecture is also true in \mathbf{R}^n for $n \geq 4$.

E. The More General Dirichlet Problem

So far, we have been concerned with \mathbf{R}^n . More generally, Brelot and G. Choquet [3] obtained the following result in a Green space \mathcal{E} (\rightarrow 193 Harmonic Functions and Subharmonic Functions): Consider a metric space that contains \mathcal{E} and in which \mathcal{E} is everywhere dense, and denote by Δ the complement of \mathcal{E} with respect to the space. Let $\{F\}$ be a family of †filters on \mathcal{E} such that each F converges to a certain point of Δ . Suppose that $u \leq 0$ whenever u is subharmonic and bounded above on \mathcal{E} and $\limsup u \leq 0$ along every F . Assume the existence of a barrier v in a neighborhood in \mathcal{E} of the limit point Q of every F ; that is, v is to be positive superharmonic, to tend to 0 along F , and to have a positive lower bound outside every neighborhood of Q . Under these assumptions, we obtain the PWB solution on \mathcal{E} as in \mathbf{R}^3 . There are various examples of Δ and F that satisfy these conditions. In particular, L. Naïm [6] investigated in detail the case where Δ is the †Martin boundary. More generally, it is possible to treat the Dirichlet problem axiomatically (\rightarrow 193 Harmonic Functions and Subharmonic Functions).

F. The Dirichlet Principle

Let D be a bounded domain with a sufficiently smooth boundary in \mathbf{R}^n and f be a piecewise C^1 -function on D with finite **Dirichlet integral** $\|f\|^2 = \int_D |\text{grad } f|^2 d\tau$, where $d\tau$ is the volume element. Suppose that f has a continuous boundary value ϕ on ∂D . The classical Dirich-

let principle asserts that the solution of the Dirichlet problem for φ has the smallest Dirichlet integral among the functions that are piecewise of class C^1 in D and assume the boundary value φ . In a general domain, H_φ minimizes $\|u - f\|$ among harmonic functions u in D . Brelot [2] discussed the principle for a family of competing functions that are defined in a domain in \mathcal{E} and whose boundary values cannot be defined in the classical manner.

121 (XI.3) Dirichlet Series

A. Dirichlet Series

For $z = x + iy$, $\lambda_n > 0$, and $\lambda_n \uparrow +\infty$, the series of the form

$$f(z) = \sum_{n=1}^{\infty} a_n \exp(-\lambda_n z) \quad (1)$$

is called a **Dirichlet series** (more precisely, a **Dirichlet series of the type** $\{\lambda_n\}$). If $\lambda_n = n$, then (1) is a power series with respect to e^{-z} . If $\lambda_n = \log n$, the series (1) becomes

$$\sum_{n=1}^{\infty} a_n/n^z, \quad (2)$$

which is called an **ordinary Dirichlet series**. If $a_n = 1$, then (2) is the \dagger Riemann zeta function.

Series of the form (2) were introduced by P. G. L. Dirichlet in 1839 and utilized in an investigation of the problems of analytic number theory. Later J. Jensen (1884) and E. Cohen (1894) extended the variable z to complex numbers. The Dirichlet series is not only a useful tool in analytic number theory, but is also investigated as a generalization of power series. The \dagger Laplace transform is the generalization of the Dirichlet series to the integral, and similar formulas often hold for both cases.

B. Convergence Regions

If the series (1) converges at $z = z_0$, then it converges in the half-plane $\operatorname{Re} z > \operatorname{Re} z_0$. Therefore there is a uniquely determined real number S such that (1) converges in $\operatorname{Re} z > S$ and diverges in $\operatorname{Re} z < S$. If (1) always converges (diverges), we put $S = -\infty$ ($+\infty$). We call S the **abscissa of convergence** (or **abscissa of simple convergence**). Similarly, there is a uniquely determined real number A such that (1) converges absolutely in $\operatorname{Re} z > A$ and is not absolutely convergent in $\operatorname{Re} z < A$. We call A the **abscissa of absolute convergence**. Furthermore, there is a uniquely determined real number U such that (1) converges uniformly in $\operatorname{Re} z > U'$ for every $U' > U$ and does not converge uniformly in $\operatorname{Re} z > U''$ for every $U'' < U$. The number U is called the **abscissa of uniform convergence**. Among these abscissas we always have the relations

$$-\infty \leq S \leq U \leq A + \infty,$$

$$A - S \leq \limsup_{n \rightarrow \infty} \frac{\log n}{\lambda_n}.$$

The latter was proved by Cohen (1894). The numbers S, A, U are determined from a_n, λ_n by means of the formulas

$$S = \limsup_{x \rightarrow \infty} \frac{1}{x} \log \left| \sum_{[x] \leq \lambda_n < x} a_n \right|, \quad (3)$$

$$A = \limsup_{x \rightarrow \infty} \frac{1}{x} \log \left(\sum_{[x] \leq \lambda_n < x} |a_n| \right), \quad (4)$$

$$U = \limsup_{x \rightarrow \infty} \frac{1}{x} \log T_x,$$

$$T_x = \sup_{-\infty < y < +\infty} \left| \sum_{[x] \leq \lambda_n < x} a_n \exp(-i\lambda_n y) \right|, \quad (5)$$

where $[]$ is the \dagger Gauss symbol. Formulas (3) and (4) were proved by T. Kojima (1914) and (5) by M. Kunieda (1916). In particular, when $\lim_{n \rightarrow \infty} (\log n)/\lambda_n = 0$, we have

$$S = U = A = \limsup_{n \rightarrow \infty} \frac{\log |a_n|}{\lambda_n} \quad (6)$$

(O. Szász, 1922; G. Valiron, 1924).

The series (1) converges uniformly in the angular domain $\{z \mid |\arg(z - z_0)| < \alpha < \pi/2\}$, where the vertex z_0 lies on the line $\operatorname{Re} z_0 = S$. Hence it represents a holomorphic function in the domain $\operatorname{Re} z > S$, but it is possible that there is no singularity on the line $\operatorname{Re} z = S$. For example, if $a_n = (-1)^n$, then the series (2) has $S = 0$, but the sum is an entire function $(2^{1-z} - 1)\zeta(z)$. Taking the analytic continuation $f(z)$ of the series (1), the infimum R of ρ such that $f(z)$ is holomorphic in $\operatorname{Re} z > \rho$ is called the **abscissa of regularity**. It is still possible that there is no singularity on the line $\operatorname{Re} z = R$. We always have $R \leq S$, and R is given by

$$R = \sup_{-\infty < y < \infty} \lim_{x \rightarrow -\infty} (\log \log^+ |\varphi(x + iy)| + x),$$

$$\varphi(z) = \sum_{n=1}^{\infty} \frac{a_n \exp(-\lambda_n z)}{\Gamma(1 + \lambda_n)}, \quad (7)$$

where $\log^+ a = \max(\log a, 0)$ (C. Tanaka, 1951). The infimum B of ρ such that $f(z)$ is bounded in $\operatorname{Re} z > \rho$ is called the **abscissa of boundedness**. We always have $R \leq B \leq A$. H. Bohr proved the following three theorems concerning these values: (1) If $\{\lambda_n\}$ are linearly independent over the ring of integers, then $A = B$ (1911). (2) If $(\lambda_{n+1} - \lambda_n)^{-1} = O(\exp \varepsilon^{\lambda_n})$ for every $\varepsilon > 0$, then $U = B$ (1913). (3) If $\limsup (\log n)/\lambda_n = 0$, then $S = U = A = B$ (1913). In the final case, the values are given by (6).

C. Properties of Functions Given by Dirichlet Series

The coefficients a_n in (1) are given in terms of the function $f(z)$ by

$$\sum_{v=1}^n a_v = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} f(z) \frac{e^{\omega z}}{z} dz, \quad (8)$$

where $c > \max(S, 0)$, $\lambda_n < \omega < \lambda_{n+1}$, and the integration contour does not pass through $\{\lambda_n\}$. If $\omega = \lambda_n$, then the term a_n in the sum of the left-hand side of (8) is replaced by $a_n/2$ (O. Perron, 1908). Furthermore, if $S < x$, then we have

$$a_n = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{x_0}^{x_0+T} f(x + iy) \exp[\lambda_n(x + iy)] dy \quad (9)$$

(J. Hadamard, 1908; C. Tanaka, 1952).

If $x = \operatorname{Re} z > S$, then $f(z) = o(|y|)$ ($|y| \rightarrow \infty$). In order to investigate its behavior more precisely, Bohr introduced

$$\mu(x) = \limsup_{|y| \rightarrow +\infty} \frac{\log |f(x + iy)|}{\log |y|}$$

in his thesis (1910) and called it the **order** over $\operatorname{Re} z = x$. The function $\mu(x)$ is nonnegative, monotone decreasing, convex, and continuous with respect to x . Bohr later found that there is

a kind of periodicity for the values of $f(z)$ over $\operatorname{Re} z = x$; this was the origin of the theory of \dagger almost periodic functions.

As for the zeros of the function $f(z)$, the following theorems are known: If $f(z)$ is not identically zero, it has only a finite number of zeros in $x \geq S + \varepsilon$, $e^{-Mx} \leq y \leq e^{Mx}$ for arbitrary positive numbers ε, M (Perron, 1908). If we denote by $N(T)$ the number of zeros in $x > S + \varepsilon$, $T < y < T + 2\delta \log T$, then $\limsup_{T \rightarrow \infty} N(T)/(\log T)^2 \leq \delta/\varepsilon$ (E. Landau, 1927).

There have been many investigations into the connection between the singularities of $f(z)$ and the coefficients a_n . If the a_n are real and positive, the point $z = S$ is always a singularity of $f(z)$. Moreover, if $S = 0$, $\operatorname{Re} a_n \geq 0$, and $\lim_{n \rightarrow \infty} (\cos(\arg a_n))^{1/\lambda_n} = 1$, then $z = 0$ is a singularity of $f(z)$ (C. Biggeri, 1939). Furthermore, if $\lambda_n/n \rightarrow \infty$, $\liminf_{n \rightarrow \infty} (\lambda_{n+1} - \lambda_n) > 0$, then the line $\operatorname{Re} z = S$ is the \dagger natural boundary of $f(z)$ (F. Carleson and Landau, 1921; A. Ostrowski, 1923). If $S = 0$, $\liminf_{n \rightarrow \infty} (\lambda_{n+1} - \lambda_n) = q > 0$, then there always exist singularities on every interval on the imaginary axis with the length $2\pi/q$ (G. Pólya, 1923). S. Mandelbrojt (1954, 1963) gave some interesting results concerning the relations between the singularities of (1) and the Fourier transform of an entire function.

If $U = -\infty$, the function $f(z)$ is an entire function. Its \dagger order (in the sense of entire function) ρ is given by

$$\rho = \limsup_{x \rightarrow -\infty} \frac{\log^+ \log^+ M(x)}{|x|},$$

$$M(x) = \sup_{-\infty < y < \infty} |f(x + iy)|.$$

There have been many investigations into the \dagger Julia direction of $f(z)$ and related topics by Mandelbrojt, Valiron, and Tanaka.

D. Tauberian Theorems

As in the case of power series, if the series $\sum a_n$ converges to s , then $f(+0) = s$ (**Abel's continuity theorem**). The converse is not necessarily true. The converse theorems, with additional conditions on a_n and λ_n , are called **Tauberian theorems**, as in the case of power series. Many theorems are known about this field. The most famous additional conditions are $\lim_{n \rightarrow \infty} \lambda_n a_n / (\lambda_n - \lambda_{n-1}) = 0$ (Landau, 1926) and $a_n = O((\lambda_n - \lambda_{n-1})/\lambda_n)$ (K. Ananda-Rau, 1928).

For the summation of Dirichlet series (especially \dagger Riesz's method of summation) \rightarrow 379 Series R. For Tauberian theorems (especially the Wiener-Ikehara-Landau theorem) of the ordinary Dirichlet series \rightarrow 123 Distribution of Prime Numbers B.

E. Series Related to Dirichlet Series

A series of the form

$$\sum_{n=1}^{\infty} \frac{n! a_n}{z(z+1)(z+2)\dots(z+n)}, \quad z \neq 0, -1, -2, \dots$$

is called a **factorial series** with the coefficients $\{a_n\}$. It converges or diverges simultaneously with the ordinary Dirichlet series $\sum a_n/n^z$ except at $z=0$ and negative integers. The series

$$\sum_{n=1}^{\infty} \frac{(z-1)(z-2)\dots(z-n)}{n!} a_n = \sum_{n=1}^{\infty} a_n \binom{z-1}{n}$$

is called a **binomial coefficient series**. It converges or diverges simultaneously with the ordinary Dirichlet series $\sum (-1)^n a_n/n^z$ except at $z=0$ and positive integers.

122 (IV.14)
Discontinuous Groups

A. Definitions [1-4]

Suppose that a group Γ acts continuously on a $^*\text{Hausdorff}$ space X , that is, for every $\gamma \in \Gamma$ and $x \in X$, an element γx of X is assigned in such a way that the mapping $x \rightarrow \gamma x$ is a homeomorphism of X onto itself and that we have $\gamma_1(\gamma_2 x) = (\gamma_1 \gamma_2)x$, $1x = x$, where 1 is the identity element of Γ . Two points $x, y \in X$ are said to be Γ -**equivalent** if there exists a $\gamma \in \Gamma$ such that $y = \gamma x$. (Γ -equivalence for subsets of X is defined similarly.)

We consider the following conditions of discontinuity of Γ . (i) For every $x \in X$ and any

infinite sequence $\{\gamma_i\}$ consisting of distinct elements of Γ , the sequence $\{\gamma_i x\}$ has no $^*\text{cluster point}$ in X . (ii) For every $x \in X$, there exists a neighborhood U_x such that $\gamma U_x \cap U_x = \emptyset$ for all but finitely many $\gamma \in \Gamma$. (ii') If $x, y \in X$ are not Γ -equivalent, there exist neighborhoods U_x, U_y of x, y , respectively, such that $\gamma U_x \cap U_y = \emptyset$ for all $\gamma \in \Gamma$. (iii) For any compact subset M of X , $\gamma M \cap M = \emptyset$ for all but finitely many $\gamma \in \Gamma$.

It is easy to see that (ii) \Rightarrow (i), (ii) + (ii') \Rightarrow (iii); if, moreover, X is $^*\text{locally compact}$, we also have (iii) \Rightarrow (ii), (ii'). When (i) holds, Γ is called a **discontinuous transformation group** of X , and when (ii) holds, Γ is called a **properly discontinuous transformation group**. In particular, when X can be identified with a $^*\text{homogeneous space}$ G/K of a locally compact group G by a compact subgroup K , the conditions (i), (ii), and (iii) for a subgroup Γ of G are all equivalent, and they are also equivalent to the condition that Γ is a $^*\text{discrete subgroup}$ of G .

For a discontinuous group Γ acting on X , the $^*\text{stabilizer}$ $\Gamma_x = \{\gamma \in \Gamma \mid \gamma x = x\}$ of $x \in X$ is always a finite subgroup. When $\Gamma_x = \{1\}$ for all $x \in X$, Γ is said to be **free** (or to **act freely** on X). If $\Gamma_x = \bigcap_{x \in X} \Gamma_x = \{1\}$, Γ is said to act $^*\text{effectively}$ on X . A point $x \in X$ is called a **fixed point** of Γ if $\Gamma_x \neq \Gamma_x$. In the following, we assume for simplicity that Γ acts effectively on X , unless otherwise specified.

Since Γ -equivalence is clearly an $^*\text{equivalence relation}$, we can decompose X into Γ -equivalence classes, or Γ - $^*\text{orbits}$. The space of all Γ -orbits, called the **quotient space** of X by Γ , is denoted by $\Gamma \backslash X$. When Γ satisfies the conditions (ii) and (ii'), the space $\Gamma \backslash X$ becomes a $^*\text{Hausdorff space}$ with respect to the topology of the quotient space. If, moreover, Γ is free, X is an (unramified) $^*\text{covering space}$ of $\Gamma \backslash X$ with the $^*\text{covering transformation group}$ Γ . (Conversely, a covering transformation group is always a free, properly discontinuous transformation group.) In general, X may be viewed as a covering space of $\Gamma \backslash X$ with ramifications, and the ramifying points (in X) are nothing but the fixed points of Γ .

B. Fundamental Regions

A complete set of representatives F of $\Gamma \backslash X$ in X (that is, a subset F of X such that $\Gamma F = X$, $\gamma F \cap F = \emptyset$ for $\gamma \in 1, \gamma \neq 1$) is called a **fundamental region** of Γ in X if it further satisfies suitable topological or geometrical requirements. Here we assume that \bar{F} , the closure of F , is the closure of its interior F^i . (In this case, \bar{F} or F^i is sometimes called the **fundamental region** of Γ instead of F itself.) Such a fundamental region exists if Γ satisfies the

conditions (ii), (ii'), and the set of fixed points is \dagger nowhere dense in X (R. Baer, F. W. Levi, 1931). A fundamental region F is called **normal** if the set $\{\gamma F\} (\gamma \in \Gamma)$ is locally finite, that is, if, for every $x \in X$, there exists a neighborhood U_x such that $\gamma F \cap U_x = \emptyset$ for all but a finite number of $\gamma \in \Gamma$. If X is \dagger connected and F is normal, then Γ is generated by the set of $\gamma \in \Gamma$ such that $\gamma \bar{F} \cap \bar{F} \neq \emptyset$. Thus it is useful to have a fundamental region in order to find a set of generators of Γ and a set of \dagger fundamental relations for them. When X has a Γ -invariant \dagger Borel measure μ and Γ is countable, then the measure $\mu(F)$ of F is independent of the choice of F . Hence it is legitimate to put $\mu(\Gamma \backslash X) = \mu(F)$; Γ is called a **discontinuous group of the first kind** (C. L. Siegel [2]) if Γ is a discontinuous transformation group which has a normal fundamental region F such that $\{\gamma | \gamma \bar{F} \cap \bar{F} = \emptyset\}$ is finite and $\mu(F) < \infty$. For instance, if X is locally compact and \bar{F} is compact ($\Leftrightarrow \Gamma \backslash X$: compact), then Γ is of the first kind.

When we are concerned only with the qualitative properties of Γ , it is sometimes convenient to relax the conditions for a fundamental region, replacing it by a **fundamental (open) set** Ω of Γ , that is, an (open) subset Ω of X such that $\Gamma \Omega = X$ and $\gamma \Omega \cap \Omega = \emptyset$ for all but a finite number of $\gamma \in \Gamma$ [5-9].

C. The Case of a Riemann Surface

Let Γ be a discontinuous group of analytic automorphisms of a \dagger Riemann surface X . In virtue of \dagger uniformization theory, it is enough, in principle, to consider the case where X is \dagger simply connected. Thus we have the following three cases:

(1) $X = \mathbb{C} \cup \{\infty\}$ (\dagger Riemann sphere). Γ is a finite group. Since Γ can also be considered as a group of motions of the sphere, it is either a cyclic, \dagger dihedral, or \dagger regular polyhedral group [10].

(2) $X = \mathbb{C}$ (complex plane). Γ is contained in the group of motions of the plane. The subgroup consisting of all parallel translations contained in Γ is a \dagger free Abelian group of rank $v \leq 2$. If $v = 0$, then Γ is a finite cyclic group. When $v > 0$, Γ consists of the transformations of the following form:

When $v = 1$, $z \rightarrow e^{k\omega} z + m\omega$ $(k, m \in \mathbb{Z})$,

When $v = 2$, $z \rightarrow e^{k\omega} z + m_1 \omega_1 + m_2 \omega_2$ $(k, m_i \in \mathbb{Z})$,

where $\omega, \omega_1, \omega_2$ are nonzero complex numbers with $\text{Im}(\omega_2/\omega_1) > 0$, and $\varepsilon = \pm 1$ in general, except in special cases when $v = 2$ and $\omega_2/\omega_1 = \zeta_4$ (resp. ζ_3 or ζ_6 , where $\zeta_l = \exp(2\pi i/l)$), in

which cases we may put $\varepsilon = \zeta_4$ (resp. ζ_3 or ζ_6). For the fundamental regions corresponding to these values of ε , see Fig. 1. In the cases $v = 1$ and 2, the \dagger automorphic functions with respect to Γ are essentially given by exponential functions and elliptic functions, respectively (\rightarrow 134 Elliptic Functions).

Fig. 1
(a) $v = 2, \varepsilon = 1$. (b) $\omega_1 = 1, \omega_2 = i, \varepsilon = i$. (c) $\omega_1 = 1, \omega_2 = \zeta_3, \varepsilon = \zeta_3$. (d) $\omega_1 = 1, \omega_2 = \zeta_3, \varepsilon = \zeta_6$.

(3) $X = \{|z| < 1\}$ (unit disk) [3, 10, 11]. By a \dagger Cayley transformation, the unit disk can be transformed to the upper half-plane $\mathfrak{H} = \{z = x + iy | y > 0\}$. Any analytic automorphism of \mathfrak{H} is given by a real \dagger linear fractional transformation (Möbius transformation) $z \rightarrow (az + b)/(cz + d)^{-1}$ ($a, b, c, d \in \mathbb{R}, ad - bc = 1$). The totality of real linear fractional transformations acts transitively on \mathfrak{H} . Hence \mathfrak{H} can be identified with the \dagger homogeneous space G/K of $G = SL(2, \mathbb{R})$ by $K = SO(2)$ (which is the stabilizer of the point $\sqrt{-1}$). Hence discontinuous groups Γ of analytic automorphisms of \mathfrak{H} are obtained as discrete subgroups of G . Actually, every element of G defines an analytic automorphism of the whole Riemann sphere, which leaves the real axis $\mathbb{R} \cup \{\infty\}$ invariant. For any $z \in \mathbb{C} \cup \{\infty\}$ and a sequence $\{\gamma_i\}$ consisting of distinct elements of Γ , a cluster point of the sequence $\{\gamma_i z\}$ in $\mathbb{C} \cup \{\infty\}$ is called a **limit point** of Γ . When only one or two limit points exist, Γ can easily be transformed to one of the groups given in (2). Otherwise, the set \mathfrak{Q} of all limit points of Γ is infinite, and either $\mathfrak{Q} = \mathbb{R} \cup \{\infty\}$ or \mathfrak{Q} is a \dagger perfect, \dagger nowhere dense subset of $\mathbb{R} \cup \{\infty\}$. When \mathfrak{Q} is infinite, Γ is called a **Fuchsoid group**.

Since \mathfrak{H} has a G -invariant \dagger Riemannian metric $ds^2 = y^{-2}(dx^2 + dy^2)$ (called the \dagger Poincaré metric), by which \mathfrak{H} becomes a **hyperbolic plane** (\dagger non-Euclidean plane with negative curvature), we can construct a fundamental region F of Γ which is a normal polygon bounded by geodesics, that is, the arcs of cir-

cles orthogonal to the real axis. A set of generators of Γ and the fundamental relations for them are easily obtained by observing the correspondence of the equivalent sides of the fundamental polygon. (Conversely, starting from a normal polygon satisfying a suitable condition, one can construct a discontinuous group Γ having F as a fundamental region. In this manner, we generally obtain a (nontrivial) continuous family of discrete subgroups of G .)

A Fuchsoid group Γ is finitely generated if and only if the fundamental polygon F has a finite number of sides, and in that case Γ is called a **Fuchsian group**. (More generally, a finitely generated discontinuous group of linear fractional transformations acting on a domain in the complex plane is called a **Kleinian group**.) A Fuchsian group Γ is of the **first kind** if and only if $\mathfrak{Q} = \mathbf{R} \cup \{\infty\}$; otherwise, it is of the **second kind**. It is also known that a discontinuous group Γ is a Fuchsian group of the first kind if and only if $\mu(\Gamma \backslash \mathfrak{H}) < \infty$ [12]. For a real point $x \in \mathbf{R} \cup \{\infty\}$, we also denote by Γ_x the stabilizer of x (in Γ). The point x is called a (**parabolic**) **cusp** of Γ if Γ_x is a free cyclic group generated by a \dagger parabolic transformation ($\neq \pm 1$). Cusps of Γ are represented by vertices of the fundamental polygon on the real axis. On the other hand, if a fixed point z of Γ lies in \mathfrak{H} , then the stabilizer Γ_z is always a finite cyclic group generated by an \dagger elliptic transformation. Hence such a point z is also called an **elliptic point** of Γ . For a Fuchsian group Γ of the first kind, let $\{z_1, \dots, z_s\}$ be a complete set of representatives of the Γ -equivalence classes of the elliptic points of Γ (which can also be chosen from among the vertices of the fundamental polygon), and let e_i be the order of Γ_{z_i} ; furthermore, let t be the number of the Γ -equivalence classes of parabolic cusps of Γ . Then the quotient space $\Gamma \backslash \mathfrak{H}$ can be compactified by adjoining t points at infinity, and the resulting space becomes a compact Riemann surface \mathfrak{R}_Γ if we define an analytic structure on it in a suitable manner. The area $\mu(\mathfrak{R}_\Gamma)$ measured by the Poincaré metric is given by the \dagger Gauss-Bonnet formula:

$$\mu(\mathfrak{R}_\Gamma) = \int_F \frac{dx dy}{y^2} \\ = 2\pi \left[2g - 2 + \sum_{i=1}^s \left(1 - \frac{1}{e_i} \right) + t \right],$$

where g is the \dagger genus of the Riemann surface \mathfrak{R}_Γ . It is known that there exists a lower bound ($= \pi/21$) for $\mu(\mathfrak{R}_\Gamma)$ [12]. Automorphic functions (or Fuchsian functions) with respect to a Fuchsian group Γ , which are essentially the same thing as algebraic functions on the Riemann surface \mathfrak{R}_Γ , have been objects of extensive study since Poincaré (1882).

D. Modular Groups [10, 13]

The group

$$\Gamma = SL(2, \mathbf{Z}) \\ = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \middle| a, b, c, d \in \mathbf{Z}, ad - bc = 1 \right\}$$

(or the corresponding group of linear fractional transformations) is called the (**elliptic**) **modular group**. The modular group Γ is a Fuchsian group of the first kind acting on \mathfrak{H} , and its fundamental region together with the correspondence of the equivalent sides is shown in Fig. 2. Fig. 3 illustrates the transformations under Γ of the fundamental triangle, where Γ is regarded as acting on the unit disk. From Fig. 2 we obtain the generators of $\Gamma \pmod{\{\pm I_2\}}$ ($I_2 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$) and the

fundamental relations:

$$\sigma_1 = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \\ \sigma_2^2 = (\sigma_2 \sigma_1)^3 = -I_2.$$

There are two Γ -equivalence classes of elliptic points of Γ , which are represented by $\zeta_4 = i$ and ζ_3 , with $[\Gamma_i : \{\pm I_2\}] = 2$, $[\Gamma_{\zeta_3} : \{\pm I_2\}] = 3$; and only one Γ -equivalence class of parabolic cusps, which coincides with $\mathbf{Q} \cup \{\infty\}$. The corresponding Riemann surface \mathfrak{R}_Γ is analytically equivalent to the Riemann sphere.

Fig. 2

Fig. 3

For a positive integer N , the totality $\Gamma(N)$ of elements in Γ satisfying the condition $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \equiv \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \pmod{N}$ forms a normal subgroup of Γ , called a **principal congruence subgroup of level N** . (For the case $N = 2$, see Fig. 4.) In general, a subgroup Γ' of Γ containing $\Gamma(N)$ for some N is called a **congruence subgroup** of Γ . (It is known that there actually exists a subgroup Γ' of Γ with a finite index, which is not a congruence subgroup.) For $N \geq 3$, $-I_2 \notin \Gamma(N)$, so that $\Gamma(N)$ is effective. (For $N = 1, 2$, we have $\Gamma(N)_5 = \{\pm I_2\}$.) If $N \geq 2$, $\Gamma(N)$ has no elliptic point. The number $t(N)$ of the equivalence classes of cusps of $\Gamma(N)$ and the genus $g(N)$ of the corresponding Rie-

mann surface $\mathfrak{H}_{\Gamma(N)}$ are given as follows:

$$t(1)=1, \quad t(2)=3,$$

$$t(N)=(1/2N)[\Gamma:\Gamma(N)] \quad (N\geq 3),$$

$$g(1)=g(2)=0,$$

$$g(N)=1+((N-6)/24N)[\Gamma:\Gamma(N)] \quad (N\geq 3),$$

where $[\Gamma:\Gamma(N)]=N^3\prod_{p|N}(1-1/p^2)$. Automorphic functions with respect to $\Gamma(N)$ are called \dagger modular functions of level N .

Fig. 4
A fundamental region of $\Gamma(2)$ that consists of six fundamental regions of $\Gamma(1)$.

E. The Case of Many Variables

Up to the present time, discontinuous groups Γ and the corresponding automorphic functions have been studied only in the following cases: (2') $X=\mathbb{C}^n$, $\Gamma\cong\mathbb{Z}^{2n}$ (the free Abelian group of rank $2n$, consisting of parallel translations) [14] (\rightarrow 3 Abelian Varieties); (3') X is a bounded domain in \mathbb{C}^n and Γ is a discontinuous group of analytic automorphisms of X . (In this case, conditions (i), (ii), (iii) are equivalent.)

In the case (3'), the group $\mathcal{A}(X)$ of all (complex) analytic automorphisms of X , endowed with its natural (\dagger compact-open) topology, becomes a \dagger Lie group, which has Γ as a discrete subgroup. When $\Gamma\backslash X$ is compact, it is known by the theory of automorphic functions (or by a theorem of Kodaira) that $\Gamma\backslash X$ becomes a \dagger projective variety, which is a \dagger minimal model [3, 14]. In particular, when X is a \dagger symmetric bounded domain, i.e., when X becomes a \dagger symmetric Riemannian space with respect to its \dagger Bergman metric, the connected component G of the identity element of $G'=\mathcal{A}(X)$ (which incidentally coincides with that of the group $I(X)$ of all \dagger isometries of X) is a \dagger semisimple Lie group of noncompact type (i.e., without compact simple factors), and X can be identified with the homogeneous space of G by a maximal compact subgroup K of G . The theory of discontinuous groups of this type, initiated by Siegel (especially in the case

where $X=\mathfrak{H}_n=Sp(n,\mathbb{R})/K$, \dagger Siegel's upper half-space; $\Gamma=Sp(n,\mathbb{Z})$, \dagger Siegel's modular group of degree n), O. Blumenthal, H. Braun, and L.-K. Hua, and continued by those in the German school such as M. Koecher, H. Maass, and others, has undergone substantial development in recent years under the influence of the theory of algebraic groups [5, 8, 14–17] (\rightarrow 32 Automorphic Functions).

On the other hand, for a symmetric Riemannian space X of negative curvature, the group of isometries $G=I(X)$ is a \dagger semisimple Lie group of noncompact type with a finite number of connected components and with a finite center, and X can be identified with the homogeneous space of G by a maximal compact subgroup. Therefore the study of discontinuous groups of isometries of X can be reduced to that of discrete subgroups of a Lie group G of this type. A typical example is the case where X is the space of all real \dagger positive definite symmetric matrices of degree n with determinant 1; this space can be identified with the quotient space $SL(n,\mathbb{R})/SO(n)$ ($A\in SL(n,\mathbb{R})$ acts on X by $X\ni S\rightarrow^{-1}ASA$). The unimodular group $\Gamma=SL(n,\mathbb{Z})$ is a discontinuous group of the first kind acting on this space X , and a method of constructing a fundamental region of Γ in X is provided by the **Minkowski reduction theory** [6, 7].

F. Discrete Subgroups of a Semisimple Lie Group

Two subgroups Γ, Γ' of a group G are called **commensurable** if $\Gamma\cap\Gamma'$ is of finite index in both Γ and Γ' . For a real \dagger linear algebraic group $G\subset GL(n,\mathbb{R})$ defined over \mathbb{Q} , a subgroup Γ commensurable with $G_{\mathbb{Z}}=G\cap GL(n,\mathbb{Z})$ is called an **arithmetic subgroup** (in the original sense) of G (examples: $SL(n,\mathbb{Z}), Sp(n,\mathbb{Z})$). An arithmetic subgroup Γ is always discrete, and when G is semisimple, the quotient space $\Gamma\backslash G$ is of finite volume ($\mu(\Gamma\backslash G)<\infty$) with respect to an invariant measure μ . Moreover, $\Gamma\backslash G$ is compact if and only if G is $\dagger\mathbb{Q}$ -compact (or $\dagger\mathbb{Q}$ -anisotropic), that is, if $G_{\mathbb{Q}}$ or $G_{\mathbb{Z}}$ consists of only \dagger semisimple elements (A. Borel, Harish-Chandra, G. D. Mostow, and T. Tamagawa [6, 7]); the same results remain true if G is \dagger Zariski connected and has no \dagger character defined over \mathbb{Q} . The proofs of these facts (and the compactification of the quotient space $\Gamma\backslash X$ for the noncompact case) depend on a construction of fundamental open sets that generalizes the reduction theory of Minkowski and Siegel [5, 8, 15–18].

For a connected semisimple Lie group G of noncompact type and a discrete subgroup Γ with $\mu(\Gamma\backslash G)<\infty$, the following **density**

theorem holds (Borel, *Ann Math.*, (2) 72 (1960)):

(i) For any linear representation ρ of G , the linear closure of $\rho(\Gamma)$ coincides with that of $\rho(G)$; (ii) if G is algebraic, Γ is t Zariski dense in G . Furthermore, suppose that G is a direct product of simple groups G_i and the center of G is finite; Γ is called **irreducible** if its projection on any (proper) partial product of $\{G_i\}$ is not discrete. For instance, if G is a $^t\mathbf{Q}$ -simple algebraic group then $\Gamma = G_{\mathbf{Z}}$ is irreducible. In general, there exists a partition of the set of indices $\{i\}$ such that Γ is commensurable with a direct product of irreducible discrete subgroups of the partial products corresponding to this partition, and these irreducible components are unique up to commensurability.

The method of constructing a discrete subgroup Γ of $G = SL(2, \mathbf{R})$ in a geometric manner using the upper half-plane can be generalized to some extent to the construction of discrete subgroups of certain groups using hyperbolic spaces of low dimensions (E. B. Vinberg). Except for these few cases, today it is known that a discrete subgroup Γ of a semisimple Lie group G (of \mathbf{R} -rank ≥ 2) with $\mu(\Gamma \backslash G) < \infty$ is arithmetic in a certain sense (\rightarrow Section G). This implies there are only very few discrete subgroups for a semisimple Lie group of higher rank. Actually a number of facts suggesting this result were already known in the 1960s. First, the only subgroups of $SL(n, \mathbf{Z})$ ($n \geq 3$), $Sp(n, \mathbf{Z})$ ($n \geq 2$) with finite index are congruence subgroups (H. Bass, M. Lazard, and J.-P. Serre; this result has been generalized to the case of an arbitrary t Chevalley group over an algebraic number field by C. C. Moore and H. Matsumoto). Second, $G_{\mathbf{Z}} = SL(n, \mathbf{Z})$, $Sp(n, \mathbf{Z})$ are maximal in G [8]. Finally, it is known (rigidity theorem) that if a connected semisimple Lie group G with a finite center does not contain a simple factor which is locally isomorphic to $SL(2, \mathbf{R})$, then any discrete subgroup Γ of G with compact quotient $\Gamma \backslash G$ has no nontrivial t deformation (i.e., all deformations are obtained from inner automorphisms of G) (A. Selberg, E. Calabi and E. Vesentini, and A. Weil [19]). This last result amounts to the vanishing of the cohomology group $H^1(\Gamma, X, \text{ad})$, and in this connection an extensive study has been made by Y. Matsushima, S. Murakami, G. Shimura, and K. G. Ramanan to determine the t Betti numbers of $\Gamma \backslash X$, and more generally the cohomology groups of the type $H(\Gamma, X, \rho)$ with an arbitrary representation ρ of G . These cohomology groups are closely related to automorphic forms with respect to Γ [8, 20].) For a t nilpotent or t solvable Lie group, a general method of constructing discrete subgroups is known; see, for example, M. Saito, *Amer. J. Math.*, 83 (1961).

G. Rigidity and Arithmeticity

A discrete subgroup Γ of a Lie group G with $\mu(\Gamma \backslash G) < \infty$ is usually called a **lattice** of G . A lattice Γ of G is said to be **uniform** if $\Gamma \backslash G$ is compact. By a theorem of Borel and Harish-Chandra [7], an arithmetic subgroup of a real linear group (defined over \mathbf{Q}) is a lattice. Using this result, Borel showed further, by a constructive method, that any semisimple Lie group has a lattice, especially a uniform one (Borel, *Topology*, 2 (1963)).

For a long time there were no known examples of nonarithmetic irreducible lattices in semisimple Lie groups other than those locally isomorphic to $SL_2(\mathbf{R})$. This naturally led to Selberg's conjecture that any irreducible (nonuniform) lattice in a semisimple Lie group G not locally isomorphic to $SL_2(\mathbf{R})$ is arithmetic (Selberg, International Colloquium on Function Theory, Bombay, 1960). The conjecture seemed to be well-grounded by the rigidity theorem of Weil and Selberg [19].

However, in 1966–1967, V. S. Makarov and Vinberg constructed nonarithmetic non-uniform lattices in $SO(n, 1)$ ($n = 3, 4, 5$) by a geometric method; the lattices are generated by t reflections [21]. Thus rigidity and arithmeticity do not necessarily coincide, and the conjecture should be considered under stronger conditions.

As for rigidity of uniform lattices, Mostow established in 1970 the following **strong rigidity theorem** [22]: If G, G' are semisimple Lie groups with trivial center and without compact factors, and are not locally isomorphic to $SL_2(\mathbf{R})$, and if Γ, Γ' are irreducible uniform lattices, then any isomorphism $\theta: \Gamma \rightarrow \Gamma'$ extends to an analytic isomorphism $\tilde{\theta}: G \rightarrow G'$ (namely, $\tilde{\theta}|_{\Gamma} = \theta$). The previous rigidity theorem is now implied by Mostow's. If X is a simply connected symmetric space, then a t locally symmetric space M covered by X is expressed as a quotient of X by a fixed-point-free properly discontinuous group Γ in the group $I(X)$ of total isometries (when the Lie algebra of $I(X)$ does not have a compact factor, this condition for Γ is equivalent to saying that it is a torsion-free discrete subgroup of the semisimple Lie group $I(X)$), and the fundamental group $\pi_1(M)$ of $M = \Gamma \backslash X$ is isomorphic to Γ . The strong rigidity theorem implies that compact locally symmetric spaces M_1 and M_2 (of higher dimensions) are isomorphic as Riemannian spaces if and only if $\pi_1(M_1)$ and $\pi_1(M_2)$ are isomorphic as abstract groups.

On the other hand, in 1973, G. A. Margulis proved the arithmeticity of irreducible non-uniform lattices in semisimple real linear groups of \mathbf{R} -rank greater than 1 (*Russian Math. Surveys*, 29 (1974) (original in Russian,

1974); *Functional Anal. Appl.* 9 (1975) (original in Russian, 1975). M. S. Raghunathan also proved independently the same fact under a slightly stronger condition. Their results, together with the rigidity of nonuniform lattices in (higher-dimensional) semisimple Lie groups of \mathbf{R} -rank 1 established by H. Garland, Raghunathan, and G. Prasad (*Inventiones Math.*, 21 (1973)), imply that the strong rigidity theorem holds similarly for nonuniform lattices.

The results of Margulis and Raghunathan show that the Selberg conjecture in the original sense is affirmative for the case of \mathbf{R} -rank greater than 1. But neither argument is applicable to uniform lattices, for they depend deeply on the fact (proved by D. A. Kazdan and Margulis) that a nonuniform lattice contains a nonidentity unipotent element. Previously, in a lecture at the international congress of mathematicians at Moscow, 1966, I. I. Pyatetskii-Shapiro generalized the definition of arithmeticity and suggested that arithmeticity of lattices should be investigated without the distinction of whether they are uniform or nonuniform. His definition is equivalent to the following [9, 24]: For a connected semisimple algebraic group G defined over \mathbf{R} , a subgroup $\Gamma \subset G = G_{\mathbf{R}}$ is an **arithmetic subgroup** (of G) if there is an algebraic group H defined over \mathbf{Q} and a surjective homomorphism $\varphi: H \rightarrow \text{Ad } G$ defined over \mathbf{R} such that the Lie group $(\text{Ker } \varphi)_{\mathbf{R}}$ is compact and that $\varphi(H_{\mathbf{Z}})$ and $\text{Ad } \Gamma$ are commensurable. The uniform lattice in G that is constructed by the method of Borel is arithmetic in this sense. In 1974, Margulis finally established the following arithmeticity theorem [23, 24]: If the \mathbf{R} -rank of G is not less than 2, an irreducible lattice Γ in G is an arithmetic subgroup of G (even if it is uniform). In the same lecture, Pyatetskii-Shapiro also extended the Selberg conjecture to such "semisimple Lie groups" as those containing p -adic Lie groups as factors. Margulis proved this Pyatetskii-Shapiro conjecture affirmatively by showing that an analog of the strong rigidity theorem holds for such groups.

As for semisimple Lie groups of \mathbf{R} -rank 1, besides the lattices constructed by Makarov and Vinberg there are only the few examples of nonarithmetic lattices in $SU(2, 1)$ presented by Mostow (*Proc. Nat. Acad. Sci. US*, 75 (1978); *Pacific J. Math.*, 86 (1980)). The problem of arithmeticity still remains open for groups locally isomorphic to $SO(n, 1)$ ($n \geq 6$), $SU(n, 1)$ ($n \geq 3$), $Sp(n, 1)$, or F_4 .

H. Geometric Discontinuous Groups [1, 25]

The study of discontinuous groups Γ acting on a Euclidean or projective space X as a transformation group of a given structure is a class-

Discontinuous Groups

ical problem. All possibilities for such Γ have been enumerated in low-dimensional cases. For instance, there are 230 kinds of discontinuous groups of \dagger Euclidean motions acting on 3-dimensional Euclidean space without fixed subspaces, which are classified into 32 \dagger crystal classes (A. Schönflies and E. S. Fedorov, 1891–1892; \rightarrow 92 Crystallographic Groups). All discontinuous groups of a Euclidean space generated by \dagger reflections have also been enumerated (H. S. M. Coxeter, 1934 [25, 26]).

I. Kleinian Groups

The last decade has seen considerable research on (finitely generated) Kleinian groups. This research is closely related to the theory of \dagger quasiconformal mappings and the \dagger moduli of Riemann surfaces.

Making use of Eichler cohomology and \dagger potentials, L. V. Ahlfors established his finiteness theorem and L. Bers his area theorem. Bers and B. Maskit investigated the boundaries of \dagger Teichmüller spaces and discovered Kleinian groups with the property that the complement of the set \mathfrak{L} of limit points is connected and simply connected.

Numerous mathematicians have subsequently discussed the classification, deformation, and stability properties of the set \mathfrak{L} , uniformization and deformation of Riemann surfaces with or without nodes, and other geometric properties. In their discussions, the theory of quasiconformal mappings has played an important role. The discontinuous groups of motions of hyperbolic 3-space have also been studied.

123 (V.7) Distribution of Prime Numbers

A. General Remarks

Given a real number x , we denote by $\pi(x)$ the
number of primes not exceeding x . A. M.

Legendre (1808) obtained empirically the for-
mula $\pi(x) \approx x/(\log x - B)$ for some constant B ,
and C. F. Gauss (1849) obtained the formula

$$\pi(x) \approx \int_2^x \frac{du}{\log u},$$

assuming the average density of primes to be
 $1/\log x$. The **Bertrand conjecture**, which asserts
the existence of at least one prime between x
and $2x$, was proved by P. L. Chebyshev (1848),
who introduced the functions

$$\theta(x) = \sum_{m=1}^{\infty} \sum_{p \leq x} \log p$$

and

$$\begin{aligned} \psi(x) &= \sum_{p^m \leq x} \log p \\ &= \theta(x) + \theta(\sqrt{x}) + \theta(\sqrt[3]{x}) + \dots \end{aligned}$$

(In this section, p represents a prime number.)
He thereby proved

$$Ax + O(\sqrt{x}) < \theta(x) < \psi(x) < (6/5)Ax + O(\sqrt{x}),$$

where $A = \log(2^{1/2} 3^{1/3} 5^{1/5} 30^{-1/30})$. G. F. B.
Riemann (1858) considered the function $\zeta(s)$
(where $s = \sigma + it$ is a complex variable), ex-
pressed by the Dirichlet series $\sum_{n=1}^{\infty} n^{-s}$, which
is convergent for $\sigma > 1$. He found relations
between the zeros of $\zeta(s)$ (\rightarrow 450 Zeta Func-
tions) and $\pi(x)$. F. Mertens (1874) obtained the
formulas

$$\sum_{p \leq x} \frac{\log p}{p} = \log x + O(1),$$

$$\sum_{p \leq x} \frac{1}{p} = \log \log x + B + O\left(\frac{1}{\log x}\right),$$

$$\prod_{p \leq x} \left(1 - \frac{1}{p}\right) = \frac{e^{-c}}{\log x} \left(1 + O\left(\frac{1}{\log x}\right)\right),$$

where c is the Euler constant and B is some
constant.

B. Prime Number Theorem

The prime number theorem

$$\lim_{x \rightarrow \infty} \frac{\pi(x) \log x}{x} = 1, \quad \text{or} \quad \pi(x) \sim \frac{x}{\log x},$$

was proved almost simultaneously (1896) by J. Hadamard and C. J. de La Vallée-Poussin. Without using the theory of entire functions, E. Landau (1908) established the formula

$$\pi(x) = \text{Li } x + O(xe^{-c\sqrt{\log x}}),$$

where

$$\text{Li } x = \lim_{\delta \rightarrow +0} \left(\int_0^{1-\delta} + \int_{1+\delta}^x \right) \frac{du}{\log u}$$

is the †logarithmic integral. It can be shown by integration by parts that

$$\begin{aligned} \text{Li } x &= \frac{x}{\log x} + \frac{1!x}{\log^2 x} + \dots \\ &\quad + \frac{(k-1)!x}{\log^k x} + O\left(\frac{x}{\log^{k+1} x}\right). \end{aligned}$$

For example, by taking $x = 10^7$, we get $\pi(x) = 664,579$, $\text{Li } x \approx 664,918$, and $x/\log x \approx 620,417$.

If the Dirichlet series $f(s) = \sum_{n=1}^{\infty} a_n n^{-s}$ satisfies the condition $\sum_{n \leq x} a_n \sim cx$, then its abscissa of convergence is 1, and we have $\lim_{s \rightarrow 1+0} (s-1)f(s) = c$. The converse is known as the †Tauberian theorem. If $F(s) = \sum_{n=1}^{\infty} a_n n^{-s}$ ($a_n \geq 0$) converges absolutely for $\sigma > 1$ and $F(s) - c/(s-1)$ is analytic for $\sigma \geq 1$, then we obtain $\sum_{n \leq x} a_n \sim cx$ (**Wiener-Ikehara-Landau theorem**, 1932). Specifically, if we put $-\zeta'(s)/\zeta(s) = \sum_{n=1}^{\infty} \Lambda(n)n^{-s}$, then the conditions of the theorem are satisfied, and we obtain $\sum_{n \leq x} \Lambda(n) = \psi(x) \sim x$.

It is easily seen that the prime number theorem is equivalent to $\psi(x) \sim x$ or $\theta(x) \sim x$. The †number-theoretic function $\Lambda(n)$ (**Mangoldt's function**) introduced above satisfies $\sum_{d|n} \Lambda(d) = \log n$. It follows from the †Möbius inversion formula that $\Lambda(n) = \sum_{d|n} \mu(d) \log(n/d)$. Hence $\Lambda(n) = \log p$ ($n = p^l$) and $= 0$ otherwise. Thus we obtain $\psi(x) = \sum_{n \leq x} \Lambda(n) = O(x)$. When $f(x) = \theta(x)$ or $\psi(x)$, it is easy to show that $\int_2^x (f(t)/t^2) dt = \log x + O(1)$ and $\liminf_{x \rightarrow \infty} f(x)/x \leq 1 \leq \limsup_{x \rightarrow \infty} f(x)/x$. However, it is not easy to prove $f(x) \sim x$. To do so, introduce the number-theoretic function $M(n)$, which satisfies $\sum_{d|n} M(d) = \log^2 n$. As before, we have $M(n) = \sum_{d|n} \mu(d) \log^2(n/d)$; hence

$$M(n) = \begin{cases} (2l-1) \log p & (n = p^l, l \geq 1), \\ 2 \log p \log q & (n = p^l q^m, l \geq 1, m \geq 1), \\ 0 & (\text{otherwise}). \end{cases}$$

Thus we obtain $\sum_{n \leq x} M(n) = 2x \log x + O(x)$. This leads to A. Selberg's well-known formula

(1949):

$$\theta(x) \log x + \sum_{p \leq x} \theta(x/p) \log p = 2x \log x + O(x),$$

which enabled him to prove $\theta(x) \sim x$. Thus he obtained for the first time a proof of the prime number theorem that does not use complex analytic methods. The simple formulas $\sum_{n=1}^{\infty} \mu(n)/n = 0$ and $\sum_{n \leq x} \mu(n) = o(x)$, obtained by H. von Mangoldt (1897), were revealed by Landau to have a deep meaning concerning the prime number theorem. Let $\pi_r(x)$ denote the number of integers not exceeding x that can be expressed as the product of r distinct primes. In generalizing the prime number theorem, Landau (1911) proved that

$$\pi_r(x) \sim \frac{1}{(r-1)!} \frac{x(\log \log x)^{r-1}}{\log x}.$$

Let us write $\mathfrak{G}(x) = \sum_{n=1}^{\infty} e^{-\pi x n^2}$. Riemann proved that

$$\begin{aligned} &\Gamma\left(\frac{s}{2}\right) \pi^{-s/2} \zeta(s) \\ &= \frac{1}{s(s-1)} + \int_1^{\infty} \mathfrak{G}(x) (x^{s/2-1} + x^{-1/2-s/2}) dx \end{aligned}$$

and obtained the well-known functional equation for the zeta function (\rightarrow 450 Zeta Functions B)

$$\pi^{-s/2} \Gamma(s/2) \zeta(s) = \pi^{-1/2+s/2} \Gamma(1/2-s/2) \zeta(1-s).$$

This enables us to extend $\zeta(s)$ as a meromorphic function to the whole complex plane. Utilizing this extended $\zeta(s)$ and the following result of O. Perron on Dirichlet series, we can estimate $\psi(x)$. Let $\sigma_0 (\neq \infty)$ be the abscissa of convergence of $F(s) = \sum_{n=1}^{\infty} f(n)n^{-s}$, and let $a > 0$, $a > \sigma_0$, and $x > 0$. If

$$\lim_{T \rightarrow \infty} \frac{1}{2\pi i} \int_{a-iT}^{a+iT} F(s) \frac{x^s}{s} ds$$

exists, then the limit is equal to $\sum'_{n \leq x} f(n)$, where \sum' means that in the summation the last term $f(x)$ is replaced by $f(x)/2$ if x is an integer. In many cases, $F(s)$ has a pole at $s = 1$, and the principal part of the sum is obtained from the residue at $s = 1$, whereas the residual part is given by a certain contour integral. To estimate $\psi(x)$, we use $-\zeta'(s)/\zeta(s)$ as $F(s)$; hence the problem arises of determining the zeros of $\zeta(s)$. Riemann conjectured that all the zeros of $\zeta(s)$ in the strip $0 \leq \sigma \leq 1$ must be situated on the vertical line $\sigma = 1/2$. If this so-called †Riemann hypothesis (\rightarrow 450 Zeta Functions) is true, then it follows that $\pi(x) = \text{Li } x + O(\sqrt{x} \log x)$. The ultimate validity of Riemann's hypothesis remains in doubt. Concerning this, the most recent major result is the following formula, obtained by I. M. Vinogradov (1958): $\pi(x) = \text{Li } x +$

$O(x \exp(-c \log^{3/5} x / \log \log^{1/5} x))$. Without using Riemann's hypothesis, J. E. Littlewood (1918) proved that

$$\limsup_{x \rightarrow \infty} \frac{\pi(x) - \text{Li } x}{(\sqrt{x} / \log x) \log \log \log x} > 0,$$

$$\liminf_{x \rightarrow \infty} \frac{\pi(x) - \text{Li } x}{(\sqrt{x} / \log x) \log \log \log x} < 0.$$

If we denote by $N(T)$ the number of zeros of $\zeta(s)$ in the domain $0 < \sigma < 1$, $0 < t < T$, then we have

$$N(T) = \frac{1}{2\pi} T \log T - \frac{1 + \log 2\pi}{2\pi} T + O(\log T).$$

Let $N_0(T)$ denote the number of zeros of $\zeta(s)$ on the interval $\sigma = 1/2$, $0 < t < T$. Selberg (1942) obtained the impressive result

$$N_0(T) > cT \log T.$$

E. C. Titchmarsh (1936) showed that there exist 1041 zeros of $\zeta(s)$ in the domain $0 < \sigma < 1$, $0 < t < 1468$ and that all lie on the line $\sigma = 1/2$. Computers have provided further results that seem to justify the Riemann hypothesis. For example, it has been calculated that there are 75,000,000 zeros of $\zeta(s)$ in the domain $0 < \sigma < 1$, $0 < t < 32,585,736.4$ and that all are simple zeros and lie on the line $\sigma = 1/2$ (R. P. Brent, *Math. Comp.*, 33 (1979)). N. Levinson proved in 1974 by another method that at least one-third of the zeros of the Riemann zeta function are on the line $\sigma = 1/2$. The minimum of the modulus of the imaginary part of the zeros with $\sigma = 1/2$ is $t = 14.13 \dots$

C. Twin Primes

Let p_n be the n th prime. We know from the prime number theorem that $p_n \sim n \log n$; more precisely, $p_n = n \log n + n \log \log n + O(n)$. A pair of primes differing only by 2 are called **twin primes**. It is still unknown whether there exist infinitely many twin primes. There exist infinitely many n satisfying $p_{n+1} - p_n < c \log p_n$ (P. Erdős, 1940). Suppose that $\zeta(1/2 + it) = O(|t|^c)$. A. E. Ingham (1937) proved that

$$p_{n+1} - p_n < p_n^\Theta, \quad \Theta = (1 + 4c)/(2 + 4c) + \varepsilon,$$

by using the following density theorem related to the zeros of $\zeta(s)$: If we denote by $N(\alpha, T)$ the number of zeros of $\zeta(s)$ in the domain $\alpha \leq \sigma \leq 1$, $0 \leq t \leq T$ ($1/2 \leq \alpha \leq 1$), then there is a positive constant c such that $N(\alpha, T) = O(T^{2(1+2c)(1-\alpha)} \log^5 T)$. The **Lindelöf hypothesis** asserts that the constant c can be made arbitrarily small. If the Riemann hypothesis holds, then the Lindelöf hypothesis also holds. It is clear that we can substitute $1/6 + \varepsilon$ ($\varepsilon > 0$) for c , ε being arbitrarily small. W. Haneke

(1963) showed that c can be replaced by $6/37 + \varepsilon$, and consequently that $\Theta \leq 61/98 + \varepsilon$. D. R. Heath-Brown and H. Iwaniec (1979) proved that $\Theta \leq 11/20 + \varepsilon$ by using the \dagger sieve method and the zero density theorem of L -functions (Section E). R. A. Rankin (1935) proved that

$$p_{n+1} - p_n > c \log p_n \log \log p_n \log \log \log p_n \times (\log \log \log p_n)^{-2}$$

holds for infinitely many n . If we denote by $\pi_2(x)$ the number of primes $p \leq x$ such that $p + 2$ is also a prime, then it has been conjectured by Hardy and Littlewood (*Acta Math.*, 44 (1922)) that

$$\pi_2(x) \sim C \int_2^x \frac{du}{\log^2 u}$$

as $x \rightarrow \infty$, where

$$C = 2 \prod_{p>2} \left\{ 1 - \frac{1}{(p-1)^2} \right\} = 1.32032 \dots$$

The numerical evidence provided by the computation $\pi_2(10^9) = 3424506$ (Brent, *Math. Comp.*, 28 (1974)) tends to indicate the truth of this conjecture. At present, $76 \cdot 3^{139} \pm 1$ seems to be the largest known pair of twin prime numbers (H. C. Williams and C. R. Zarnke, *Math. Comp.*, 26 (1972)).

D. Prime Numbers in Arithmetic Progressions

Let k be a positive integer, $\chi(n)$ be a residue character modulo k (\rightarrow 295 Number-Theoretic Functions D), and $L(s, \chi) = \sum_{n=1}^{\infty} \chi(n)n^{-s}$ ($\sigma > 1$) be the \dagger Dirichlet L -function. The function $L(s, \chi)$ of s defined by this series can be extended to an analytic function in the whole complex plane in the same way as the Riemann zeta function. In particular, when χ is the principal character, then $L(s, \chi)$, thus extended, is a meromorphic function whose only pole is situated at $s = 1$ and is simple; otherwise the function $L(s, \chi)$ is holomorphic on \mathbb{C} .

Using this function $L(s, \chi)$ and in connection with his research concerning the \dagger class numbers of quadratic forms, P. G. L. Dirichlet (1837) proved that there exist infinitely many primes in the arithmetical progression $l, l+k, l+2k, \dots$, where l is the initial term and k a common difference relatively prime to l . This result is called the **Dirichlet theorem** (or **prime number theorem for arithmetic progressions**).

Suppose that α runs over all integral ideals in a \dagger quadratic number field K of discriminant d . Then the \dagger Dedekind zeta function $\zeta_K(s)$ of K is defined by $\sum (N\alpha)^{-s}$ for $\sigma > 1$. By virtue of the decomposition law of prime ideals (\rightarrow 347 Quadratic Fields C), we have $\zeta_K(s) = \zeta(s)L(s, \chi)$, where $\chi(n) = (d/n)$ is the \dagger Kronecker symbol.

Utilizing $\zeta_K(s)$, we obtain formulas concerning the \dagger class number $h(d)$ of the field K . If $d > 0$, then $h(d) = (\sqrt{d/2\log \varepsilon})L(1, \chi)$, where ε is the \dagger fundamental unit of K . On the other hand, if $d < 0$, then $h(d) = (w\sqrt{-d/2\pi})L(1, \chi)$, where w denotes the number of the roots of unity contained in K . It follows that $L(1, \chi) \geq 2\log((1 + \sqrt{5}/2)/\sqrt{|d|})$. Let χ be a character modulo k induced by a primitive character χ^0 . Since we have $L(s, \chi) = L(s, \chi^0) \prod_{p|k} (1 - \chi^0(p)p^{-s})$, it can be shown that $L(1, \chi) \neq 0$ for a real character χ . It is easy to prove that $L(1, \chi) \neq 0$ for a complex character χ . These statements then lead to the Dirichlet theorem. The proof was simplified by H. N. Shapiro (1951). Besides Landau's three proofs for $L(1, \chi) \neq 0$ for real character χ (1908), there are elegant proofs by T. Estermann (1952), Selberg (1949), and others. For a character $\chi \bmod k$, we always have $L(1, \chi) = O(\log k)$, while $L(1, \chi)^{-1} = O(\log k)$ with one possible exception, which may occur only if χ is a real character. Even in this case, we have $L(1, \chi)^{-1} = O(k^\varepsilon)$ (where $\varepsilon > 0$ is arbitrary, but O depends on ε). This result was obtained by K. L. Siegel (1934) from his study concerning class numbers of imaginary quadratic number fields. His proof was simplified by Estermann (1948) and S. D. Chowla (1950). The importance of the prime number theorem for arithmetic progressions was revealed when it was applied to the Goldbach problem (\rightarrow 4 Additive Number Theory C). Concerning this problem, the manner in which the remainder term depends on the modulus k became an object of investigation. The Page-Siegel-Walfisz theorem is convenient to use: Denote by $\pi(x; k, l)$ the number of primes not exceeding x and of the form $ky + l$, where $(k, l) = 1$. If $x \geq \exp(k^\varepsilon)$ (where $\varepsilon > 0$ is arbitrary), then we have

$$\pi(x; k, l) = \frac{\text{Li } x}{\varphi(k)} + O\left(\frac{x e^{-c(\varepsilon)\sqrt{\log x}}}{\varphi(k)}\right).$$

Further research on the distribution of zeros of $L(s, \chi)$ is necessary for the study of $\pi(x; k, l)$ when x takes smaller values. If χ is a nonprincipal real character, then $L(s, \chi)$ may have at most one real zero β_1 around 1; this is called **Siegel's zero**. Because of this fact, when x is small we are unable to obtain any formula to indicate the uniform distribution of primes. However, we have the following deep result, obtained by E. Fogels (1962). For a given positive ε , there exist $c_0(\varepsilon)$ and $c(\varepsilon)$ such that $\pi(x; k, l) > c(\varepsilon)x/\varphi(k)k^\varepsilon \log x$, provided that $x \geq k^{c_0(\varepsilon)}$. On the other hand, Titchmarsh (1930), using the \dagger sieve method, obtained $\pi(x; k, l) = O(x/\varphi(k) \log x)$ for $x \geq k^{c_0}$. A theorem of this type is called the **Burn-Titchmarsh theorem** (\rightarrow Section E). Fogels's theorem is based on the following theorem by Yu. V. Linnik (1947) and

K. Prachar (1957), which is an extension of Page's theorem (1935): We let δ be the function defined by $\delta = 1 - \beta_1$ if $L(s, \chi)$ has an exceptional real zero β_1 , and $\delta = c_1/\log(k(|t| + 2))$ otherwise (where c_1 is a suitably small number). If we denote by β the real part of any zero ($\neq \beta_1$) of $L(s, \chi)$, then the theorem states that

$$\beta \leq 1 - \frac{c_1}{\log(k(|t| + 2))} \log\left(\frac{c_1 e}{\delta \log(k(|t| + 2))}\right),$$

provided that $\delta \log(k(|t| + 2)) \leq c_1$. Linnik called this result the **Deuring-Heilbronn phenomenon**. Using this theorem and the zero density theorem, Linnik (1944) proved that $p(k, l) \ll k^L$, where $p(k, l)$ is the least prime in the arithmetic progression $l, l + k, l + 2k, \dots$ and L is a constant. We call L **Linnik's constant**. M. Jutila (1977) and Chen Jing-Run (1979) proved that $L \leq 80$ and $L \leq 17$, respectively.

Let s be positive, b_j, z_j ($1 \leq j \leq s$) be complex, and l, m be real numbers satisfying $\max |z_j| \geq 1$, $l \geq s$, and $m \geq 0$. Under these conditions P. Turán (1953) obtained the following fundamental theorem, which is called the **power sum theorem**:

$$\max_{m \leq r \leq l+m} |b_1 z_1^r + \dots + b_s z_s^r| \geq \left(\frac{l}{8e(l+m)}\right)^l \min_{1 \leq j \leq s} |b_1 + \dots + b_j|.$$

This theorem is effective in research on the distribution of zeros of zeta functions. Based on this new method, Turán (1961), S. Knapowski (1962), and Fogels (1965) reached the results cited above.

Another method of research, considered to be a new sieve method, on the distribution of primes was introduced by Selberg and A. I. Vinogradov. This method was followed by W. B. Jurkat and H. E. Richert (1965). Linnik, A. Rényi (1950), and E. Bombieri (1965) founded still another method, called the **large sieve method**, by which P. T. Batemann, Chowla, and P. Erdős studied the value of $L(1, \chi)$.

E. Sieve Method

Let A be a set of integers, and P a set of primes. For each $p \in P$, let Ω_p be a set of residues mod p , and $\omega(p)$ the number of residues belonging to Ω_p . The sieve method is a device for estimating (from above or below) the number of integers n belonging to the set $S(A, P, \Omega_p) = \{n | n \in A, n \bmod p \notin \Omega_p \text{ for } p \in P\}$. The combinatorial methods of the Brun, Busstab, and Richert sieves are interesting and efficient but quite complicated. Here, we shall briefly describe the **Selberg sieve**. As an example, denote by $S(x; q, l)$ the number of n satisfying $n \equiv l \bmod q$, $n \leq x$, $(n, D) = 1$, where q

is a prime not exceeding x , $z \leq x$, $D = \prod_{p \leq z} p$, and $(l, q) = 1$; then

$$S(x; q, l) = \sum_{\substack{n \leq x \\ n \equiv l \pmod{q}}} \sum_{d|(n, D)} \mu(d) \leq \sum_{\substack{n \leq x \\ n \equiv l \pmod{q}}} \left(\sum_{d|(n, D)} \lambda_d \right)^2,$$

where $\lambda_1 = 1$ and λ_d is arbitrary for $d > 1$. Thus the problem reduces to the optimization of λ_d . Proceeding in this manner, C. Hooley (1967) and Y. Motohashi (1975), using analytic methods, obtained certain deep results relating to the Brun-Titchmarsh theorem. Using the large sieve, H. L. Montgomery and R. C. Vaughan (1973) expressed this theorem in a precise form: $\pi(x, q, l) < 2x/\varphi(q) \log(x/q)$ for all $q < x$.

Let n_1, n_2, \dots, n_Z be Z natural numbers not exceeding N , and $Z(p, a)$ the number of n_j 's such that $n_j \equiv a \pmod{p}$. Rényi (1950) proved that

$$\sum_{p \leq \sqrt[3]{N/12}} p \sum_{a=1}^{p-1} \left\{ Z(p, a) - \frac{Z}{p} \right\}^2 \leq 2NZ.$$

Set $a_n = 1$ for $n = n_j$ and $a_n = 0$ otherwise, and set $S(\alpha) = \sum_{n \leq N} a_n \exp(2\pi i n \alpha)$; then

$$p \sum_{a=1}^{p-1} \left\{ Z(p, a) - \frac{Z}{p} \right\}^2 = \sum_{a=1}^{p-1} \left| S\left(\frac{a}{p}\right) \right|^2.$$

In view of this simple fact, Bombieri (1965) and P. X. Gallagher (1968) extended the problem and proved that, in general,

$$\sum_{q \leq Q} \sum_{\substack{a=1 \\ (a, q)=1}}^q \left| \sum_{\substack{M < n \leq M+N \\ a_n \exp\left(2\pi i \frac{a}{q} n\right)}} a_n \right|^2 \leq (N + 2Q^2) \sum_{M < n \leq M+N} |a_n|^2.$$

Similar results can be obtained for character sums $\sum_{M < n \leq M+N} a_n \chi(n)$. In this connection Montgomery proved that

$$S(\{n; M < n \leq M+N\}; P, \Omega_p) \leq (N + 2Q^2) \left\{ \sum_{q \leq Q} \prod_{p|q} \frac{\omega(p)}{p - \omega(p)} \right\}^{-1},$$

where

$$P(z) = \prod_{\substack{p \in P \\ p \leq z}} p.$$

Using these methods, the following estimate was obtained by Bombieri:

$$\sum_{q \leq x^{1/2}(\log x)^{-B}} \max_{y \leq x} \max_{\substack{l \\ (q, l)=1}} \left| \pi(y, q, l) - \frac{1}{\varphi(q)} \int_2^y \frac{du}{\log u} \right| \ll x(\log x)^{-A},$$

where A is arbitrary and B is a certain func-

tion of A (Vaughan). These methods, known collectively as the **large sieve**, were first directed toward proving the **Rényi theorem** stating that every sufficiently large even integer can be represented as the sum of a prime and an almost prime integer (M. B. Barban). Afterward, combining Richert's sieve with this large sieve, Chen Jing-Run (1973) improved this result to a remarkable degree (\rightarrow 4 Additive Number Theory C). Several applications of Bombieri's theorem have been demonstrated by P. D. T. A. Elliot and H. Halberstam (1966): e.g., the estimation of the number of representations of n as $p + x^2 + y^2$ (Hooley, Linnik) and the estimation of $\sum_{p \leq n} d(n-p)$ (Linnik, B. M. Bredihin).

Let $N(\alpha, T, \chi)$ denote the number of zeros of $L(s, \chi)$ in the rectangle $\alpha \leq \sigma \leq 1$, $|t| \leq T$. Combining the large sieve with new Fourier integral techniques and the Turán † power-sum method, Gallagher (1970) proved that there exists a positive constant c satisfying

$$\sum_{\chi \pmod{Q}} N(\alpha, T, \chi) \ll (QT)^{c(1-\alpha)},$$

$$\sum_{q \leq Q} \sum_{\chi \pmod{q}} N(\alpha, T, \chi) \ll (QT)^{c(1-\alpha)}.$$

Similar results were also obtained by G. Halasz and Montgomery (1969) using another method, which was further exploited by Jutila, M. H. Huxley, and Iwaniec. In particular, Heath-Brown and Iwaniec (1979) deduced that $\pi(x+y) - \pi(x) \geq cy(\log x)^{-1}$ if $y \geq x^{1/20+\varepsilon}$. Combined with the Deuring-Heilbronn phenomenon, the zero density theorem above not only establishes the Linnik theory, but also yields the following result, due to K. A. Rodoskiĭ, T. Tatzuzaawa, and A. I. Vinogradov:

$$\pi(x; q, l) = \frac{1}{\varphi(q)} \int_2^x \frac{du}{\log u} - E \frac{\chi_1(l)}{\varphi(q)} \int_2^x \frac{u^{\beta-1}}{\log u} du + O\left(\frac{1}{\varphi(q)} x^{1-\frac{c}{\Delta}}\right)$$

if $x \geq \exp(\log q \log \log q)$, where $E = 1$ or 0 according as Siegel's zero β exists or not, and where

$$\Delta = \text{Max}(\log q, (\log x)^{2/5} (\log \log x)^{1/5}).$$

Throughout these researches, estimates of the type

$$\sum_{\chi \pmod{q}} \left| L\left(\frac{1}{2} + it, \chi\right) \right|^4 \ll \varphi(q) \{|t| + 2\} \log^c \{q(|t| + 2)\}$$

and

$$\sum_{\chi \pmod{q}} \int_{-T}^T \left| L\left(\frac{1}{2} + it, \chi\right) \right|^4 dt \ll \varphi(q) (T+2) \log^c q(T+2)$$

are of great importance and have been studied by A. F. Lavrik (1968), Linnik (1961), Huxley (1972), and K. Ramachandra (1975).

F. The Prime Ideal Theorem in Algebraic Number Fields

In an algebraic number field of finite degree, the prime number theorem is replaced by the **prime ideal theorem** (T. Mitsui, 1956, Fogels, 1962), which is based on the theory of the Hecke $\dagger L$ -function (E. Hecke, 1917; Landau, 1918). Let K be a finite Galois extension over an algebraic number field k of finite degree. Suppose that \mathfrak{p} is a prime ideal of k and is not ramified in K . The \dagger Frobenius automorphism of a prime divisor of \mathfrak{p} in K determines a conjugate class C of the Galois group of K/k . Let $\pi(x; C)$ denote the number of prime ideals in k associated with the class C in the above sense and whose norm does not exceed x . Then we have

$$\pi(x, C) = \frac{h(C)}{[K:k]} \text{Li } x + O(xe^{-c\sqrt{\log x}}),$$

where $h(C)$ is the number of elements contained in C and c is a positive constant depending on K/k . This is an extension of Chebotarev's theorem (E. Artin, 1923).

124 (XI.8) Distribution of Values of Functions of a Complex Variable

A. General Remarks

Suppose that we are given a function $f: A \rightarrow B$ and that the variables z, w take on values in A, B , respectively. A **value distribution** of $f(z)$ is a set of points z where $f(z)$ takes on a certain value w (called w -points of $f(z)$). Value distribution theory is usually concerned with the study of value distributions of complex \dagger analytic functions. Value distribution theory has been developed extensively and deeply for the case where A is the finite plane $|z| < \infty$ or the unit disk $|z| < 1$ and B is the extended complex plane $|w| \leq \infty$, and there are many interesting results in this case (\rightarrow 272 Meromorphic Functions). Value distributions for analytic functions on general domains or on Riemann

surfaces or of several complex variables have also been studied.

B. The Case of $|z| < R \leq \infty$

For a †transcendental entire function $f(z)$, every value (including ∞) is a value of the †cluster set of $f(z)$ at the point at infinity (†Weierstrass's theorem). This theorem was improved in the following way by E. Picard in 1879: A transcendental entire function $f(z)$ has an infinite number of w -points for any finite value w except for at most one finite value (†Picard's theorem). A value w for which the w -points are at most finite is said to be a Picard's exceptional value. E. Borel gave a precise form of this theorem, taking into consideration the order of a function, and G. Julia proved the existence of Julia's directions (\rightarrow 272 Meromorphic Functions; 429 Transcendental Entire Functions). After other results in value distribution theory had been obtained by J. Hadamard, G. Valiron, and others, R. Nevanlinna published an important work in 1925 in which he established the so-called **Nevanlinna theory** of meromorphic functions in $|z| < R \leq \infty$, unifying results obtained up until that time, and which became the starting point of the subsequent value distribution theory (\rightarrow 272 Meromorphic Functions). T. Shimizu and L. V. Ahlfors gave a geometric meaning to the Nevanlinna †characteristic function $T(r)$. Ahlfors established the theory of covering surfaces by metricotopological methods in 1935, and applied it to obtain the Nevanlinna theory and many other results on meromorphic functions. This theory revealed that the topological meaning of the number 2 of Picard's exceptional values is closely related to the †Euler characteristic 2 of the sphere. H. Selberg established the value distribution theory of †algebroidal functions and gave a precise form of G. Rémoundos's theorem, which corresponds to Picard's theorem for algebroidal functions.

Moreover, as an extension of the value distribution theory of meromorphic functions, there is the theory of holomorphic curves or of systems of entire functions. Let f_0, f_1, \dots, f_n ($n \geq 1$) be entire functions without common zeros for all and for which $f_0 : f_1 : \dots : f_n$ is not constant. Put $f = (f_0, f_1, \dots, f_n)$. This is a reduced representation of a nonconstant holomorphic curve $f: C \rightarrow P^n(C)$. For $\alpha = (\alpha_0, \alpha_1, \dots, \alpha_n) \in C^{n+1} - \{0\}$, considering the zeros of

$$(\alpha, f) = \alpha_0 f_0 + \alpha_1 f_1 + \dots + \alpha_n f_n \quad (\neq 0),$$

we can extend Picard's theorem and the Nevanlinna theory for meromorphic functions to holomorphic curves.

We define the characteristic function $T(r) (= T(r, f))$ as

$$T(r) = \frac{1}{2\pi} \int_0^{2\pi} \log |f| d\theta \Big|_{r_0}^r,$$

$$|f| = (|f_0|^2 + |f_1|^2 + \dots + |f_n|^2)^{1/2},$$

where r_0 is a fixed positive number and $A(r)|_{r_0}^{r_0} = A(r) - A(r_0)$. Using a bivector $[ff'] = (f_i f'_j - f_j f'_i)$ of f and $f' = (f'_0, f'_1, \dots, f'_n)$, we have another representation of $T(r)$:

$$T(r) = \frac{1}{\pi} \int_{r_0}^r \frac{ds}{s} \int_0^s \int_0^{2\pi} \frac{|[ff']|^2}{|f|^2} t dt d\theta.$$

f is transcendental when $\lim T(r)/\log r = \infty$, and the number

$$\lambda = \dim \{(c_0, c_1, \dots, c_n) \in C^{n+1} \mid c_0 f_0 + c_1 f_1 + \dots + c_n f_n = 0\}$$

is the degeneracy index of f . It holds that $0 \leq \lambda \leq n-1$. As an extension of Picard's theorem, J. Dufresnoy stated that, for transcendental holomorphic curves f and among α in general position, the zeros of (α, f) are infinite except for at most $n + \lambda + 1$. X ($\subset C^{n+1} - \{0\}$) is in general position when any p ($\leq n+1$) vectors in X are linearly independent. In connection with this result, there are many Picard-type theorems, and when $\lambda > 0$, there are some particular results for holomorphic curves. H. Cartan, H. and J. Weyl, and Ahlfors extended the Nevanlinna theory to holomorphic curves as follows. For $\alpha = (\alpha_0, \alpha_1, \dots, \alpha_n) \in C^{n+1} - \{0\}$, we put

$|\alpha|$ = the length of α ,

$$|\alpha f| = |(\alpha, f)|/|\alpha||f|, \quad (\alpha, f) \neq 0,$$

and define the proximity function

$$m(r, \alpha) = \frac{1}{2\pi} \int_0^{2\pi} \log \frac{1}{|\alpha f|} d\theta$$

and the counting function

$$N(r, \alpha) = \frac{1}{2\pi} \int_0^{2\pi} \log |(\alpha, f)| d\theta \Big|_{r_0}^r.$$

Then we have the first main theorem: For any α for which $(\alpha, f) \neq 0$,

$$T(r) + m(r_0, \alpha) = N(r, \alpha) + m(r, \alpha);$$

and the second main theorem: When $\lambda = 0$, for any $\alpha_1, \alpha_2, \dots, \alpha_q$ in general position,

$$(q - n - 1)T(r) < \sum_{j=1}^q N(r, \alpha_j) + S(r),$$

where $S(r) = O(\log r T(r))$ except for r in a set e of finite logarithmic measure, (i.e., $\int_e d \log r < \infty$). For $\lambda > 0$, it is conjectured that “ $q - n - 1$ ” can be changed into “ $q - n - \lambda - 1$.” This is unsolved except for some special cases.

Some results show relations between exceptional values and the order as in the case of meromorphic functions. Nevanlinna theory has been extended to the associated curves f^p ($p = 1, 2, \dots, n; f^1 = f$) for $\lambda = 0$, and there have been attempts to extend this theory of holomorphic curves even further by generalizing domains or ranges.

C. The Case of General Domains

The value distributions of meromorphic functions defined in a general domain or an open Riemann surface depend on the function-theoretic "size" of the set of singularities (\rightarrow 169 Function-Theoretic Null Sets) or the type of the Riemann surface (\rightarrow 367 Riemann Surfaces). For instance, we have the following theorem of Picard type: A single-valued meromorphic function with a set of singularities of \dagger logarithmic capacity zero takes on every value infinitely often in any neighborhood of each singularity except for at most an F_σ -set of values of logarithmic capacity zero (**Hällström-Kametani theorem**). For the study of value distribution at general singularities, it is useful to investigate cluster sets (\rightarrow 62 Cluster Sets). In order to generalize the Nevanlinna theory to the case of general domains or Riemann surfaces, we take their exhaustions depending on a real parameter r and define the \dagger counting function and so on (\rightarrow 272 Meromorphic Functions). G. J. Hällström established the value distribution theory of meromorphic functions defined in the complementary domain D of a compact set E of logarithmic capacity zero by taking $D_r = \{z \mid v(z) < r\}$ as the exhaustion of D , where $v(z)$ denotes the Evans potential for E , i.e., $v(z)$ is the potential corresponding to a positive mass distribution μ on E of total mass 1 which tends to $+\infty$ as z tends to any point of E . Thus the number of Picard's exceptional values is not greater than $2 + \xi$, where $\xi = \limsup_{r \rightarrow \infty} F(r)/T(r)$ with $-n(r)$ = the Euler characteristic of D_r and $F(r) = \int_0^r n(r) dr$ (Hällström-Tsuji theorem). J. Tamura, L. Sario, and others studied the value distributions of meromorphic functions defined on Riemann surfaces. Sario succeeded in extending the Nevanlinna theory to analytic mappings of a Riemann surface \mathfrak{R} into another Riemann surface \mathfrak{S} by introducing a suitable metric in \mathfrak{S} to define the \dagger proximity function.

In the Nevanlinna theory on general domains, we must sometimes impose conditions that the functions must satisfy in order to obtain a concrete conclusion, for instance, the condition that ξ be finite in the Hällström-Tsuji theorem. But it is also important to determine the domains where some result can

be obtained without imposing any additional conditions on the functions. The Hällström-Kametani theorem is an example. Although the set of exceptional values in this theorem cannot be replaced generally by a smaller set than an F_σ -set of logarithmic capacity zero, we have the following theorem: Let E be a \dagger Cantor set with successive ratios $\xi_n = 2l_n/l_{n-1}$, where l_n denotes the length of the segments that remain after repeating n times the process of deleting an open segment from the middle of another segment. Then any single-valued meromorphic function with E as the set of singularities has at most 3 Picard's exceptional values if $\lim_{n \rightarrow \infty} \xi_n = 0$ and at most 2 if $\xi_{n+1} = o(\xi_n^2)$ (L. Carleson, K. Matsumoto). By weakening the conditions on E , one can get several improvements of this result.

125 (XII.7) Distributions and Hyperfunctions

A. History

The advancement of analysis, particularly in the field of partial differential equations and harmonic analysis, necessitated the generalization of the notion of functions and derivatives. For instance, "functions" such as Dirac's \dagger delta function and \dagger Heaviside's function were used by physicists and engineering scientists

Distributions and Hyperfunctions

even though the former is not a function and the latter is not a differentiable function in the classical sense. The finite parts of divergent integrals, used by J. Hadamard to investigate the fundamental solutions of wave equations (1932), and the Riemann-Liouville integrals due to M. Riesz (1938) were the notions that eventually led to the theory of generalized functions. The rudiments of the idea of distribution, however, can also be found in other earlier works. S. Bochner (1932) and T. Carleman (1944) discussed the Fourier transforms of locally integrable functions on the reals with growth as large as a polynomial. S. L. Sobolev introduced the notion of generalized derivative and also of generalized solution of differential equations by means of integration by parts in studying the Cauchy problem for hyperbolic equations (1936); J. Leray (1934), K. O. Friedrichs (1939), and C. B. Morrey, Jr. (1940) also discussed generalized derivatives. On the other hand, L. Fantappiè (1943) investigated analytic functionals that are elements of the dual of the space of analytic functions and applied them to the theory of partial differential equations. Based on a systematic generalization of these investigations, L. Schwartz [1] established the theory of distributions (1945), which not only provided a mathematical foundation for a number of formal methods that had been used in mathematical physics but also gave new and powerful tools for the theories of differential equations (L. Hörmander [2]) and \dagger Fourier transforms. Furthermore, it has been applied to \dagger representation theory of locally compact groups, the theory of probability, and the theory of manifolds (G. de Rham [3]). As will be seen in Section B, distributions are defined as continuous \dagger functionals on a certain function space, and it is essential to select a function space appropriate to the problems concerned. For this reason, I. M. Gel'fand and G. E. Shilov defined various classes of generalized functions [4] as a natural extension of Schwartz's theory. In this direction there are also various classes of ultradistributions introduced by C. Roumieu [5] and A. Beurling.

Another but completely different approach was given by M. Sato [6, 15] in the form of the theory of hyperfunctions (1958). Intuitively a hyperfunction is the sum of (ideal) boundary values of holomorphic functions at the real axis. We obtain in this way an ultimate class of localizable generalized functions. Sato employed the relative (or local) cohomology theory to define the "boundary values" and to prove their localizing property. Such an algebraic approach to generalized functions led naturally to an algebraic treatment of systems of linear partial differential operators [7], called **algebraic analysis** by comparison with

algebraic geometry. Independently, Hörmander established a similar theory for distributions using Fourier analysis (\rightarrow 274 Micro-local Analysis).

B. Definition of Distributions

Let $\varphi(x)$ be a complex-valued function of $x = (x_1, \dots, x_n)$ defined on an open set Ω in the n -dimensional Euclidean space \mathbf{R}^n . By the **support** (or **carrier**) of φ , denoted by $\text{supp } \varphi$, we mean the \dagger closure of $\{x \mid \varphi(x) \neq 0\}$ in Ω . For multi-indices p , i.e., n -tuples $p = (p_1, \dots, p_n)$ of nonnegative integers, we set $|p| = p_1 + \dots + p_n$. For a function $\varphi(x)$ of class $C^{|p|}$, we write

$$D^p \varphi = \frac{\partial^{|p|} \varphi(x)}{\partial x_1^{p_1} \dots \partial x_n^{p_n}}. \quad (1)$$

In particular, $D^{(0, \dots, 0)} \varphi = \varphi$. To indicate the variables x we shall adopt the notation D_x^p .

$\mathcal{D}(\Omega)$ denotes the set of all complex-valued functions of class C^∞ defined on Ω with \dagger compact support, which is a \dagger linear space under the usual addition and scalar multiplication in function spaces. A sequence $\{\varphi_m\}$ in $\mathcal{D}(\Omega)$ is said to converge to 0 (the function identically equal to zero) as $m \rightarrow \infty$, denoted by $\varphi_m \Rightarrow 0$, if there exists a compact set E in Ω such that E contains $\text{supp } \varphi_m$ for every m , and for every p , $\{D^p \varphi_m\}$ converges uniformly to 0 as $m \rightarrow \infty$.

We sometimes abbreviate $\mathcal{D}(\Omega)$ either as \mathcal{D} or, when we want to indicate the variables x , as \mathcal{D}_x .

A complex-valued \dagger linear functional T defined on $\mathcal{D}(\Omega)$ is called a **distribution on Ω** if it is continuous on $\mathcal{D}(\Omega)$, i.e., $\varphi_m \Rightarrow 0$ implies $T(\varphi_m) \rightarrow 0$. The set of all distributions on Ω is denoted by $\mathcal{D}'(\Omega)$ (or \mathcal{D}'). For distributions S and T , the sum $S + T$ and scalar multiple αT are defined by $(S + T)(\varphi) = S(\varphi) + T(\varphi)$ and $(\alpha T)(\varphi) = \alpha T(\varphi)$, respectively, which are also distributions. Hence $\mathcal{D}'(\Omega)$ is a \dagger linear space.

C. Examples of Distributions

(1) Let $f(x)$ be a \dagger measurable and \dagger locally integrable function on Ω . Then a distribution T_f is defined by $T_f(\varphi) = \int \varphi(x) f(x) dx$. Here dx is the \dagger Lebesgue measure and the domain of integration is Ω (in fact, $\text{supp } \varphi$). If $T_f = T_g$, then $f(x) = g(x)$ \dagger almost everywhere. Thus we can identify the distribution T_f with the corresponding function f , and sometimes T_f will be denoted simply by f .

(2) Let μ be a \dagger Radon measure on Ω , i.e., a complex-valued \dagger regular completely additive set function on the \dagger Borel sets in Ω . Then a distribution T_μ is defined by $T_\mu(\varphi) = \int \varphi(x) \mu(dx)$. Example (1) is a special case where

$\mu(dx) = f(x)dx$. Two Radon measures μ and ν coincide if $T_\mu = T_\nu$. If the measure is concentrated at the origin, then $T_\mu(\varphi) = c\varphi(0)$, denoted by $c\delta$, and δ is called **Dirac's distribution**.

Sometimes δ is denoted by δ_x , $\delta_{(x)}$, or $\delta(x)$ to indicate that it operates on functions of x . A distribution $T \in \mathcal{D}'(\Omega)$ is a measure if and only if $T(\varphi_m) \rightarrow 0$ whenever the supports $\text{supp } \varphi_m$ of a sequence $\varphi_m \in \mathcal{D}(\Omega)$ are in a fixed compact set in Ω and φ_m converges uniformly to zero. A distribution T is called a **positive distribution** if $T(\varphi) \geq 0$ for any $\varphi \in \mathcal{D}(\Omega)$ that has non-negative values at all points x in Ω . Every positive distribution is equal to a T_μ corresponding to a positive measure μ .

(3) For given p the distribution $\delta^{(p)}$ is defined by $\delta^{(p)}(\varphi) = (-1)^{|p|} D^p \varphi(0) \cdot \delta^{(0, \dots, 0)} = \delta$.

(4) Let $g(x)$ be a function defined but not integrable on an interval (a, b) , and assume that for any positive number ε it is integrable on $(a + \varepsilon, b)$. Moreover, assume that

$$g(x) = \sum_{v=1}^n A_v (x-a)^{-\lambda_v} + h(x),$$

where $\text{Re } \lambda_v > 1$, λ_v is not an integer, and $h(x)$ is integrable on (a, b) . Then

$$\int_{a+\varepsilon}^b g(x) dx - \sum A_v (\lambda_v - 1)^{-1} \varepsilon^{1-\lambda_v} = F(\varepsilon)$$

tends to a finite value as $\varepsilon \rightarrow 0$. This limit is called the **finite part** (in French *partie finie*) of the integral $\int_a^b g(x) dx$, denoted by $\text{Pf} \int_a^b g(x) dx$:

$$\begin{aligned} \text{Pf} \int_a^b g(x) dx \\ = - \sum_v \frac{A_v}{\lambda_v - 1} (b-a)^{1-\lambda_v} + \int_a^b h(x) dx. \end{aligned}$$

In the same way, for every $\varphi \in \mathcal{D}(\mathbf{R}^1)$, $T(\varphi) = \text{Pf} \int_a^b g(x) \varphi(x) dx$ is defined, and T is a distribution which will be denoted by $\text{Pf} g$, and which is frequently called a **pseudofunction**. This notion is extended to the n -dimensional case and used to express the fundamental solutions (\rightarrow Section EE; Appendix A, Table 15.V) of \dagger hyperbolic partial differential equations.

D. Localization of Distributions

Let Ω' be an open subset of Ω . Every function $\varphi \in \mathcal{D}(\Omega')$ can be extended to a function $\bar{\varphi} \in \mathcal{D}(\Omega)$ by setting $\bar{\varphi}(x) = 0$ for $x \notin \Omega'$. Thus if $T \in \mathcal{D}'(\Omega)$, then a distribution $S \in \mathcal{D}'(\Omega')$ is defined by $S(\varphi) = T(\bar{\varphi})$ for every $\varphi \in \mathcal{D}(\Omega')$, and S is called the **restriction** of T to Ω' . Two distributions T and S are said to be equal in Ω' if their restrictions to Ω' are equal. If every point in Ω has a neighborhood where $T = S$, then $T = S$. In this sense a distribution is determined completely by its local data, although the

notion of pointwise value, having exact meaning for functions, has no meaning for distributions. Moreover, we can construct a distribution with given local data in the following way: Suppose that an \dagger open covering $\{\Omega_j\}$ of Ω and a set of distributions $T_j \in \mathcal{D}'(\Omega_j)$ are given and that T_j and T_k are equal in $\Omega_j \cap \Omega_k$ for any j and k . Then there exists a unique distribution $T \in \mathcal{D}'(\Omega)$ such that $T = T_j$ in Ω_j for each j . (Define $T(\varphi) = \sum T_j(\alpha_j \varphi)$ for a \dagger partition of unity $\{\alpha_j\}$ subordinate to $\{\Omega_j\}$). Namely, the distributions \mathcal{D}' form a \dagger sheaf of linear spaces over \mathbf{R}^n . It is not \dagger flabby but is soft, i.e., for any distribution T defined on a neighborhood of a closed set F in \mathbf{R}^n , there is a distribution on \mathbf{R}^n that coincides with T on a neighborhood of F .

For each distribution $T \in \mathcal{D}'(\Omega)$ there is a largest open subset Ω' of Ω on which T vanishes. Its complement is called the **support** (or **carrier**) of T and is denoted by $\text{supp } T$. The support of the distribution given in example (1) coincides with that of the function f . The support of $\delta^{(p)}$ is the origin.

E. Derivatives of Distributions

In example (1) in Section C, if $f(x)$ is a function of class C^k , then by integration by parts $T_{D^p f}(\varphi) = (-1)^{|p|} T_f(D^p \varphi)$ for $|p| \leq k$. The right-hand side defines a distribution even if f is not differentiable. In view of this example, we define **derivatives** $D^p T$ of any distribution T by

$$(D^p T)(\varphi) = (-1)^{|p|} T(D^p \varphi), \quad \varphi \in \mathcal{D}_x. \quad (2)$$

Any distribution is infinitely differentiable. Any locally integrable function is infinitely differentiable in the sense of distributions, and its derivatives $D^p T_f$ are called **distribution derivatives** (or **generalized derivatives** or **weak derivatives**).

For example: (1) $D^p \delta = \delta^{(p)}$; (2) (1-dimensional case) $dx_+/dx = 1$, $d1/dx = \delta$, where $x_+ = \max(x, 0)$ and $1(x)$ is **Heaviside's function**, which is equal to 1 for $x \geq 0$ and to 0 for $x < 0$.

F. The Operation of Linear Differential Operators on Distributions

Let T be a distribution and $\alpha(x)$ a C^∞ -function on Ω . Then we can define the product αT by $(\alpha T)(\varphi) = T(\alpha \varphi)$, where the right-hand side is a continuous linear functional on $\mathcal{D}(\Omega)$ since the multiplication $\varphi \mapsto \alpha \varphi$ is continuous in $\mathcal{D}(\Omega)$. We define the **dual operator** (or **conjugate operator**) $P'(x, D)$ of a linear differential operator $P(x, D) = \sum a_p(x) D^p$ by

$$P'(x, D)\varphi = \sum (-1)^{|p|} D^p(a_p(x)\varphi(x)), \quad (3)$$

where the $a_p(x)$ are C^∞ -functions on Ω . Com-

binning differentiation of distributions, multiplication by functions, and addition, we can apply partial differential operators to distributions, and we have $(P(x, D)T)(\varphi) = T(P'(x, D)\varphi)$.

Linear differential operators commute with restriction mappings. In particular, we have $\text{supp } P(x, D)T \subset \text{supp } T$. In other words, linear differential operators are \dagger sheaf homomorphisms on the sheaf \mathcal{D}' of distributions over Ω . On the other hand, every continuous sheaf homomorphism on \mathcal{D}' is a linear differential operator whose order is finite on each compact set in Ω . Even when no continuity is assumed, a sheaf homomorphism on \mathcal{D}' is a linear differential operator except on a discrete subset of Ω (J. Peetre).

G. The Topology of \mathcal{D} and \mathcal{D}'

Let $\emptyset = K_1 \subset K_2 \subset \dots$ be a sequence of compact sets in Ω that exhausts Ω . For every nondecreasing sequence of positive numbers $\{a_j\} = \{a_0, a_1, \dots\}$ and nondecreasing sequence of nonnegative integers $\{k_j\} = \{k_0, k_1, \dots\}$ we set

$$\rho_{\{a_j\}, \{k_j\}}(\varphi) = \sup_{j \geq 0} \sup_{|p| \leq k_j} \sup_{x \notin K_j} |D^p \varphi(x)| \quad (4)$$

for $\varphi \in \mathcal{D}(\Omega)$. We define a \dagger locally convex topology of the space $\mathcal{D}(\Omega)$ by taking the totality of the \dagger seminorms $\rho_{\{a_j\}, \{k_j\}}$ as a fundamental system of continuous seminorms. Then $\mathcal{D}(\Omega)$ is a \dagger nuclear \dagger (LF)-space, and the convergence $\varphi_m \rightarrow 0$ of a sequence φ_m is identical to the convergence $\varphi_m \rightarrow 0$ in this topology. A subset $B \subset \mathcal{D}(\Omega)$ is \dagger bounded in the topology if and only if there exist a compact set $E \subset \Omega$ such that $\text{supp } \varphi \subset E$ for every $\varphi \in B$, and positive numbers M_p for each p such that $\sup |D^p \varphi(x)| \leq M_p$ for every $\varphi \in B$.

The topology of the space $\mathcal{D}'(\Omega)$ is the \dagger strong topology of the \dagger dual of $\mathcal{D}(\Omega)$; the \dagger topology of uniform convergence on every bounded set in $\mathcal{D}(\Omega)$. Under this topology $\mathcal{D}'(\Omega)$ is a \dagger nuclear \dagger reflexive linear topological space. With respect to this topology, the linear differential operators of Section F are continuous in \mathcal{D}' .

By virtue of the following convergence theorems, various limiting processes concerning distributions can be treated easily. If the limit $\lim T_j(\varphi) = T(\varphi)$ exists for every $\varphi \in \mathcal{D}$, where $\{T_j\}$ is a sequence of distributions, then $T \in \mathcal{D}'$ and $\{T_j\}$ is convergent to the distribution T (**convergence theorem**). Moreover, for any p , $D^p T_j$ is convergent to $D^p T$ (**theorem of termwise differentiation**). Any bounded set in \mathcal{D} or \mathcal{D}' is totally bounded. Thus weak convergence of a sequence $\{T_j\}$ implies strong convergence (convergence in the topology of the space \mathcal{D}') (**strong convergence theorem**).

H. Distributions Depending on a Parameter

Consider distributions T_λ depending on a parameter λ , where λ ranges over the real line, the complex plane, or more generally an open set in Euclidean space. The convergence theorem and the strong convergence theorem also hold in the case of a continuous parameter λ . Thus T_λ is **continuous (differentiable) with respect to the parameter λ** if $T_\lambda(\varphi)$ is continuous (differentiable) with respect to λ for any $\varphi \in \mathcal{D}$. If T_λ is continuous with respect to λ , then $D_x^p T_\lambda$ is also continuous with respect to λ . If T_λ is differentiable with respect to a real variable λ , then $D_x^p T_\lambda$ is also differentiable, and $\partial D_x^p T_\lambda / \partial \lambda = D_x^p (\partial T_\lambda / \partial \lambda)$. The same facts hold for the case of several real variables. For a complex parameter λ , T_λ is **holomorphic with respect to λ** if $T_\lambda(\varphi)$ is holomorphic for any $\varphi \in \mathcal{D}$. The fundamental properties of holomorphic functions also hold in this case.

If T_λ is defined and continuous in an interval $[a, b]$, then the **integral $T = \int T_\lambda d\lambda$ with respect to λ** exists in \mathcal{D}' and we have

$$T(\varphi) = \int_a^b T_\lambda(\varphi) d\lambda, \quad \varphi \in \mathcal{D}.$$

I. Distributions with Compact Support

We denote by $\mathcal{E}(\Omega)$ (abbreviated to \mathcal{E}) the space of all complex valued C^∞ -functions on Ω . $\mathcal{E}(\Omega)$ is a nuclear \dagger Fréchet space with the locally convex topology defined by the seminorms

$$\rho_{p, K}(\varphi) = \sup_{x \in K} |D^p \varphi(x)| \quad (5)$$

as p ranges over all multi-indices and K ranges over all compact sets in Ω .

We denote by $\mathcal{E}'(\Omega)$ (abbreviated to \mathcal{E}') the \dagger strong dual of $\mathcal{E}(\Omega)$, i.e., the set of all continuous linear functionals on $\mathcal{E}(\Omega)$ equipped with the topology of uniform convergence on bounded sets in $\mathcal{E}(\Omega)$. $\mathcal{E}'(\Omega)$ is a nuclear \dagger (DF)-space. If $T \in \mathcal{E}'(\Omega)$, then its restriction to $\mathcal{D}(\Omega)$ is a distribution with compact support. Conversely if T is a distribution with compact support in Ω , then choosing $\alpha \in \mathcal{D}(\Omega)$ which is identically equal to 1 on a neighborhood of the support of T , we define a linear functional S on $\mathcal{E}(\Omega)$ by $S(\varphi) = T(\alpha\varphi)$. Then $S \in \mathcal{E}'(\Omega)$, and S is independent of the choice of α . In this sense, we can consider that S is the extension of T to $\mathcal{E}(\Omega)$ and identify S and T ; thus $\mathcal{E}'(\Omega)$ coincides with the set of all distributions with compact support in Ω .

J. Structure Theorems for Distributions

A distribution $T \in \mathcal{D}'(\Omega)$ is said to be of order at most k if $|T(\varphi)| \leq \rho_{\{a_j\}, \{k_j\}}(\varphi)$ for $\{k_j\} = \{k, k, k, \dots\}$

and for some $\{a\}$. A distribution of order 0 is a measure. Every **distribution of finite order** can be represented as a finite linear combination of derivatives (in the sense of distributions) of measures or locally integrable functions. The restriction of any distribution to a relatively compact open subset Ω' can be represented in this way because it is of finite order. Therefore the distributions form the smallest class of generalized functions that contains all locally integrable functions, is stable under differentiation, and forms a sheaf. Furthermore, for any distribution T there exists a sequence $\{\varphi_j\} \subset \mathcal{D}$ that converges to T in the distribution sense.

A closed set F is said to be **regular** if for every point a in F we have a neighborhood U of a and constants ω and $1 \geq \alpha > 0$ such that every pair of points x and y in $F \cap U$ is connected by a curve contained in F with length less than or equal to $\omega|x - y|^\alpha$. If the support of a distribution T is contained in a regular closed set F , then

$$T = \sum D^{p_j} T_{\mu_j}$$

(the expression is not necessarily unique, and the sum is locally finite), where the μ_j are complex-valued measures with support contained in F . In particular, if the support of a distribution T contains only one point a , then T can be represented uniquely as a finite linear combination

$$T = \sum_{|p| \leq m} \alpha_p D^p \delta_{(x-a)}$$

of derivatives of the distribution $\delta_{(x-a)}$ defined by $\delta_{(x-a)}(\varphi) = \varphi(a)$.

K. Tensor Products of Distributions

Let $\Omega_x \subset \mathbf{R}^n$ and $\Omega_y \subset \mathbf{R}^m$ be open sets. If $T \in \mathcal{D}'(\Omega_x)$ and $S \in \mathcal{D}'(\Omega_y)$, then there is a unique distribution $T \otimes S \in \mathcal{D}'(\Omega_x \times \Omega_y)$, called the **tensor product** (or **direct product**), such that $T \otimes S(\varphi(x)\psi(y)) = T(\varphi)S(\psi)$ for any $\varphi \in \mathcal{D}(\Omega_x)$ and $\psi \in \mathcal{D}(\Omega_y)$. More directly we have Fubini's theorem: $T \otimes S(\varphi(x, y)) = T_x(S_y(\varphi(x, y))) = S_y(T_x(\varphi(x, y)))$ for any $\varphi \in \mathcal{D}(\Omega_x \times \Omega_y)$. If F and G are linear spaces of distributions on Ω_x and Ω_y , respectively, then the \dagger tensor product $F \otimes G$ is identified with the linear combinations of tensor products $T \otimes S$ of $T \in F$ and $S \in G$, which form a linear space of distributions on $\Omega_x \times \Omega_y$. When F and G have \dagger locally convex topologies, the \dagger completed tensor products $F \hat{\otimes} G$ and $F \hat{\otimes} G$ are also usually identified with subspaces of $\mathcal{D}'(\Omega_x \times \Omega_y)$. For example, we have $\mathcal{D}'(\Omega_x) \hat{\otimes} \mathcal{D}'(\Omega_y) = \mathcal{D}'(\Omega_x \times \Omega_y)$, $\mathcal{E}'(\Omega_x) \hat{\otimes} \mathcal{E}'(\Omega_y) = \mathcal{E}'(\Omega_x \times \Omega_y)$ and $\mathcal{E}(\Omega_x) \hat{\otimes} \mathcal{E}(\Omega_y) = \mathcal{E}(\Omega_x \times \Omega_y)$ (including the topologies). Similarly, we have $\mathcal{D}(\Omega_x) \hat{\otimes} \mathcal{D}(\Omega_y) = \mathcal{D}(\Omega_x \times \Omega_y)$,

but the left-hand side has a strictly weaker topology than the right-hand side. Spaces of distributions with parameters (\rightarrow Section H) are often identified with completed tensor products of spaces of distributions [8–11].

L. The Kernel Theorem

Let Ω_x and Ω_y be as above. Every distribution K on $\Omega_x \times \Omega_y$ induces the continuous linear mapping $L_K: \mathcal{D}(\Omega_x) \rightarrow \mathcal{D}'(\Omega_y)$ defined by $(L_K(\varphi(x)))(\psi(y)) = K(\varphi(x)\psi(y))$, $\psi \in \mathcal{D}(\Omega_y)$. Conversely every continuous linear mapping $L: \mathcal{D}(\Omega_x) \rightarrow \mathcal{D}'(\Omega_y)$ is equal to L_K for a $K \in \mathcal{D}'(\Omega_x \times \Omega_y)$ and the correspondence $K \mapsto L_K$ is a topological isomorphism of the locally convex space $\mathcal{D}'(\Omega_x \times \Omega_y)$ onto $L(\mathcal{D}(\Omega_x), \mathcal{D}'(\Omega_y))$ equipped with the topology of uniform convergence on the bounded sets (L. Schwartz's kernel theorem, [8–11]). K is called the **kernel (distribution)** of the mapping L_K .

L_K is a continuous linear mapping $\mathcal{D}(\Omega_x) \rightarrow \mathcal{E}(\Omega_y)$ (resp. $\mathcal{D}(\Omega_x) \rightarrow \mathcal{E}'(\Omega_y)$) if and only if $K \in \mathcal{D}'(\Omega_x) \hat{\otimes} \mathcal{E}(\Omega_y)$ (resp. $\mathcal{D}'(\Omega_x) \hat{\otimes} \mathcal{E}'(\Omega_y)$), in which case K is said to be **regular** (resp. **compact**) in y . L_K can be extended to a continuous linear mapping $\mathcal{E}'(\Omega_x) \rightarrow \mathcal{D}'(\Omega_y)$ (resp. $\mathcal{E}(\Omega_x) \rightarrow \mathcal{D}'(\Omega_y)$) if and only if $K \in \mathcal{E}'(\Omega_x) \hat{\otimes} \mathcal{D}'(\Omega_y)$ (resp. $\mathcal{E}'(\Omega_x) \hat{\otimes} \mathcal{D}'(\Omega_y)$), in which case K is said to be **regular** (resp. **compact**) in x . K is said to be **regular** (resp. **compact**) if it is regular (resp. compact) both in x and y . L_K can be extended to a continuous linear mapping $\mathcal{E}'(\Omega_x) \rightarrow \mathcal{E}(\Omega_y)$ (resp. $\mathcal{E}(\Omega_x) \rightarrow \mathcal{E}'(\Omega_y)$) if and only if $K \in \mathcal{E}'(\Omega_x \times \Omega_y)$ (resp. $\mathcal{E}'(\Omega_x \times \Omega_y)$). Then K is said to be **regularizing** (resp. **compactifying**) [8, 10].

M. Convolution

For distributions S and T on \mathbf{R}^n , assume that either S or T has a compact support or more generally that $\text{supp } T \cap (\{x\} - \text{supp } S)$ is locally uniformly bounded with respect to x . Then the correspondence

$$\varphi \in \mathcal{D} \rightarrow S_{(x)} T_{(y)}(\varphi(x+y))$$

defines a distribution called the **convolution** of S and T and is denoted by $S * T$. In particular, $T_f * T_g = T_{f * g}$, where $f * g$ is the \dagger convolution of functions f and g , and T_f , T_g , and $T_{f * g}$ denote the distributions corresponding to f , g , and $f * g$, respectively. For example: $T * \delta = \delta * T = T$, $D^p T * S = T * (D^p S) = D^p (T * S)$.

Thus a solution of the partial differential equation $P(D)T = S$ with constant coefficients is given by the convolution $S * E$ of S with a \dagger fundamental solution E of $P(D)$, whenever the convolution exists.

If $T \in \mathcal{D}'$ and $\varphi \in \mathcal{D}$, the convolution $T * \varphi$ is equal to a function f of class C^∞ (or the

distribution corresponding to f), and $f(y) = T_{(x)}(\varphi(y-x))$. f is called the **regularization** of T . For distributions S and T , assume that $|f(x)g(y-x)|$ is integrable on \mathbf{R}^n for any regularization $f = S * \varphi$ and $g = T * \psi$. Then there exists a unique distribution V such that

$$V * (\varphi * \psi) = \int f(x)g(y-x)dx.$$

This distribution V is called the **generalized convolution** and is denoted by $S * T$ (C. Chevalley).

N. Tempered Distributions \mathcal{S}'

We denote by $\mathcal{S}(\mathbf{R}^n)$ (abbreviated to \mathcal{S}) the space of all † rapidly decreasing functions of class C^∞ on \mathbf{R}^n . \mathcal{S} is a nuclear Fréchet space with the locally convex topology defined by the seminorms

$$\rho_{p,q}(\varphi) = \sup_x |x^p D^q \varphi(x)|, \quad (6)$$

as p and q range over all multi-indices, where $x^p = x_1^{p_1} \dots x_n^{p_n}$. We denote by $\mathcal{S}'(\mathbf{R}^n)$ (abbreviated to \mathcal{S}') the strong dual of $\mathcal{S}(\mathbf{R}^n)$. Its elements are called **tempered distributions** (or **slowly increasing distributions**) and are identified with their restrictions to $\mathcal{D}(\mathbf{R}^n)$. A distribution $T \in \mathcal{D}'$ can be continuously extended to \mathcal{S} if and only if any regularization $f = T * \varphi$ of T is a slowly increasing continuous function (i.e., there is a polynomial $P(x)$ such that $|f(x)| \leq |P(x)|$). $\mathcal{S}'(\mathbf{R}^n)$ is a nuclear (DF)-space. Let $1 < p < \infty$, and let q be the † conjugate exponent. The strong dual of the † function space $\mathcal{D}_{L_q}(\mathbf{R}^n)$ is denoted by $\mathcal{D}'_{L_p}(\mathbf{R}^n)$. Since \mathcal{S} is dense in \mathcal{D}_{L_q} , \mathcal{D}'_{L_p} is identified with a linear subspace of \mathcal{S}' . The strong dual of $\mathcal{D}'_{L_p}(\mathbf{R}^n)$ is equal to $\mathcal{D}_{L_q}(\mathbf{R}^n)$. Let $\mathcal{B}(\mathbf{R}^n)$ be the closed linear subspace of $\mathcal{B}(\mathbf{R}^n)$ consisting of all functions φ such that $D^p \varphi \in C_\infty(\mathbf{R}^n)$ for all p (— 168 Function Spaces). It is also the closure of \mathcal{S} in \mathcal{B} . The strong dual of \mathcal{B} is denoted by $\mathcal{B}'_{L_1}(\mathbf{R}^n)$. Its elements are called **integrable distributions** because the strong dual of $\mathcal{D}'_{L_1}(\mathbf{R}^n)$ is equal to $\mathcal{B}(\mathbf{R}^n)$ so that the integral $T(1)$ has a meaning. Here 1 is the function identically equal to 1.

† Sobolev spaces $W_p^l(\mathbf{R}^n)$ and † Besov spaces $B_{p,q}^s(\mathbf{R}^n)$ are also linear subspaces of $\mathcal{S}'(\mathbf{R}^n)$.

O. Fourier Transforms

The Fourier transform

$$\mathcal{F}\varphi(x) = (\sqrt{2\pi})^{-n} \int \varphi(\xi) \exp(-ix\xi) d\xi \quad (7)$$

is an isomorphism of \mathcal{S}_ξ onto \mathcal{S}_x , where $x\xi = x_1\xi_1 + \dots + x_n\xi_n$. The Fourier transform

$\mathcal{F}T \in \mathcal{S}'_\xi$ of $T \in \mathcal{S}'_x$ is defined by

$$(\mathcal{F}T)(\varphi) = T(\mathcal{F}\varphi), \quad \varphi \in \mathcal{S}. \quad (8)$$

The **inverse Fourier transform** is defined similarly, except that $-i$ is replaced by i . For example: (1) $\mathcal{F}1 = (\sqrt{2\pi})^n \delta$, where 1 is the distribution corresponding to the function 1. (2) $\mathcal{F}(D^p T) = i^{|p|} x^p \mathcal{F}T$.

A function φ of class C^∞ is called a **slowly increasing C^∞ -function** if φ and its derivatives of any order are slowly increasing continuous functions. The space \mathcal{O}_M is the set of all such functions. Its image under the Fourier transform $\mathcal{F}(\mathcal{O}_M)$, denoted by \mathcal{O}'_C , coincides with the set of all distributions T such that any regularization $f = T * \varphi$ is a rapidly decreasing C^∞ -function. A member of the space \mathcal{O}'_C is called a **rapidly decreasing distribution**. If $\alpha \in \mathcal{O}_M$ ($\beta \in \mathcal{O}'_C$) and $T \in \mathcal{S}'$, then $\alpha T \in \mathcal{S}'$ and $\mathcal{F}(\alpha T) = (\sqrt{2\pi})^{-n} \mathcal{F}\alpha * \mathcal{F}T$ ($\beta * T \in \mathcal{S}'$ and $\mathcal{F}(\beta * T) = (\sqrt{2\pi})^n \mathcal{F}\beta \mathcal{F}T$). If T is a distribution with compact support in \mathbf{R}^n , then its Fourier transform is the entire function $f(\zeta) = (\sqrt{2\pi})^{-n} T(\exp(-ix\xi))$, where $\zeta = \xi + i\eta \in \mathbf{C}^n$. For a convex compact set K in \mathbf{R}^n , define its **supporting function** H_K by $H_K(\eta) = \sup_{x \in K} x\eta$.

Paley-Wiener theorem. An entire function $f(\zeta)$ on \mathbf{C}^n is the Fourier transform of a distribution (resp. a function of class C^∞) with support in K if and only if (i) for any $\varepsilon > 0$ there is a constant C_ε such that $|f(\zeta)| \leq C_\varepsilon \exp(H_K(\eta) + \varepsilon|\zeta|)$ on \mathbf{C}^n , and (ii) there are constants C and N such that $|f(\xi)| \leq C(1+|\xi|)^N$ (resp. for any N there is a constant C such that $|f(\xi)| \leq C(1+|\xi|)^{-N}$) on \mathbf{R}^n .

P. Fourier Series and Distributions on Tori

The n -dimensional † torus \mathbf{T}^n is the quotient space of \mathbf{R}^n with respect to the equivalence relation $x_j \equiv y_j \pmod{\mathbf{Z}}$ ($j = 1, \dots, n$). The space $\mathcal{D}'(\mathbf{T}^n)$ of distributions on \mathbf{T}^n is defined to be the strong dual of $\mathcal{D}(\mathbf{T}^n) = \mathcal{E}(\mathbf{T}^n)$. The volume element dx of \mathbf{T}^n is defined from that of \mathbf{R}^n . Thus, for an integrable function f , we can define a distribution T_f by

$$T_f(\varphi) = \int_{\mathbf{T}^n} f(x)\varphi(x)dx, \quad \varphi \in \mathcal{D}(\mathbf{T}^n).$$

Consider the family of functions $f_p(x) = \exp(2\pi i p x)$, where p ranges over all n -tuples of integers. Then any distribution T on \mathbf{T}^n has the **Fourier series** expansion $T = \sum c_p f_p(x)$, where the Fourier coefficients $c_p = T(f_{-p})$ are slowly increasing, i.e., $|c_p| \leq C(1+|p|^2)^k$ for some k and C . Conversely if $\{c_p\}$ is a slowly increasing sequence, then $\sum c_p f_p$ converges to a distribution T on \mathbf{T}^n .

Q. Substitution

Let $f = (f_1, \dots, f_m)$ be a C^∞ -mapping from an open set Ω in \mathbf{R}^n into an open set $\tilde{\Omega}$ in \mathbf{R}^m , and assume that the t rank of the Jacobian matrix $(\partial f_i / \partial x_j)$ ($i = 1, \dots, m; j = 1, \dots, n$) is equal to m in a neighborhood of the t inverse image E of the support of a distribution $S = S_{(y)} \in \mathcal{D}'(\tilde{\Omega})$. In a neighborhood U of E , we can choose $u_1 = g_1(x), \dots, u_{n-m} = g_{n-m}(x)$ so that the transformation $(y, u) = (f(x), g(x))$ has the inverse transformation $x = \psi(y, u)$ of class C^∞ . If the support of $\varphi \in \mathcal{D}(\Omega)$ is contained in U , then defining $\tilde{\varphi}$ by

$$\tilde{\varphi}(y) = \int_{\mathbf{R}^{n-m}} \varphi(\psi(y, u)) J(y, u) du,$$

we have $\tilde{\varphi} \in \mathcal{D}(\tilde{\Omega})$, where $J(y, u)$ is the absolute value of the t Jacobian of $\psi(y, u)$, and $\tilde{\varphi}$ is independent of the choice of g_1, \dots, g_{n-m} . Now we define $T(\varphi) = S(\tilde{\varphi})$ if $\text{supp } \varphi \subset U$, and $T(\varphi) = 0$ if $\text{supp } \varphi$ does not intersect E . Since a distribution can be determined by its local behavior, we have a distribution $T \in \mathcal{D}'(\Omega)$ with support E , which is denoted by $T = S \circ f = S(f) = S_{f(x)}$ and is called the **substituted distribution** of $S_{(y)}$ by $y = f(x)$. It is also called the **pullback** of S by f and is denoted by f^*S . The chain rule for derivatives of composites

$$\frac{\partial}{\partial x_j} (S \circ f) = \sum_{i=1}^m \frac{\partial f_i}{\partial x_j} \left(\frac{\partial S}{\partial y_i} \circ f \right) \quad (9)$$

also holds.

For example: (1) If $S = \delta_{(y)}^{(q)}$ ($y \in \mathbf{R}^m$), then E is the surface $f_1(x) = f_2(x) = \dots = f_m(x) = 0$. Assuming that (f_1, \dots, f_m) satisfies the condition in the previous paragraph, we obtain the distribution $\delta^{(q)}(f_1, \dots, f_m)$ with support contained in a surface. From the fact $\delta^{(q)} = D_y^q \delta$, we can write

$$\delta^{(q)}(f_1, \dots, f_m) = \frac{\partial^{(q)} \delta(f_1, \dots, f_m)}{(\partial f_1)^{q_1} \dots (\partial f_m)^{q_m}}$$

(Gel'fand-Shilov notation). (2) For the mapping $f(x) = Ax + b$, where A is an $n \times n$ regular matrix and b is an n -vector, we can define the substituted distribution of S by $f = f(x)$ for any $S \in \mathcal{D}'(\mathbf{R}^n)$. For instance, $\delta_{(x-b)}(\varphi) = \varphi(b)$, $\delta_{(x^2-c^2)} = (2c)^{-1}(\delta_{(x-c)} + \delta_{(x+c)})$ ($c > 0, x \in \mathbf{R}^1$).

R. Distributions and Currents on a Differentiable Manifold

Let M be an n -dimensional t differentiable manifold of class C^∞ . Let $\{(U_\alpha, \psi_\alpha)\}$ be an t atlas. Then a **distribution** T on M is defined to be a collection of distributions T_α on $\psi_\alpha(U_\alpha) \subset \mathbf{R}^n$ such that T_β on $\psi_\beta(U_\alpha \cap U_\beta)$ is equal to $T_\alpha \circ (\psi_\alpha \circ \psi_\beta^{-1})$ for any α and β . Since the distributions obey the same transformation law as

functions under coordinate transformation, this definition has an invariant meaning, and every locally integrable function on M is regarded as a distribution. More generally, a distribution t cross section of a t vector bundle of class C^∞ is defined in the same way. The most important is the case of the $^t p$ -fold exterior power of the t cotangent bundle. Its distribution cross sections, i.e., t exterior differential forms of order p with distribution coefficients, are called **currents** of degree p . If M is t oriented, then the space of currents of degree p on M is identified with the dual space of the locally convex space $\mathcal{D}^{(n-p)}(M)$ of all differential forms of degree $n-p$, of class C^∞ and with compact support in M . For example, if C is an $(n-p)$ -dimensional t singular chain, a current T_C of degree p is defined by $T_C(\alpha) = \int_C \alpha$. If M is not t orientable, we have to consider either the double covering \tilde{M} of M or the cross sections of the tensor product of the bundle of $(n-p)$ -covectors and the orientation bundle [1, 3]. Currents were introduced by de Rham to prove his celebrated isomorphism theorem of the t de Rham cohomology groups defined by differential forms and the t singular cohomology groups defined by singular cochains (\rightarrow 105 Differentiable Manifolds).

S. Gel'fand-Shilov Generalized Functions

Let E and F be t locally convex spaces for which a continuous linear injection $i: E \rightarrow F$ with dense range is defined. Then the dual $i': F' \rightarrow E'$ is a continuous linear injection with weak*-dense range. Therefore if we shrink the function space E , we obtain a larger space E' of continuous linear functionals. Gel'fand and Shilov [4] introduced many function spaces E , called **fundamental spaces** or **test function spaces**, and defined corresponding spaces E' of **generalized functions**. Their motivations were in applications to the theory of partial differential equations, where Fourier transforms play an essential role and Schwartz's framework of tempered distributions is too restrictive. They considered a pair of function spaces E and \tilde{E} such that the Fourier transformation $\mathcal{F}: E \rightarrow \tilde{E}$ is an isomorphism of locally convex spaces. Then the Fourier transformation defined to be the dual of \mathcal{F} gives an isomorphism $\tilde{E}' \rightarrow E'$ of spaces of generalized functions. The function spaces E and \tilde{E} are often spaces of entire functions, so that the Gel'fand-Shilov generalized functions are not necessarily localizable in \mathbf{R}^n . As typical examples of spaces E and \tilde{E} we shall mention only spaces of type S in the next section.

L. Ehrenpreis's **analytically uniform spaces**

[12] are also a class of generalized function spaces introduced from a similar point of view.

T. Spaces of Type S

Let $\alpha, \beta, A, B, \bar{A}$, and \bar{B} be n -dimensional vectors. By $A > B$ we mean $A_j > B_j$ ($j = 1, \dots, n$). We use notations $A^p = A_1^{p_1} \dots A_n^{p_n}$, $p^{\alpha} = p_1^{\alpha_1} \dots p_n^{\alpha_n}$. (i) For $\alpha \geq 0$, $A > 0$ the space $S_{\alpha, A}$ consists of all C^∞ -functions φ such that seminorms

$$\rho_{q, \bar{A}}(\varphi) = \sup_x \sup_p \frac{|x^p D^q \varphi(x)|}{\bar{A}^p p^{p\alpha}} \quad (10)$$

are finite for all $\bar{A} > A$ and q . For example, $S_{0, A}$ is the space of all functions of class C^∞ with support in $\{x \mid |x_j| \leq A_j, j = 1, \dots, n\}$. (ii) For $\beta \geq 0$, $B > 0$ the space $S^{\beta, B}$ consists of all C^∞ -functions φ such that the seminorms

$$\rho_{p, \bar{B}}(\varphi) = \sup_x \sup_q \frac{|x^p D^q \varphi(x)|}{\bar{B}^q q^{\beta p}} \quad (11)$$

are finite for all $\bar{B} > B$ and q . (iii) For $\alpha, \beta \geq 0$ and $A, B > 0$, the space $S_{\alpha, A}^{\beta, B}$ consists of all C^∞ -functions such that the seminorms

$$\rho_{A, B}(\varphi) = \sup_x \sup_p \sup_q \frac{|x^p D^q \varphi(x)|}{A^p B^q p^{p\alpha} q^{\beta p}} \quad (12)$$

are finite for all $\bar{A} > A$ and $\bar{B} > B$. The topologies for these spaces are given in terms of the seminorms (10), (11), and (12), respectively. These spaces are generically called **spaces of type S**.

$$\mathcal{F}(S_{\alpha, A}) = S^{\alpha, A} \quad (\alpha > 0),$$

$$\mathcal{F}(S^{\beta, B}) = S_{\beta, B} \quad (\beta > 0),$$

$$\mathcal{F}(S_{\alpha, A}^{\beta, B}) = S_{\beta, B}^{\alpha, A} \quad (\alpha + \beta > 1).$$

$$\mathcal{F}(S_{0, A}) = S^{0, A'},$$

$$\mathcal{F}(S^{0, B}) = S_{0, B'},$$

$$\mathcal{F}(S_{\alpha, A}^{\beta, B}) = S_{\beta, B'}^{\alpha, A'} \quad (\alpha + \beta = 1),$$

where $A' = A \exp(1/A)$ and $B' = B \exp(1/B)$.

We set $S_\alpha = \bigcup S_{\alpha, A}$, $S^\beta = \bigcup S^{\beta, B}$, and $S_\alpha^\beta = \bigcup S_{\alpha, A}^{\beta, B}$, where A and B range over all positive n -dimensional vectors. $S_\alpha^\beta \neq \{0\}$ if and only if one of the following conditions is satisfied: (i) $\alpha + \beta \geq 1$, $\alpha > 0$, $\beta > 0$; (ii) $\alpha > 1$, $\beta = 0$; (iii) $\alpha = 0$, $\beta > 1$. In such a case the space S_α^β of generalized functions contains the tempered distributions $\mathcal{S}'(\mathbf{R}^n)$.

U. Ultradistributions

The localizing property of distributions is proved mainly from the existence of \dagger partitions of unity by functions in \mathcal{D} . Therefore if a test function space admits partitions of unity, the corresponding class of generalized functions

forms a sheaf. Roumieu [5] took the space $\mathcal{D}_{\{M_p\}}(\Omega)$ of \dagger ultradifferentiable functions of class $\{M_p\}$ with compact support. We can also use the space $\mathcal{D}_{(M_p)}(\Omega)$ of class (M_p) . The corresponding generalized functions are called **ultradistributions of class $\{M_p\}$** and of class (M_p) , respectively. Here M_p is a sequence of positive numbers satisfying the logarithmic convexity $M_p^2 \leq M_{p-1} M_{p+1}$ and the Denjoy-Carleman condition $\sum M_p / M_{p+1} < \infty$. $\mathcal{D}_{\{M_p\}}(\Omega)$ (resp. $\mathcal{D}_{(M_p)}(\Omega)$) is the space of all functions $\varphi \in \mathcal{D}(\Omega)$ such that there are constants k and C (resp. for any $k > 0$ there is a C) for which we have $|D^s \varphi(x)| \leq C k^{|s|} M_{|s|}$. In particular, the **Gevrey classes** $\{s\} = \{p^{1/s}\}$ and $(s) = (p^{1/s})$ defined for $s > 1$ are important, and they appear often in theory of differential equations. Almost all results for distributions have been extended to ultradistributions under appropriate conditions on M_p , which are satisfied by Gevrey sequences $p^{1/s}$ (\rightarrow [14] in particular). Closely connected are A. Beurling's test function spaces $\mathcal{D}_\omega(\Omega)$ (\rightarrow [13]), where ω is a function on \mathbf{R}^n continuous at the origin, satisfying $0 = \omega(0) \leq \omega(\xi + \eta) \leq \omega(\xi) + \omega(\eta)$ for all ξ and η in \mathbf{R}^n and such that $\int \omega(\xi)(1 + |\xi|)^{-n-1} d\xi < \infty$. $\mathcal{D}_\omega(\Omega)$ is defined to be the space of all $\varphi \in \mathcal{D}(\Omega)$ such that the Fourier transform $\hat{\varphi}$ satisfies $\int |\hat{\varphi}(\xi)| \exp(\lambda \omega(\xi)) d\xi < \infty$ for any $\lambda > 0$. If $\omega(\xi) = \log(1 + |\xi|)$, then $\mathcal{D}_\omega = \mathcal{D}$; if $\omega(\xi) = |\xi|^{1/s}$, then $\mathcal{D}_\omega = \mathcal{D}_{(s)}$. Let $\tilde{\omega}(\xi) = \omega(-\xi)$. The space $\mathcal{D}'_\omega(\Omega)$ of **Beurling's generalized distributions** is defined to be the strong dual of $\mathcal{D}_\omega(\Omega)$.

V. Hyperfunctions

In this and the following sections we mean by a cone $\Gamma \subset \mathbf{R}^n$ a convex open cone with vertex at 0. For two cones Γ, Δ , we write $\Delta \in \Gamma$ if $\Delta \cap \mathbf{S}^{n-1}$ is relatively compact in $\Gamma \cap \mathbf{S}^{n-1}$, where $\mathbf{S}^{n-1} = \{x \mid |x| = 1\}$. By a **wedge** we mean an open subset of \mathbf{C}^n of the form $\Omega + i\Gamma$, where $\Omega \subset \mathbf{R}^n$ is an open subset and $\Gamma \subset \mathbf{R}^n$ is a cone. Γ is called the opening of the wedge and Ω its edge. By an **infinitesimal wedge** (0-wedge for short) or a **tuboid** of opening Γ and edge Ω , we mean a complex open set U such that $U \subset \Omega + i\Gamma$ and that for any $\Delta \in \Gamma$, U contains the part of $\Omega + i\Delta$ which is contained in some complex neighborhood of the edge Ω . The symbol $\Omega + i\Gamma_0$ will represent any one of such open sets, and $\mathcal{O}(\Omega + i\Gamma_0)$ (the inductive limit of) the totality of functions holomorphic on some of them.

A **hyperfunction** $f(x)$ on an open set $\Omega \subset \mathbf{R}^n$ is an equivalence class of formal expressions of the form

$$f(x) = \sum_{j=1}^N F_j(x + i\Gamma_j 0), \quad (13)$$

where $F_j(z) \in \mathcal{O}(\Omega + i\Gamma_j 0)$. $\{F_j(z)\}$ is called a set

of **defining functions** of $f(x)$. Here the equivalence relation is given as

$$F_j(x + i\Gamma_j 0) + F_k(x + i\Gamma_k 0) = (F_j + F_k)(x + i\Gamma_j \cap \Gamma_k 0) \quad (14)$$

if $\Gamma_j \cap \Gamma_k \neq \emptyset$, that is, we can contract two terms into a single term as above and, conversely, can decompose, if possible, a term in the inverse way. These are considered to be modifications of the expression of the same hyperfunction. The totality of hyperfunctions on Ω is denoted by $\mathcal{B}(\Omega)$. It is a linear space by virtue of the linear structure naturally induced from that of holomorphic functions, combined with the above equivalence relation.

The symbol $F_j(x + i\Gamma_j 0)$, which represents by itself a hyperfunction, is called the **boundary value** of $F_j(z)$ to the real axis. It is merely formal and does not imply any topological limit, though there is some justification for the terminology as will be seen in Section Z.

In the case of one variable, we have only two kinds of wedges $\Omega + i\mathbf{R}^\pm$, hence a hyperfunction can be expressed by two terms:

$$F_+(x + i0) - F_-(x - i0). \quad (15)$$

Some examples of hyperfunctions of one variable are $\delta(x) = -(2\pi i)^{-1}((x + i0)^{-1} - (x - i0)^{-1})$; $\mathbf{1}(x) = -(2\pi i)^{-1}(\log(-x - i0) - \log(-x + i0))$; $\text{Pf } x^{-1} = ((x + i0)^{-1} + (x - i0)^{-1})/2$.

W. Localization of Hyperfunctions

If $\Omega' \subset \Omega$ is an open subset, the restriction mapping $\mathcal{B}(\Omega) \rightarrow \mathcal{B}(\Omega')$ is induced from that for holomorphic functions. With this structure the correspondence $\Omega \mapsto \mathcal{B}(\Omega)$ becomes a * presheaf. It is in fact a sheaf, because it can be expressed by the terminology of relative (or local) cohomology as follows: Let $H_\Omega^k(\mathbf{C}^n, \mathcal{F})$ denote the k th **relative cohomology group** of the pair $(\mathbf{C}^n, \mathbf{C}^n \setminus \Omega)$ (also called the k th **local cohomology group** with support in Ω) with coefficients in a sheaf \mathcal{F} on \mathbf{C}^n . (It is by definition the k th * derived functor of $\mathcal{F} \mapsto \Gamma_\Omega(\mathbf{C}^n, \mathcal{F}) =$ the totality of sections of \mathcal{F} defined on a neighborhood of Ω and with support in Ω and is calculated as the k th cohomology group of the * complex $\Gamma_\Omega(\mathbf{C}^n, \mathcal{L})$, where \mathcal{L} denotes any **flabby resolution** (i.e., * resolution by * flabby sheaves) of \mathcal{F} .) Let $\mathcal{H}_{\mathbf{R}^n}^k(\mathcal{F})$ denote the k th **derived sheaf** of \mathcal{F} to \mathbf{R}^n . (It is by definition the sheaf on \mathbf{R}^n associated with the presheaf $\Omega \mapsto H_\Omega^k(\mathbf{C}^n, \mathcal{F})$.) Then the cohomological definition of the sheaf of hyperfunctions is $\mathcal{B} = \mathcal{H}_{\mathbf{R}^n}^n(\mathcal{O})$ (the orientation being neglected). A fundamental theorem by Sato says that $\mathbf{R}^n \subset \mathbf{C}^n$ is **purely n -codimensional** with respect to \mathcal{O} (i.e., $\mathcal{H}_{\mathbf{R}^n}^k(\mathcal{O}) = 0$ for $k \neq n$), and moreover $H_\Omega^k(\mathbf{C}^n, \mathcal{O}) = 0$ for $k \neq n$ for any open set $\Omega \subset \mathbf{R}^n$.

Then by the general theory it can be shown that the remaining $H_\Omega^n(\mathbf{C}^n, \mathcal{O})$ agrees with the section module $\mathcal{B}(\Omega)$ of $\mathcal{H}_{\mathbf{R}^n}^n(\mathcal{O})$. Since $H^n(V, \mathcal{O}) = 0$ for any open set $V \subset \mathbf{C}^n$ (B. Malgrange), it follows further that the sheaf \mathcal{B} is flabby, i.e., its sections on any open set can always be extended to the whole space.

If U is a * Stein neighborhood of Ω , then $H_\Omega^n(\mathbf{C}^n, \mathcal{O})$ can be expressed using the covering cohomology as the quotient space

$$\mathcal{O}(U \# \Omega) \Big/ \sum_{j=1}^n \mathcal{O}(U \#_j \Omega), \quad (16)$$

where

$$\begin{aligned} U \# \Omega &= \{z \in U \mid \text{pr}_k(z) \notin \text{pr}_k(\Omega) \text{ for all } k\}, \\ U \#_j \Omega &= \{z \in U \mid \text{pr}_k(z) \notin \text{pr}_k(\Omega) \text{ for } k \neq j\}, \end{aligned} \quad (17)$$

and pr_k is the projection from \mathbf{C}^n to the k th coordinate. Then the isomorphism $H_\Omega^n(\mathbf{C}^n, \mathcal{O}) = \mathcal{B}(\Omega)$ is induced by the correspondence

$$\begin{aligned} \mathcal{O}(U \# \Omega) \ni F(z) &\mapsto [F(z)] \\ &= \sum_\sigma \text{sgn } \sigma F(x + i\Gamma_\sigma 0) \in \mathcal{B}(\Omega), \end{aligned} \quad (18)$$

where Γ_σ is the σ -orthant $\{y \in \mathbf{R}^n \mid \sigma_j y_j > 0, j = 1, \dots, n\}$ and $\text{sgn } \sigma = \sigma_1 \dots \sigma_n$. $F(z)$ is called a **defining function** of the corresponding hyperfunction. For one variable, any complex neighborhood $U \supset \Omega$ is Stein, and the above isomorphism reads $\mathcal{O}(U \setminus \Omega)/\mathcal{O}(U) = \mathcal{B}(\Omega)$, from which the naturality of the sign in (15) follows.

Thus the notion of support is also legitimate for hyperfunctions. The sheaf of hyperfunctions \mathcal{B} does not admit partitions of unity as for \mathcal{D}' . It is, however, flabby. Consequently, given a decomposition of a closed set into locally finite closed subsets $E = \bigcup_{\lambda \in \Lambda} E_\lambda$ and a hyperfunction f with support in E , we can always find hyperfunctions f_λ with support in E_λ such that $f = \sum_{\lambda \in \Lambda} f_\lambda$. For distributions this property holds only under some regularity assumption for the decomposition.

There are several practical criteria to determine whether or not a hyperfunction is zero in some open set Ω . These are called the **edge of the wedge theorem**. A hyperfunction $F(x + i\Gamma 0)$ with single expression is zero if and only if $F(z)$ itself is zero. $F_1(x + i\Gamma_1 0) = F_2(x + i\Gamma_2 0)$ if and only if they stick together to a function in $\mathcal{O}(\Omega + i(\Gamma_1 + \Gamma_2)0)$ (Epstein type). (Note that $\Gamma_1 + \Gamma_2$ is equal to the convex hull of $\Gamma_1 \cup \Gamma_2$, e.g., $\Gamma + (-\Gamma) = \mathbf{R}^n$ (Bogolyubov type).) $\sum_{j=1}^N F_j(x + i\Gamma_j 0) = 0$ if and only if there exist $G_{jk}(z) \in \mathcal{O}(\Omega + i(\Gamma_j + \Gamma_k)0)$, $j, k = 1, \dots, N$, such that $G_{jk}(z) = G_{kj}(z)$ and $F_j = \sum_{k=1}^N G_{jk}$, $j = 1, \dots, N$ (A. Martineau [19]). These are interpretations of cohomology in terms of coverings and have global variants concerning the envelope of holomorphy.

The real analytic functions $\varphi \in \mathcal{A}(\Omega)$ on Ω are naturally included in $\mathcal{B}(\Omega)$ via the ex-

Distributions and Hyperfunctions

pression $\varphi(x + i\Gamma 0)$ for any Γ or with $\Gamma = \mathbf{R}^n$. They form a subsheaf. Let f be a hyperfunction on Ω . The complement in Ω of the largest open subset $\Omega' \subset \Omega$, where $f(x)$ is real analytic, is called the **singular support** of $f(x)$ and is denoted by $\text{singsupp } f$. If Ω is bounded and $\text{singsupp } f \subset K$, then we can choose an expression of the form (13), where $F_j(z)$ can be continued analytically to $\Omega \setminus K$. If $\text{supp } f \subset K$, then these $F_j(z)$ satisfy $\sum F_j(x) = 0$ on $\Omega \setminus K$ in the usual sense.

X. Operations on Hyperfunctions

The **derivatives** of a hyperfunction $f(x)$ with the expression (13) are defined through the defining functions as $D^p f(x) = \sum (D_z^p F_j)(x + i\Gamma_j 0)$. The **product** by a real analytic function $\psi(x)$ is defined by $\psi(x)f(x) = \sum (\psi F_j)(x + i\Gamma_j 0)$. Combining these, we have the operation of a linear partial differential operator with real analytic coefficients $P(x, D)$ on hyperfunctions. It is a \dagger sheaf homomorphism.

Let $f \in \mathcal{B}(\Omega)$ and $D \subset \Omega$ be a compact set with piecewise smooth boundary. If $\text{singsupp } f \cap \partial D = \emptyset$, then by means of the special expression (13) mentioned at the end of Section W the **definite integral** is defined as

$$\int_D f(x) dx = \sum_{j=1}^N \int_{D_j} F_j(z) dz,$$

where D_j is a path deformed from D in such a way that $\partial D_j = \partial D$ and $F_j(z)$ is holomorphic on D_j . The result is independent of the choice of deformations or of the boundary value expression employed.

If $\text{supp } f \subset D$, the result is also independent of D ; hence it can be written as $\int_{\mathbf{R}^n} f(x) dx$. If $f(x, t)$ is a hyperfunction of the two groups of variables $(x, t) \in \Omega \times V$ such that $\text{singsupp } f \cap \partial D \times V = \emptyset$, then the integral $\int_D f(x, t) dx \in \mathcal{B}_t(V)$ is defined by the same method. It commutes with differentiation or integration with respect to t .

If $f(x) = \sum F_j(x + i\Gamma_j 0)$, $g(x) = \sum G_k(x + i\Delta_k 0)$, then we can define the **product** by $f(x)g(x) = \sum (F_j G_k)(x + i\Gamma_j \cap \Delta_k 0)$ under the assumption that $\Gamma_j \cap \Delta_k \neq \emptyset$ for every pair j, k . Especially, the product $f(x)g(t)$ is always legitimate for two hyperfunctions depending on different groups of variables. (It can also be interpreted as the tensor product.)

A real analytic coordinate transformation $x = \Phi(\tilde{x}) : \tilde{\Omega} \rightarrow \Omega$ extends naturally to a holomorphic coordinate transformation $z = \Phi(\tilde{z})$ on a complex neighborhood. A 0-wedge $\Omega + i\Gamma 0$ is transformed by Φ^{-1} to a twisted wedge containing, for each $x \in \Omega$ and $\Delta \in \Gamma$, a 0-wedge $\tilde{\Omega}_{\tilde{x}} + i(D\Phi^{-1})_x \Delta 0$ with some (real) neighborhood $\tilde{\Omega}_{\tilde{x}}$ of $\tilde{x} = \Phi^{-1}(x)$, where $(D\Phi^{-1})_x$ is the

derivative or the Jacobian matrix of the mapping Φ^{-1} at x . Thus the pullback $\Phi^* f(\tilde{x}) = f(\Phi(\tilde{x})) \in \mathcal{B}(\tilde{\Omega})$ of $f(x) \in \mathcal{B}(\Omega)$ by the transformation $x = \Phi(\tilde{x})$ can be defined by substituting $z = \Phi(\tilde{z})$ into the defining functions. It is consistent with the definition of the coordinate transformation for real analytic functions. Also, the law of the change of variables for the definite integral is the same as that for real analytic functions. This can be extended to the general operation of **substitution** as mentioned in Section Q for distributions or even to much more general operations (\rightarrow Section CC).

The **convolution** $(f * g)(x) = \int_{\mathbf{R}^n} f(x - t)g(t) dt$ is defined under the same assumption on support as in the case of distributions. It can be defined either literally as the composition of the above operations, or directly by way of the defining functions: For example, if g has compact support $\subset D$ and $\sum G_k(x + i\Delta_k 0)$ is an expression as mentioned at the end of Section W, then by choosing a suitable deformation D_k of D , we have

$$(f * g)(x) = \sum_{j,k} \left[\int_{D_k} F_j(z - \tau) G_k(\tau) d\tau \right]_{z \rightarrow x + i(\Gamma_j + \Delta_k) 0}.$$

Y. Hyperfunctions and Analytic Functionals

The totality $\mathcal{B}[K]$ of hyperfunctions with support in a compact set K becomes a nuclear Fréchet space. It is the dual of the nuclear (DF)-space $\mathcal{A}(K)$ of real analytic functions defined on a neighborhood of K . Thus $\mathcal{B}[K]$ is the space of analytic functionals with \dagger porter in the real compact set K . The duality is given by the definite integral $\langle f, \varphi \rangle = \int_{\mathbf{R}^n} f(x)\varphi(x) dx$ for $f \in \mathcal{B}[K]$ and $\varphi \in \mathcal{A}(K)$. A sequence $\{f_k(x)\}$ in $\mathcal{B}[K]$ converges if and only if it admits an expression (13) for a common fixed set of 0-wedges $\Omega + i\Gamma_j 0$, $j = 1, \dots, N$, such that the defining functions $F_{kj} \in \mathcal{O}(\Omega + i\Gamma_j 0)$ are also holomorphic on a fixed complex neighborhood U of $\Omega \setminus K$ and converges locally uniformly in $\Omega + i\Gamma_j 0 \cup U$, where Ω is a (real) neighborhood of K .

$\mathcal{B}[K]$ is isomorphic to $H_K^n(\mathbf{C}^n, \mathcal{O})$, and the above duality is a special case of the **Martineau-Harvey duality** $H_K^n(\mathbf{C}^n, \mathcal{O}) = \mathcal{O}(K)'$ for a Stein compact set $K \subset \mathbf{C}^n$. In the 1-dimensional case this is due to G. Köthe. If $K = [a_1, b_1] \times \dots \times [a_n, b_n]$, then $H_K^n(\mathbf{C}^n, \mathcal{O})$ can be represented, including the topology, by the quotient space

$$\mathcal{O}(U \# K) \Big/ \sum_{j=1}^n \mathcal{O}(U \#_j K),$$

where U is a Stein neighborhood of K and $U \# K$, $U \#_j K$ are defined in the same way as (17). If we choose $U = U_1 \times \dots \times U_n$, then by

way of a defining function $F(z) \in \mathcal{O}(U \setminus K)$ for $f \in \mathcal{B}[K]$ the inner product is given by the contour integral

$$\int_{\mathbb{R}^n} f(x) \varphi(x) dx = (-1)^n \oint_{\gamma_1} \dots \oint_{\gamma_n} F(z) \varphi(z) dz_1 \dots dz_n,$$

where $\gamma_j \subset U_j$ is a closed path surrounding $[a_j, b_j]$ once in the positive sense. Similar integral formulas are known for some special K of various types.

Starting from analytic functionals we can reconstruct the sheaf of hyperfunctions. For example, we can put $\mathcal{B}(\Omega)$ = the totality of locally finite sums of analytic functionals with support in Ω modulo the rearrangement of supports by decomposition (Martineau [17]). If Ω is bounded, we can also put $\mathcal{B}(\Omega) = \mathcal{B}[\bar{\Omega}] / \mathcal{B}[\partial\Omega]$ (Schapira [18]). The proof of localizability and/or flabbiness is based on the decomposability of support (which is the dual of the exact sequence $0 \rightarrow \mathcal{A}(K \cup L) \rightarrow \mathcal{A}(K) \oplus \mathcal{A}(L) \rightarrow \mathcal{A}(K \cap L) \rightarrow 0$) and the denseness of $\mathcal{B}[K] \subset \mathcal{B}[L]$ (which is the dual of the unique continuation property $0 \rightarrow \mathcal{A}(L) \rightarrow \mathcal{A}(K)$) for a pair $K \subset L$ with the same family of connected components. Note that in no way is the topology of $\mathcal{B}[K]$ localizable, or equivalently, $\mathcal{B}(\Omega)$ does not admit a reasonable topology.

Z. Embedding of Distributions

As the dual of the natural mapping $\mathcal{A}(K) \rightarrow \mathcal{E}(K)$ we have the topological embedding $\mathcal{E}'(K) \hookrightarrow \mathcal{A}'(K) = \mathcal{B}[K]$. This embedding conserves the support and hence gives rise to an embedding of sheaf $\mathcal{D}' \hookrightarrow \mathcal{B}$ (R. Harvey).

For a distribution T with compact support a set of its defining functions as a hyperfunction is given by $F_\sigma(z) = T_x(W(z-x, \Gamma_\sigma))$, σ being the multisignature, where $W(z, \Gamma_\sigma) = \int_{S^{n-1} \cap \Gamma_\sigma} W(z, \omega) d\omega$ and $W(z, \omega)$ is the component of a Radon decomposition of $\delta(x)$ (\rightarrow Section CC). If $\text{supp } T \subset K = [a_1, b_1] \times \dots \times [a_n, b_n]$, then as a hyperfunction it is represented by the following element of $\mathcal{O}(\mathbb{C}^n \setminus K)$:

$$F(z) = T_x \left(\frac{1}{(2\pi i)^n (x_1 - z_1) \dots (x_n - z_n)} \right). \tag{19}$$

It is in fact in $\mathcal{O}((\mathbb{P}^1)^n \setminus K)$ and vanishes at infinity, where $\mathbb{P}^1 = \mathbb{C}^1 \cup \{\infty\}$ is the Riemann sphere. These formulas are valid also for hyperfunctions, and they give defining functions of some canonical types. Especially, the one given by (19) is called the **standard defining function** and is characterized by the foregoing properties.

For the above-mentioned defining functions

for a distribution T , we have the following convergence in the sense of distributions on \mathbb{R}^n :

$$T_x = \sum_{\sigma} \text{sgn } \sigma \lim_{\epsilon \downarrow 0} F_{\sigma}(x + i\epsilon y_{\sigma}) \quad \text{for } y_{\sigma} \in \Gamma_{\sigma}.$$

More generally if the limit

$$\lim_{\epsilon \downarrow 0} F_j(x + i\epsilon y_j) \quad \text{for } y_j \in \Gamma_j \tag{20}$$

exists in $\mathcal{D}'(\Omega)$, then the distribution defined as this limit admits $\{F_j(z)\}$ as a set of defining functions when it is considered as a hyperfunction. However, for an arbitrary set of defining functions for a distribution, (20) does not necessarily converge in $\mathcal{D}'(\Omega)$. (This is because we can add terms with any bad behavior which cancel each other formally.) If a distribution admits the boundary value expression with only one term, or if the dimension is one, then the convergence of (20) in $\mathcal{D}'(\Omega)$ necessarily holds.

The convergence of (20) in $\mathcal{D}'(\Omega)$ is equivalent to the locally uniform estimate for the defining functions of the type $F_j(z) = O(|y|^{-M})$ for some $M > 0$. These assertions can be generalized to ultradistributions. For $\mathcal{D}'_{(M_p)}(\Omega)$ (resp. $\mathcal{D}'_{(M_p)}(\Omega)$) the last growth condition for the defining functions reads as follows: $F_j(z) = O(\exp M^*(L/|y|))$ for some L (resp. every $L > 0$), where $M^*(\rho) = \sup_p \log(\rho^p p! M_0 / M_p)$; especially for $M_p = p!^s$ we have $M^*(\rho) \sim \rho^{1/(s-1)}$.

AA. Hyperfunctions on a Real Analytic Manifold

Sticking the hyperfunctions on coordinate patches by the transformation law mentioned in Section X, we can define the sheaf of hyperfunctions on a real analytic manifold. More generally, for a real analytic vector bundle over a real analytic manifold, we can consider the sheaf of its hyperfunction local cross sections, which is also flabby. Thus, especially on a real analytic manifold M , we can obtain a concrete flabby resolution of the constant sheaf \mathbf{C}_M of length $\dim M$ by the sheaves of differential forms with hyperfunction coefficients: $0 \rightarrow \mathbf{C}_M \rightarrow \mathcal{B}_M^{(0)} \xrightarrow{d} \mathcal{B}_M^{(1)} \xrightarrow{d} \dots \rightarrow \mathcal{B}_M^{(\dim M)} \rightarrow 0$. With this sequence we can calculate the relative cohomology groups of open pairs with coefficients in \mathbb{C} by an analytic method. This is an extension of the de Rham theory for distributions [16].

If M is a compact manifold equipped with a nowhere vanishing real analytic density globally defined on M , then we have the topological duality $\mathcal{B}(M) = \mathcal{A}(M)'$. The inner product is given by the definite integral with respect to the density.

The Fourier series is an example of hyperfunctions on real analytic manifolds. The series $\sum c_p \exp(2\pi i p x)$ converges in $\mathcal{B}(\mathbf{T}^n)$ and defines a periodic hyperfunction if and only if c_p is of **infra-exponential growth**, i.e., $c_p = O(e^{\varepsilon|p|})$ for any $\varepsilon > 0$. \mathbf{T}^n has the global complex neighborhood $(\mathbf{P}^1)^n$, and $f(x) \in \mathcal{B}(\mathbf{T}^n)$ has the corresponding boundary value expression

$$F_\sigma(z) \in \mathcal{O}(\{|z_1|^{\sigma_1} < 1, \dots, |z_n|^{\sigma_n} < 1\}),$$

which represents the terms in the Fourier series such that $\sigma_j p_j > 0$.

BB. Fourier Hyperfunctions

In place of \mathcal{S} we take as the basic space the space \mathcal{P}_* of **exponentially decreasing real analytic functions** in the sense of M. Sato [15]: $f(x) \in \mathcal{P}_*$ if and only if there exist $\delta > 0$ and $\varepsilon > 0$ such that for any $\delta' < \delta$ and $\varepsilon' < \varepsilon$, $f(x)$ extends holomorphically to the neighborhood $\{\operatorname{Im} z| < \delta'\}$ of the real axis and has order $O(e^{-\varepsilon'|\operatorname{Re} z|})$ there. \mathcal{P}_* is endowed with the structure of nuclear (DF)-space via the inductive limit for $\delta > 0$, $\varepsilon > 0$. The classical Fourier transform \mathcal{F} acts isomorphically on \mathcal{P}_* . (In fact, δ and ε change their roles under \mathcal{F} .) The strong dual of \mathcal{P}_* is called the space of **Fourier hyperfunctions** and is denoted by \mathcal{Q} . It is a nuclear Fréchet space. It contains \mathcal{S}' as a dense subspace in view of the continuous and dense inclusion $\mathcal{P}_* \hookrightarrow \mathcal{S}$. It also contains classical locally integrable functions of **infra-exponential growth**, i.e., of order $e^{\varepsilon|x|}$ for any $\varepsilon > 0$. Thus by the duality we obtain a wider extension of Fourier transformation on \mathcal{Q} .

In the following a 0-wedge of the form $\mathbf{R}^n + i\Gamma 0$ will be called a 0-wedge of the form $\mathbf{D}^n + i\Gamma 0$ at the same time if it is a tubular domain (i.e., with fixed imaginary part $\Gamma 0$). Then an element $f(x) \in \mathcal{Q}$ can be expressed in the form (13), where each $F_j(z)$ is holomorphic in a 0-wedge $\mathbf{D}^n + i\Gamma_j 0$ and is of infra-exponential growth there locally uniformly in $\operatorname{Im} z$. The inner product of such $f(x)$ with $\varphi \in \mathcal{P}_*$ is given by the definite integral

$$\int f(x)\varphi(x)dx = \sum_{j=1}^N \int_{\operatorname{Im} z=y_j} F_j(z)\varphi(z)dz,$$

where the $y_j \in \Gamma_j 0$ are fixed. Given a cone Δ we define its **dual cone** by $\Delta^\circ = \{\eta \in \mathbf{R}^n | \langle \eta, y \rangle \geq 0 \text{ for all } y \in \Delta\}$. If $F_j(z)$ are all of exponential decrease in $\operatorname{Re} z$ locally uniformly with respect to $\operatorname{Im} z \in \Gamma_j 0$ and $\operatorname{Re} z/|\operatorname{Re} z| \notin \Delta^\circ$, then the definite integral

$$\begin{aligned} G(\zeta) &= (\sqrt{2\pi})^{-n} \int e^{-ix\zeta} f(x) dx \\ &= \sum_{j=1}^N (\sqrt{2\pi})^{-n} \int_{\operatorname{Im} z=y_j} e^{-iz\zeta} F_j(z) dz \end{aligned} \quad (21)$$

converges locally uniformly for ζ in some 0-wedge $\mathbf{D}^n - i\Delta 0$, and defines there a holomorphic function of infra-exponential growth. Thus we obtain a Fourier hyperfunction $G(\zeta - i\Delta 0)$ that agrees with $\mathcal{F}f$ calculated by the duality. For a general $f(x) \in \mathcal{Q}$, the Fourier transform in the manner of Sato is calculated as follows: First we decompose $f(x)$ into the sum $\sum f_k(x)$ for which the defining functions of $f_k(x)$ decrease exponentially outside Δ_k° . Then we calculate $G_k(\zeta)$ by (21) and put $\mathcal{F}f = \sum G_k(\zeta - i\Delta_k 0)$. An example of such decomposition is given by multiplication by $\chi_\sigma(x) = \prod_{j=1}^n 1/(1 + \exp \sigma_j x_j)$, which decreases exponentially outside $\Gamma_\sigma = \{\sigma_j x_j \geq 0\}$.

The relation between \mathcal{Q} and \mathcal{B} is more complicated than the relation $\mathcal{S}' \subset \mathcal{D}'(\mathbf{R}^n)$. The growth condition for \mathcal{Q} is interpreted as a condition concerning germs at infinity. Thus \mathcal{Q} can be considered to be a sheaf on the directional compactification $\mathbf{D}^n = \mathbf{R}^n \cup \mathbf{S}_\infty^{n-1}$ such that $\mathcal{Q}|_{\mathbf{R}^n} = \mathcal{B}$. Just as the sheaf \mathcal{B} is obtained from \mathcal{O} , the sheaf \mathcal{Q} is obtained as the n th derived sheaf $\mathcal{H}_{\mathbf{D}^n}^n(\tilde{\mathcal{O}})$ from the sheaf $\tilde{\mathcal{O}}$ on $\mathbf{D}^n + i\mathbf{R}^n$ consisting of germs of holomorphic functions of infra-exponential growth with respect to $\operatorname{Re} z$. We have $H_\Omega^k(\mathbf{D}^n + i\mathbf{R}^n, \tilde{\mathcal{O}}) = 0$ for $k \neq n$ for any open set $\Omega \subset \mathbf{D}^n$. Especially, \mathcal{Q} is flabby, and the decomposition of support is available to calculate the Fourier transform. The symbol \mathcal{Q} employed at the beginning to express the global Fourier hyperfunctions corresponds to $\mathcal{Q}(\mathbf{D}^n)$, and $\mathcal{Q}(\mathbf{R}^n) = \mathcal{B}(\mathbf{R}^n)$ by definition. The canonical restriction mapping $\mathcal{Q}(\mathbf{D}^n) \rightarrow \mathcal{B}(\mathbf{R}^n)$ is surjective but not injective.

As for tempered distributions \mathcal{S}' , we can introduce various subclasses of Fourier hyperfunctions, e.g., **exponentially decreasing Fourier hyperfunctions** $\bigcup_{\delta>0} \exp(-\delta\sqrt{x^2+1})\mathcal{Q}$, real analytic functions of infra-exponential growth $\tilde{\mathcal{O}}(\mathbf{D}^n)$, etc. We can also consider operations such as convolution and multiplication between adequate pairs, and apply differential operators with suitable coefficients. Concerning these we can avail ourselves of the same formulas as given in Section O.

A hyperfunction with compact support is naturally considered as a Fourier hyperfunction, and its Fourier transform agrees with the inner product $\langle f(x), (\sqrt{2\pi})^{-n} \exp(-ix\xi) \rangle$, which gives an entire function of exponential type.

Paley-Wiener theorem. An entire function $f(\zeta)$ is the Fourier transform of a hyperfunction with support in a compact convex set K in \mathbf{R}^n if and only if it satisfies condition (i) of Section O.

The theory of Fourier hyperfunctions described above is mainly due to Sato and T. Kawai [20]. They are not the largest class of generalized functions stable under the Fourier

transformation. Following a suggestion of Sato, S. Nagamachi and N. Mugibayashi, Y. Saburi, and Y. Ito have extended them to the **modified Fourier hyperfunctions** in which the radial compactification \mathbf{D}^{2n} of \mathbf{C}^n is employed instead of the horizontal compactification $\mathbf{D}^n + i\mathbf{R}^n$ in the above theory. If we discard the localizing property, they can be extended further to the **Fourier ultrahyperfunctions** or **ultradistributions** of J. Sebastião e Silva (1958), M. Hasumi (1961), and M. Morimoto (1973).

CC. Micro-Analyticity of Hyperfunctions

The boundary value expression (13) for a hyperfunction $f(x)$ can be interpreted conversely as the description of the state of analytic continuation of $f(x)$ to the complex domain. Thus we say that f is **micro-analytic** at (x_0, ξ_0) if on a neighborhood of x_0 it admits the analytic continuation into the half-space $\langle \text{Im } z, \xi_0 \rangle < 0$ in the sense that it admits an expression (13) satisfying $\Gamma_j \cap \{ \langle \text{Im } z, \xi_0 \rangle < 0 \} \neq \emptyset$ for every j . The set of points $(x_0, \xi_0) \in \Omega \times S^{n-1}$, where $f \in \mathcal{B}(\Omega)$ is not micro-analytic, is called the **singularity spectrum** or **singular spectrum** of f and is denoted by S.S. f . We have by definition $\text{S.S.}F(x + i\Gamma 0) \subset \Omega \times (\Gamma^0 \cap S^{n-1})$. Micro-analyticity can be characterized by the Fourier transformation as follows: f is micro-analytic at (x_0, ξ_0) if and only if there exists a Fourier hyperfunction $g(x)$ such that the Fourier transform $\hat{g}(\xi)$ decreases exponentially on a conical neighborhood of ξ_0 and that $f - g$ is real analytic on a neighborhood of x_0 . A hyperfunction $f(x)$ is real analytic in a neighborhood of x_0 if and only if it is micro-analytic at (x_0, ξ) for any $\xi \in S^{n-1}$.

With this notion we can clarify the operations on hyperfunctions. (In the following S^{n-1} is identified with $(\mathbf{R}^n \setminus \{0\})/\mathbf{R}^+$ and $+$ denotes the sum in the latter.) We have

$$\text{S.S.}(fg) \subset \{ (x, \lambda\xi + (1-\lambda)\eta) \mid (x, \xi) \in \text{S.S.}f, (x, \eta) \in \text{S.S.}g, 0 \leq \lambda \leq 1 \} \cup \text{S.S.}f \cup \text{S.S.}g,$$

$$\text{S.S.}f(\Phi(\tilde{x})) \subset \{ (\tilde{x}, {}^tD\Phi\xi) \mid (\Phi(\tilde{x}), \xi) \in \text{S.S.}f \},$$

and these operations are legitimate if and only if 0 does not appear in the direction component of the right-hand side. We also have

$$\text{S.S.} \int f(x, t) dx \subset \{ (x, \xi) \mid (x, t, \xi, 0) \in \text{S.S.}f \text{ for a } t \},$$

$$\text{S.S.}(f * g) \subset \{ (x + y, \xi) \mid (x, \xi) \in \text{S.S.}f, (y, \xi) \in \text{S.S.}g \}$$

under suitable conditions for support.

The classical **decomposition formula of Radon** (or the **plane wave decomposition** of δ)

$$\delta(x) = \frac{(n-1)!}{(-2\pi i)^n} \int_{S^{n-1}} \frac{d\omega}{(x\omega + i0)^n} \tag{22}$$

can be interpreted as the decomposition of δ into hyperfunctions with S.S. in the single direction ω . By the convolution, this formula supplies similar decomposition for a general hyperfunction (called the singular spectrum decomposition). (22) can be generalized to

$$\delta(x) = \frac{(n-1)!}{(-2\pi i)^n} \int_{S^{n-1}} \frac{\det(\text{grad}_\omega \Psi(x, \omega))}{(\Phi(x, \omega) + i0)^n} d\omega, \tag{23}$$

where the twisted phase $\Phi(x, \omega)$ satisfies (i) $\Phi(x, \omega)$ is a real analytic function of positive type (i.e., $\text{Re } \Phi(x, \omega) = 0$ implies $\text{Im } \Phi(x, \omega) \geq 0$) and (ii) $\Phi(x, \omega)$ is homogeneous of order 1 in ω and $\Phi(0, \omega) = 0$, $\text{grad}_x \Phi(0, \omega) = \omega$; and the vector $\Psi(x, \omega)$ is such that $\langle \Psi(x, \omega), x \rangle = \Phi(x, \omega)$. If $\Phi(x, \omega)$ further satisfies $\Phi(x, \omega) \neq 0$ for $x \neq 0$, then the component becomes a hyperfunction (even a distribution) of x whose S.S. is precisely one point $(0, \omega)$, and this fact is useful in theoretical applications [7, 21] (\rightarrow 274 Microlocal Analysis).

DD. Structure Theorems of Hyperfunctions

A hyperfunction whose support is concentrated at the origin is expressed as the infinite derivative $J(D)\delta(x) = \sum a_p D^p \delta(x)$ of the Dirac measure, with the coefficients satisfying $\lim(|a_p|p!)^{1/p} = 0$. Such an operator $J(D)$ is called a **local operator** with constant coefficients and acts on \mathcal{B} as a sheaf homomorphism. Its total symbol $J(\zeta)$ is an entire function of infra-exponential growth or of type $[1, 0]$. By way of such an operator, a general (Fourier) hyperfunction can be written in the form $J(D)g(x)$ with a continuous function on \mathbf{R}^n (of infra-exponential growth).

If $0 \in \text{supp } f \subset \{ \langle v, x \rangle \geq 0 \}$, then $\text{S.S.}f \ni (0, \pm v)$ (**Holmgren type theorem** of Kashiwara and Kawai), and furthermore, the direction component of S.S. f at 0 has the form of $\{ \pm v \} \cup \rho^{-1}(E)$ with some $E \subset S^{n-2}$, where $\rho: S^{n-1} \setminus \{ \pm v \} \rightarrow S^{n-2}$ is the projection to the equator (the **watermelon-slicing theorem** of Morimoto, Kashiwara, and K. Kataoka). E is called the reduced S.S. of f at 0. These theorems have many applications in the theory of linear partial differential equations and also in physics.

A hyperfunction $f(x)$ with support in the hyperplane $x_n = 0$ has several further remarkable properties in x_n . It admits a formal expansion of the form $\sum_{k=0}^\infty f_k(x') \delta^{(k)}(x_n)$, where $x' = (x_1, \dots, x_{n-1})$ and $f_k(x') = \int_{-\infty}^\infty f(x) x_n^k / k! dx_n$. The sum converges in the sense of the topology if f has compact support. It reduces locally to a finite sum if f is a distribution, and the k th term represents the k -ple layer distribution of mass, electric charge, etc. For a general f the coefficients $\{ f_k(x') \}$ do not neces-

sarily determine f , though they are determined by f .

EE. Complex Powers of Polynomials

Among examples of special generalized functions the most important are those of the form f_+^λ , where $f_+ = \max\{f(x), 0\}$ (or more generally it can be replaced by zero on some connected components of $\{f(x) > 0\}$), and $\lambda \in \mathbb{C}$ denotes a holomorphic parameter. (The discussion is the same for $f_- = \max\{-f(x), 0\}$.) The simplest example, x_+^λ , is defined as the analytic continuation of the locally integrable function x_+^λ for $\operatorname{Re} \lambda > -1$ by repeated use of the formula $x_+^\lambda = (\lambda + 1)^{-1} D_x x_+^{\lambda+1}$, and becomes meromorphic in λ with simple poles at $\lambda = -1, -2, \dots$. As a hyperfunction we have $x_+^\lambda = \{(-x + i0)^\lambda - (-x - i0)^\lambda\}/2i \sin \pi \lambda$. At a negative integer $\lambda = -n$, x_+^λ has residue $(-1)^{n-1} \delta^{(n-1)}(x)/(n-1)!$ and finite part $[-(2\pi i)^{-1} z^{-n} \log(-z)]$. The latter is often denoted by x_+^{-n} . In general, for a germ of a real-valued real analytic function $f(x)$ we can find a differential operator $P(\lambda, x, D_x)$ with polynomial coefficients in λ and a monic polynomial $b(\lambda)$ of minimum degree such that

$$P(\lambda, x, D_x) f_+^{\lambda+1} = b(\lambda) f_+^\lambda \quad (24)$$

(Sato, I. N. Bernshtein, Kashiwara, J.-E. Björk [22]). This formula gives the analytic continuation of f_+^λ just as for x_+^λ . The polynomial $b(\lambda)$ is called the ***b*-function** or the **Sato-Bernshtein polynomial** and contains valuable information regarding the singularity of f . It has only negative rational roots (Kashiwara).

We have $f \cdot f_\pm^\lambda = f_\pm^{\lambda+1}$; hence $f_+^{-1} - f_-^{-1}$ (suitably interpreted as above) gives a solution of the division problem $u \cdot f = 1$. Thus if f is a polynomial, its inverse Fourier transform gives a tempered fundamental solution of $f(-iD)$. Furthermore, when f is the relative invariant of a * prehomogeneous vector space, we can calculate $b(\lambda)$ explicitly by way of the holonomy diagram. Also, the Fourier transform of f_+^λ can be calculated explicitly by way of the real holonomy diagram as a linear combination of the corresponding objects for the dual prehomogeneous vector space with coefficients similar to the * Maslov index. The simplest example is

$$\begin{aligned} \mathcal{F} x_\pm^\lambda &= (\sqrt{2\pi})^{-1} (\mp i) e^{-\pi i \lambda / 2} \Gamma(\lambda + 1) (\xi \mp i 0)^{-\lambda-1} \\ &= (\sqrt{2\pi})^{-1} (\mp i) \Gamma(\lambda + 1) \{e^{\mp \pi i \lambda / 2} \xi_-^{-\lambda-1} \\ &\quad - e^{\pm \pi i \lambda / 2} \xi_+^{-\lambda-1}\}. \end{aligned}$$

Among practical examples are the following classical formulas: Let $P(x)$ be a nondegenerate real quadratic form and $Q(\xi)$ its * dual form, and let q denote the number of negative

eigenvalues of $P(x)$. Then

$$\begin{aligned} \mathcal{F} P_+^\lambda &= -(\sqrt{2\pi})^{-n} 2^{2\lambda+n} \pi^{n/2-1} \Gamma(\lambda+1) \Gamma(\lambda+n/2) \\ &\quad \times |\det P|^{-1/2} \{\sin \pi(\lambda+q/2) Q_+^{-\lambda-n/2} \\ &\quad - \sin \pi((n-q)/2) Q_-^{-\lambda-n/2}\}. \end{aligned}$$

Here the arguments in the Γ -factor $(\lambda+1)(\lambda+n/2)$ give the b -function of $P(x)$. If $q = n-1$, we further have, letting $P_\pm^\lambda = P_\pm^\lambda \mathbf{1}(\pm \langle x, v \rangle)$ for an eigenvector v corresponding to the unique positive eigenvalue,

$$\begin{aligned} \mathcal{F} P_\pm^\lambda &= (2\pi)^{-n/2} 2^{2\lambda+n-1} \pi^{n/2-1} \Gamma(\lambda+1) \\ &\quad \times \Gamma(\lambda+n/2) |\det P|^{-1/2} \{e^{\mp \pi i(\lambda+n/2)} Q_\pm^{-\lambda-n/2} \\ &\quad + e^{\pm \pi i(\lambda+n/2)} Q_\mp^{-\lambda-n/2} + Q_-^{-\lambda-n/2}\}. \end{aligned}$$

From these formulas (taking the finite part if necessary) we obtain the fundamental solution of the wave equation, the Laplacian, and their iterations. These are exactly the distributions introduced by Hadamard, M. Riesz, and others, as mentioned in Section A (\rightarrow Appendix A, Table 15.V).

126 (IX.22) Dynamical Systems

A. History

The theory of dynamical systems began with the investigation of the motion of planets in ancient astronomy. Qualitative investigation of mechanics in antiquity and the Middle Ages culminated in the work of J. Kepler and G. Galilei in 17th century. At the end of that century, I. Newton founded his celebrated Newtonian mechanics, by means of which

Kepler's law on the motion of planets and Galileo's observations of movement can be explained theoretically. Following this, L. Euler, J. L. Lagrange, P. S. Laplace, W. R. Hamilton, C. G. J. Jacobi, and others developed the theory using analytical methods, and founded analytical dynamics. From the end of the 18th century through the 19th century, the [†]three-body problem attracted the attention of many mathematicians. At the end of the 19th century, H. Bruns and H. Poincaré found that general solutions of the three-body problem could not be obtained by [†]quadrature, and this gave rise to a crisis of analytical dynamics. But this was resolved by Poincaré himself. He pointed out the importance of the qualitative theory based on topological methods, and obtained many fundamental results. A. M. Lyapunov with his theory of stability and G. D. Birkhoff with his many important concepts of topological dynamics established foundations of the new qualitative theory.

In 1937 A. A. Andronov and L. S. Pontryagin introduced the concept of structural stability, which attracted the attention of S. Lefschetz. Lefschetz's school investigated structural stability and [†]nonlinear oscillations, and obtained many important results (H. F. de Baggis, L. Markus, M. M. Peixoto, and others). In about 1960, S. Smale initiated study of differentiable dynamical systems under the influence of Lefschetz's school. Smale and his school founded a new theory of differentiable dynamical systems using [†]differential topology. D. V. Anosov generalized the work of E. Hopf and G. A. Hedlund on [†]geodesic flows of closed surfaces of [†]constant negative curvature and established the concept of Anosov systems, which played an important role in Smale's theory. The work of Hopf, Hedlund, and Anosov is closely related to [†]ergodic theory. Ya. G. Sinai and R. Bowen obtained important results in ergodic theory. The concept of structural stability and its generalization are essential in the [†]catastrophe theory of R. Thom (→ 51 Catastrophe Theory); the theory of bifurcation of dynamical systems is another essential part of catastrophe theory. D. Ruelle and F. Takens proposed a new mathematical mechanism for the generation of turbulence using Smale's theory and Hopf bifurcation. The new theory of dynamical systems developed by Smale and others is now applied to the mathematical explanation of chaotic phenomena in many branches of science. Finally, we mention that in the 1960s A. N. Kolmogorov, V. I. Arnold, and J. Moser obtained remarkable results on the existence of quasi-periodic solutions for the *n*-body problem, which turned out to solve the long-standing problem of the stability of the solar system.

B. Definitions of Dynamical Systems

In the study of the evolution of physical, biological, and other systems, we construct mathematical models of the systems. Usually, the state of a given system is completely described by a collection of continuous parameters, which may be related in some cases. Thus the space X of all possible states of the system can be regarded as a Euclidean space or a subset of a Euclidean space defined by some equations. In general, we assume that the space X of all possible states of the system forms a [†]topological space, and we call it a **state space** or a **phase space**. Second, we assume that the law of evolution of states in time is given, by which we can tell the state x_1 at any time t_1 if we know the state x_0 at time t_0 . Assigning x_1 to x_0 , we have a mapping $\pi(t_1, t_0): X \rightarrow X$ for any times t_0 and t_1 , which satisfies the following conditions: (i) $\pi(t_2, t_1) \circ \pi(t_1, t_0) = \pi(t_2, t_0)$; (ii) $\pi(t_0, t_0) = 1_X$, the identity mapping of X . Finally, we assume that the mapping $\pi(t_1, t_0)$ depends only on $t = t_1 - t_0$. Writing $\pi_t = \pi(t_1, t_0)$ if $t = t_1 - t_0$, we have the following conditions from (i) and (ii) above: (i') $\pi_s \circ \pi_t = \pi_{s+t}$, $s, t \in \mathbf{R}$; (ii') $\pi_0 = 1_X$.

In general, the theory of topological dynamics can be regarded as the study of topological transformation groups (\rightarrow 431 Transformation Groups) originating in the topological investigations of problems arising from classical mechanics. Here, we restrict our attention to some important special cases.

(1) Let X be a topological space and \mathbf{R} the additive topological group of real numbers. Let $\varphi: X \times \mathbf{R} \rightarrow X$ be a continuous mapping. For each $t \in \mathbf{R}$, we define a mapping $\varphi_t: X \rightarrow X$ by $\varphi_t(x) = \varphi(x, t)$, $x \in X$. If the family of mappings $\{\varphi_t\}_{t \in \mathbf{R}}$ satisfies the following conditions, we say that (X, φ) is a **(continuous) \mathbf{R} -action**, a **(continuous) flow**, or a **(continuous) dynamical system** on X , and that X is the **phase space**: (i) $\varphi_s \circ \varphi_t = \varphi_{s+t}$ for all $s, t \in \mathbf{R}$; (ii) $\varphi_0 = 1_X$.

Let (X, φ) be a flow. Then $\varphi_t: X \rightarrow X$ is a [†]homeomorphism with $(\varphi_t)^{-1} = \varphi_{-t}$ for each $t \in \mathbf{R}$. For each $x \in X$, define a mapping $\varphi^x: \mathbf{R} \rightarrow X$ by $\varphi^x(t) = \varphi(x, t)$, $t \in \mathbf{R}$. The mapping φ^x is called a **motion** through x , and its image $C(x) = \{\varphi^x(t) | t \in \mathbf{R}\}$ is called the **orbit** or the **trajectory** through x . An orbit is nonempty, and two orbits are either identical or mutually disjoint. The family of orbits fills up the phase space X and is called the **phase portrait**.

Let \mathbf{R}_+ be the additive [†]semigroup of all nonnegative real numbers. If we replace \mathbf{R} by \mathbf{R}_+ in the definition of a (continuous) flow, we obtain a definition of a **(continuous) semiflow**. For a semiflow (X, φ) , the mapping $\varphi_t: X \rightarrow X$, $t \in \mathbf{R}_+$ is in general not a homeomorphism but a continuous mapping.

Let (X, φ) and (Y, ψ) be flows. A homeomorphism $h: X \rightarrow Y$ is called a **topological equivalence** from (X, φ) to (Y, ψ) if it maps each orbit of φ onto an orbit of ψ preserving orientations of orbits (i.e., there exists an increasing homeomorphism $\alpha_x: \mathbf{R} \rightarrow \mathbf{R}$ for each $x \in X$ such that $h\varphi(x, t) = \psi(h(x), \alpha_x(t))$ for all $t \in \mathbf{R}$). Two flows are **topologically equivalent** if there exists a topological equivalence from one to the other. If two flows are topologically equivalent, their phase portraits have the same topological structure. Two flows (X, φ) and (Y, ψ) are **flow equivalent** if there exist a $c > 0$ and a homeomorphism $h: X \rightarrow Y$ such that $h\varphi(x, t) = \psi(h(x), ct)$ for all $t \in \mathbf{R}$. Such an h is a topological equivalence from (X, φ) to (Y, ψ) .

(2) Let X be a topological space and \mathbf{Z} the additive group of integers. If we replace \mathbf{R} by \mathbf{Z} in the definition of a continuous flow, we obtain a definition of a **(continuous) \mathbf{Z} -action**, a **discrete flow**, or a **discrete dynamical system** on X . If (X, φ) is a discrete flow, then $f = \varphi_1: X \rightarrow X$ is a homeomorphism and $\varphi_n = f^n$ for all $n \in \mathbf{Z}$. Conversely, for a given homeomorphism $f: X \rightarrow X$, define a mapping $\varphi: X \times \mathbf{Z} \rightarrow X$ by $\varphi(x, n) = f^n(x)$, $x \in X$ and $n \in \mathbf{Z}$. Then (X, φ) is a discrete flow such that $\varphi_n = f^n$ for $n \in \mathbf{Z}$. So we identify a homeomorphism with a discrete flow. Thus the orbit of a homeomorphism $f: X \rightarrow X$ through x is $C(x) = \{f^n(x) | n \in \mathbf{Z}\}$.

Let \mathbf{Z}_+ be the additive semigroup of all nonnegative integers. If we replace \mathbf{R} by \mathbf{Z}_+ in the definition of a continuous flow, we obtain a definition of a **discrete semiflow** on X . For a discrete semiflow (X, φ) , the mapping $\varphi_n: X \rightarrow X$, $n \in \mathbf{Z}_+$ is in general not a homeomorphism but a continuous mapping. We can identify a continuous mapping $f: X \rightarrow X$ with a discrete semiflow (X, φ) in a natural way as above.

Let $f: X \rightarrow X$ and $g: Y \rightarrow Y$ be two homeomorphisms (continuous mappings). A homeomorphism $h: X \rightarrow Y$ such that $h \circ f = g \circ h$ is called a **topological conjugacy** from f to g . And f and g are called **topologically conjugate** if there exists a topological conjugacy from f to g . Topologically conjugate homeomorphisms have the same phase portrait in a topological sense.

(3) Let M be a [†]differentiable manifold of class C^r ($1 \leq r \leq \infty$ or $r = \omega$). A continuous flow (M, φ) is a **flow of class C^r** , a **C^r -flow**, a **differentiable dynamical system of class C^r** , or a **one-parameter group of transformations of class C^r** , if $\varphi: M \times \mathbf{R} \rightarrow M$ is of class C^r . A **semiflow of class C^r** is defined similarly.

Let (M, φ) and (N, ψ) be C^r -flows. A topological equivalence $h: M \rightarrow N$ from (M, φ) to (N, ψ) is called a **C^r -equivalence** if it is a [†] C^r -diffeomorphism. Two flows are **C^r -equivalent** if there is a C^r -equivalence from one to the other. Classification of C^r -flows by C^r -equivalence is

difficult and sometimes too unwieldy to work with. On the other hand, there are many problems which can be solved by the knowledge of the topological structure of the phase portrait of C^r -flows.

(4) Let (M, π) be a discrete flow on a differentiable manifold M of class C^r . If $\pi: M \times \mathbb{Z} \rightarrow M$ is of class C^r , then (M, π) is called a **Z-action of class C^r** , a **discrete flow of class C^r** , a **discrete C^r -flow**, or a **discrete dynamical system of class C^r** . If (M, π) is a discrete C^r -flow, then $f = \pi_1: M \rightarrow M$ is a C^r -diffeomorphism. Conversely, a C^r -diffeomorphism $f: M \rightarrow M$ defines a discrete C^r -flow in a natural way on M , and we identify a C^r -diffeomorphism $f: M \rightarrow M$ with the discrete C^r -flow on M defined by f . A **discrete semiflow of class C^r** is defined similarly, and a C^r -mapping $f: M \rightarrow M$ is identified with a discrete semiflow of class C^r on M defined by f .

Let $f: M \rightarrow M$ and $g: N \rightarrow N$ be C^r -diffeomorphisms (C^r -mappings) of differentiable manifolds M and N of class C^r . A topological conjugacy from f to g is called a **C^r -conjugacy** if it is a C^r -diffeomorphism. f and g are **C^r -conjugate** if there is a C^r -conjugacy from f to g .

C. Examples and Remarks

(1) Let D be an open set of \mathbb{R}^n and $f: D \rightarrow \mathbb{R}^n$ a continuous mapping. Consider the autonomous system of ordinary differential equations

$$dx/dt = f(x), \quad x \in D. \quad (1)$$

We assume that for each $x \in D$ there exists a unique nonextendable solution $\varphi(x, t)$ with the initial condition $\varphi(x, 0) = x$ defined on a maximal interval (a_x, b_x) , $-\infty \leq a_x < 0 < b_x \leq \infty$ (\rightarrow 316 Ordinary Differential Equations (Initial Value Problems)). The set $\{\varphi(x, t) | a_x < t < b_x\}$ is called the **trajectory** through x . By the uniqueness assumption, we have $\varphi(\varphi(x, t), s) = \varphi(x, t + s)$ whenever both sides of the equality are defined. When $(a_x, b_x) = \mathbb{R}$ for all $x \in D$, then equation (1) is called **complete**. If (1) is complete, the mapping $\varphi: D \times \mathbb{R} \rightarrow D$ defined by the solutions $\varphi(x, t)$ determines a continuous flow (D, φ) . Furthermore, if f is of class C^r , then (D, φ) is of class C^r . If (1) is not complete, then there exists a continuous positive scalar function $\alpha: D \rightarrow \mathbb{R}$ such that

$$dx/dt = \alpha(x)f(x), \quad x \in D, \quad (2)$$

is complete. The trajectories of (1) and (2) through x coincide for all $x \in D$, and thus the phase portraits of (1) and (2) are the same.

(2) Let M be a differentiable manifold of class C^∞ . A vector field of class C^r on M ($1 \leq r \leq \infty$) gives rise to an autonomous system

of ordinary differential equations in a coordinate neighborhood of each point of M , and it generates a local one-parameter group of local transformations of class C^r . If M is compact, this local one-parameter group of local transformations is uniquely extended to a one-parameter group of transformations of class C^r (\rightarrow 105 Differentiable Manifolds). Thus a vector field of class C^r on M generates a unique C^r -flow on M if M is compact. Therefore, sometimes we identify a vector field of class C^r with the C^r -flow generated by it.

(3) Let (M, φ) be a C^r -flow. Then $\varphi_1: M \rightarrow M$ is a C^r -diffeomorphism, which we call the **time-one mapping (time-one map)** of (M, φ) . Thus every C^r -flow (M, φ) induces a C^r -diffeomorphism as a time-one mapping. But the set of C^1 -diffeomorphisms that are time-one mappings of C^1 -flows is of the first category in the space of all C^1 -diffeomorphisms with C^1 topology (J. Palis). Thus most C^1 -diffeomorphisms are not expressed as time-one mappings of C^1 -flows.

(4) Let M be a compact differentiable manifold of class C^∞ with dimension m and (M, φ) a C^r -flow ($1 \leq r \leq \infty$). An $(m-1)$ -dimensional closed submanifold Σ of M is called a **cross section** of (M, φ) if the following conditions are satisfied: (i) For any $x \in X$, there exist $t_1 > 0$ and $t_2 < 0$ such that $\varphi_{t_1}(x), \varphi_{t_2}(x) \in \Sigma$; (ii) Every orbit intersects Σ transversally whenever it meets Σ . Let Σ be a cross-section of (M, φ) and $x \in \Sigma$. Let t_1 be the least positive number with $\varphi_{t_1}(x) \in \Sigma$. Such a t_1 exists for every $x \in \Sigma$, and $f: \Sigma \rightarrow \Sigma$ defined by $f(x) = \varphi_{t_1}(x)$, $x \in \Sigma$ is a C^r -diffeomorphism. We call this diffeomorphism f the **first-return mapping (first-return map)** or the **Poincaré mapping (Poincaré map)** for Σ .

(5) Let N be a compact differentiable manifold of class C^∞ and $f: N \rightarrow N$ a C^r -diffeomorphism ($1 \leq r \leq \infty$). Define an equivalence relation \sim on $N \times \mathbb{R}$ generated by $(x, t + 1) \sim (f(x), t)$ for $x \in X$, $t \in \mathbb{R}$. Then the quotient space $N(f) = N \times \mathbb{R} / \sim$ has a natural differentiable structure of class C^r , and a C^r -flow $(N(f), \psi)$ is defined by $\psi([x, t], s) = [x, t + s]$ for $x \in N$, $t, s \in \mathbb{R}$, where $[x, t] \in N(f)$ is the equivalence class of (x, t) . The flow $(N(f), \psi)$ thus obtained is called the **suspension** of f . The suspension $(N(f), \psi)$ has a cross section $\Sigma = \{[x, 0] | x \in N\}$, and the Poincaré mapping for Σ is C^r -conjugate to f . Conversely, if (M, φ) has a cross section Σ and the Poincaré mapping for Σ is $f: \Sigma \rightarrow \Sigma$, then the suspension $(\Sigma(f), \psi)$ is C^r -equivalent to (M, φ) .

(6) Let U be an open set of \mathbb{R}^n and $f: U \rightarrow \mathbb{R}^n$ a continuous mapping. Consider the difference equation

$$x_{m+1} = f(x_m), \quad x_m \in U. \quad (3)$$

For each $x \in U$, let $\varphi(x, m)$ be the solution of (3)

with $\varphi(x, 0) = x$. If $f(U) \subset U$, then $\varphi(x, m)$ exists for all $m \in \mathbf{Z}_+$ and $x \in U$, and φ defines a discrete semiflow on U . If $f: U \rightarrow U$ is a homeomorphism, then $\varphi(x, m)$ exists for all $m \in \mathbf{Z}$ and $x \in U$, and φ defines a discrete flow on U (\rightarrow 104 Difference Equations).

D. Basic Concepts

For simplicity we assume that the phase spaces of dynamical systems are metric spaces, and we denote their metrics by d .

(1) Let (X, φ) be a continuous flow on a metric space X and $x \in X$. A subset A of X is called **invariant** if $\varphi_t(A) \subset A$ for all $t \in \mathbf{R}$. A subset of X is invariant if and only if it is a union of orbits. A subset A of X is **positively** (resp. **negatively**) **invariant** if $\varphi_t(A) \subset A$ for all $t \geq 0$ (resp. $t \leq 0$). The subset $C_+(x) = \{\varphi^x(t) | t \geq 0\}$ (resp. $C_-(x) = \{\varphi^x(t) | t \leq 0\}$) is called the **positive** (resp. **negative**) **semiorbit** or the **positive** (resp. **negative**) **half-trajectory** starting from x . A subset is positively (resp. negatively) invariant if and only if it is a union of positive (resp. negative) semiorbits. A subset is invariant if and only if it is both positively and negatively invariant.

The union and the intersection of invariant sets are invariant. If A is invariant, then its closure \bar{A} , its interior $\text{Int } A$, its boundary ∂A , and its complement $A^c = X - A$ are invariant. If A is invariant, then $\varphi(A \times \mathbf{R}) \subset A$ and the restriction mapping $\varphi|_A \times \mathbf{R}$ defines a continuous flow $(A, \varphi|_A \times \mathbf{R})$ on A . The flow thus obtained is called the **restriction** of (X, φ) on A .

(2) A point $x \in X$ is a **singular point**, an **equilibrium point**, a **critical point**, a **rest point**, or a **fixed point** if $C(x) = \{x\}$ (\rightarrow 290 Nonlinear Oscillation). A point is **regular** or **nonsingular** if it is not a singular point. The set of all singular points is a closed invariant set, and the set of all nonsingular points is an open invariant set. If A is a positively invariant set which is homeomorphic to the closed unit ball in \mathbf{R}^n , then there exists a singular point in A (*Brouwer fixed-point theorem).

A point $x \in X$ is **periodic** if there exists a $T \neq 0$ such that

$$\varphi(x, t + T) = \varphi(x, t) \quad (4)$$

holds for all $t \in \mathbf{R}$. If x is periodic, the motion φ^x and the orbit $C(x)$ are said to be **periodic**. A point x is periodic if and only if there exists a $T \neq 0$ with $\varphi(x, T) = x$. A singular point is periodic. For a periodic point x , a number T satisfying (4) is called a **period** of x . If x is nonsingular and periodic, then there exists a smallest positive period T_0 of x , and any period is an integral multiple of T_0 . An orbit of a nonsingular periodic point is called a **closed**

orbit. If C is a closed orbit, then all points of C are nonsingular periodic points, and their smallest positive periods coincide. A closed orbit is compact.

(3) Let x be a point of X . A point $y \in X$ is called an ω -**limit** (resp. α -**limit**) **point** or a **positive** (resp. **negative**) **limit point** of x if there exists a sequence $\{t_n\}$ of real numbers such that (i) $t_n \rightarrow \infty$ (resp. $t_n \rightarrow -\infty$) as $n \rightarrow \infty$ and (ii) $\varphi(x, t_n) \rightarrow y$ as $n \rightarrow \infty$. The set of all ω -limit (resp. α -limit) points of x is denoted by $\omega(x)$ (resp. $\alpha(x)$) and is called the ω -**limit** (resp. α -**limit**) **set** of x . For each $x \in X$, $\omega(x)$ and $\alpha(x)$ are closed invariant sets, and the following equalities hold: $C_+(x) = C_+(x) \cup \omega(x)$, $C_-(x) = C_-(x) \cup \alpha(x)$, and $C(x) = C(x) \cup \alpha(x) \cup \omega(x)$. If x is a periodic point, $\bar{C}(x) = C(x) = \alpha(x) = \omega(x)$. If C is a closed orbit, then $\bar{C} = C = C(x) = \alpha(x) = \omega(x)$ for all $x \in C$. If A is a compact invariant set and $x \in A$, then $\alpha(x)$ and $\omega(x)$ are nonempty.

Assume that X is locally compact and $x \in X$. Then $\omega(x)$ is connected if it is compact, and none of the connected components of $\omega(x)$ is compact if $\omega(x)$ is not compact.

(4) Let x be a point of X . Let $J_+(x)$ (resp. $J_-(x)$) be the set of all points y satisfying the following condition: There exist a sequence $\{t_n\}$ of numbers and a sequence $\{x_n\}$ of points in X such that (i) $t_n \rightarrow \infty$ (resp. $t_n \rightarrow -\infty$) as $n \rightarrow \infty$, (ii) $x_n \rightarrow x$ as $n \rightarrow \infty$, and (iii) $\varphi(x_n, t_n) \rightarrow y$ as $n \rightarrow \infty$. The set $J_+(x)$ (resp. $J_-(x)$) is a closed invariant set containing $\omega(x)$ (resp. $\alpha(x)$), called the **first positive** (resp. **negative**) **prolongational limit set** of x . If X is locally compact, then $J_+(x)$ is connected if it is compact, and none of the connected components of $J_+(x)$ is compact when $J_+(x)$ is not compact.

Notions of higher prolongations have been defined and investigated by T. Ura, J. Auslander, and P. Seibert.

(5) For a discrete flow, we can similarly define basic notions such as an invariant set, fixed point, periodic point, and so on defined in Sections D(1)–D(4) by replacing \mathbf{R} by \mathbf{Z} . The propositions and theorems stated above hold for discrete flows, except those concerning connectedness.

E. Recursive Concepts and Dispersive Concepts

(1) Let (X, φ) be a flow on a metric space X . Let $x \in X$ be a point such that there exist a neighborhood U of x and a $T > 0$ satisfying the condition $U \cap \varphi_t(U) = \emptyset$ for $t \geq T$. Then x is called **wandering**. The set of all wandering points is an open invariant set. A point is **nonwandering** if it is not wandering. The set Ω of all nonwandering points is a closed invariant set and is called the **nonwandering set**.

The following conditions are equivalent: (i) x is nonwandering, (ii) $x \in J_+(x)$, (iii) $x \in J_-(x)$. The nonwandering set Ω contains all singular points, closed orbits, and $\omega(x)$ and $\alpha(x)$ for all $x \in X$.

(2) A point $x \in X$ is **positively** (resp. **negatively**) **Poisson stable** if $x \in \omega(x)$ (resp. $x \in \alpha(x)$). It is **Poisson stable** if it is both positively and negatively Poisson stable. A positively Poisson stable point and a negatively Poisson stable point are nonwandering. The following conditions are equivalent: (i) x is positively Poisson stable, (ii) $\overline{C_+(x)} = \omega(x)$, (iii) $C(x) \subset \omega(x)$, (iv) for any neighborhood U of x and $T > 0$, there exists a $t > T$ with $\varphi(x, t) \in U$. If X is \dagger complete and $x \in X$ is positively Poisson stable but not periodic, then $\omega(x) - C(x)$ is \dagger dense in $\omega(x)$. This implies that if X is complete, then $C(x)$ is periodic if and only if $C(x) = \omega(x)$.

(3) If all the points of the phase space X are wandering, then (X, φ) is called **completely unstable**. If all the points of X are nonwandering, then (X, φ) is called **regionally recurrent**. If A is an invariant set such that the restriction of (X, φ) on A is regionally recurrent, then (X, φ) is said to be **regionally recurrent on A** . If (X, φ) is regionally recurrent and X is locally compact, then the set of all Poisson stable points is dense in X .

For a given flow (X, φ) , we obtain a sequence of invariant sets $\{\Omega_n\}$ and a sequence of restriction flows $\{(\Omega_n, \varphi_n)\}$ such that (i) $(\Omega_0, \varphi_0) = (X, \varphi)$; (ii) Ω_{n+1} is the nonwandering set of (Ω_n, φ_n) , $n \geq 0$; and (iii) $(\Omega_{n+1}, \varphi_{n+1})$ is the restriction of (X, φ) on Ω_{n+1} . Then $X = \Omega_0 \supset \Omega_1 \supset \dots \supset \Omega_n \supset \dots$. Put $\Omega_\omega = \bigcap_n \Omega_n$. Then Ω_ω is an invariant set of (X, φ) , and we denote the restriction of (X, φ) on Ω_ω by $(\Omega_\omega, \varphi_\omega)$. Starting from $(\Omega_\omega, \varphi_\omega)$, we obtain similarly a sequence of invariant sets $\{\Omega_{\omega+n}\}$ and a sequence of flows $\{(\Omega_{\omega+n}, \varphi_{\omega+n})\}$. If we obtain an ordinal number γ such that $\Omega_\gamma = \Omega_{\gamma+1} \neq \emptyset$ by continuing this process, then we call Ω_γ the set of **central motions**. In this case, the flow $(\Omega_\gamma, \varphi_\gamma)$ is regionally recurrent, and every invariant subset of X on which (X, φ) is regionally recurrent is contained in Ω_γ . When X is \dagger separable and Ω_1 is compact and nonempty, then the minimum of such ordinal γ is an \dagger ordinal of at most the second number class.

(4) Let \mathcal{R} be the set of all $x \in X$ satisfying the following condition: For each ε , $T > 0$, there exist a sequence $\{x_0 = x, x_1, \dots, x_k = x\}$ of points in X and a sequence $\{t_0, t_1, \dots, t_{k-1}\}$ of numbers such that $t_i \geq T$ and $d(\varphi_{t_i}(x_i), x_{i+1}) < \varepsilon$ for $0 \leq i \leq k-1$. The set \mathcal{R} is a closed invariant set containing the nonwandering set Ω and is called the **chain recurrent set**. If $X = \mathcal{R}$, then (X, φ) is called **chain recurrent**. The restriction $(\mathcal{R}, \varphi|_{\mathcal{R} \times \mathbf{R}})$ of (X, φ) on \mathcal{R} is chain recurrent (C. C. Conley).

(5) A nonempty closed invariant set is called a **minimal set** if none of its nonempty proper closed subsets is invariant. For a nonempty compact subset A of X , the following conditions are equivalent: (i) A is minimal, (ii) $\overline{C(x)} = A$ for all $x \in A$, (iii) $\overline{C_+(x)} = A$ for all $x \in A$, (iv) $\overline{C_-(x)} = A$ for all $x \in A$, (v) $\omega(x) = A$ for all $x \in A$, (vi) $\alpha(x) = A$ for all $x \in A$. A point $x \in X$ is **positively** (resp. **negatively**) **Lagrange stable** if $\overline{C_+(x)}$ (resp. $\overline{C_-(x)}$) is compact. If $\overline{C(x)}$ is compact, then x is called **Lagrange stable**. Every nonempty compact invariant set contains a compact minimal set. If $x \in X$ is positively (resp. negatively) Lagrange stable, then $\omega(x)$ (resp. $\alpha(x)$) contains a compact minimal set.

A closed invariant set A is called a **saddle set** if there exists a neighborhood U of A such that every neighborhood of A contains a point x such that $C_+(x) \not\subset U$ and $C_-(x) \not\subset U$. Otherwise A is called a **nonsaddle set**. For a point x of X , let $E(x)$ be the subset of X consisting of the points y satisfying the following condition: There exist a sequence $\{x_n\}$ of points in X and two sequences $\{t_n\}$, $\{s_n\}$ of numbers such that (i) $x_n \rightarrow x$, $t_n \rightarrow \infty$, $s_n \rightarrow -\infty$ as $n \rightarrow \infty$ and (ii) $\varphi(x_n, t_n) \rightarrow y$, $\varphi(x_n, s_n) \rightarrow y$ as $n \rightarrow \infty$. For a subset B of X , put $E(B) = \bigcup_{x \in B} E(x)$. Let $\{S_\alpha\}$ be the family of all saddle minimal sets and $\{F_\beta\}$ the family of all nonsaddle minimal sets. If the phase space X is compact, then the nonwandering set $\Omega = (\bigcup_\beta F_\beta) \cup (\bigcup_\alpha E(S_\alpha)) = (\bigcup_\beta F_\beta) \cup E(\bigcup_\alpha S_\alpha)$ (T. Saito).

(6) A point $x \in X$ is said to be **recurrent** if for any $\varepsilon > 0$ there exists a $T > 0$ such that the ε -neighborhood U of $\varphi^x([t, t+T])$ contains $C(x)$ for all $t \in \mathbf{R}$. If x is recurrent, the motion φ^x and the orbit $C(x)$ are said to be **recurrent**. Every orbit of a compact minimal set is recurrent, and if the phase space is complete, then the closure of a recurrent orbit is a compact minimal set (Birkhoff).

A set D of real numbers is called **relatively dense** if there exists a $T > 0$ such that $D \cap (t, t+T) \neq \emptyset$ for all $t \in \mathbf{R}$. Assume that $x \in X$ is Lagrange stable, then x is recurrent if and only if for every $\varepsilon > 0$ the set $\{t \mid d(x, \varphi(x, t)) < \varepsilon\}$ is relatively dense.

(7) A flow (X, φ) is **dispersive** if for any $x, y \in X$ there exist neighborhoods U_x of x and U_y of y and a $T > 0$ such that $U_x \cap \varphi_t(U_y) = \emptyset$ for all $t \geq T$. The following conditions are equivalent: (i) (X, φ) is dispersive; (ii) For any $x, y \in X$, there exist neighborhoods U_x of x and U_y of y and a $T > 0$ such that $U_x \cap \varphi_t(U_y) = \emptyset$ if $|t| \geq T$; (iii) $J_+(x) = \emptyset$ for all $x \in X$.

A flow (X, φ) is **parallelizable** if there exist a subset S of X and a homeomorphism $h: X \rightarrow S \times \mathbf{R}$ such that (i) $\varphi(S \times \mathbf{R}) = X$ and (ii) $h \circ \varphi(x, t) = (x, t)$ for all $x \in S$ and $t \in \mathbf{R}$. A flow (X, φ) is parallelizable if and only if there is a subset S of X satisfying the following con-

ditions: (i) For each $x \in X$ there exists a unique $\tau(x) \in \mathbf{R}$ with $\varphi(x, \tau(x)) \in S$; (ii) $\tau: X \rightarrow \mathbf{R}$ is continuous. A parallelizable flow is dispersive. A flow on a locally compact separable metric space is parallelizable if and only if it is dispersive (V. V. Nemytskiĭ, V. V. Stepanov).

An open set U of X is called a **tube** if there exist a $T > 0$ and a subset S of U satisfying the following conditions: (i) $\varphi(S \times (-T, T)) = U$, (ii) For each $x \in U$ there is a unique $\tau(x) \in \mathbf{R}$ with $|\tau(x)| < T$ such that $\varphi(x, \tau(x)) \in S$. The set S in the above definition is called a **local section**. If $x \in X$ is a regular point, then there exists a tube containing x (M. Bebutov, H. Whitney). The notion of a local section is a generalization of Poincaré's "surface sans contact" [1] or Birkhoff's "surface of section" [4], and it is related to the notion of the cross section.

(8) For discrete flows (homeomorphisms), basic notions, such as a nonwandering set, Poisson stability, regional recurrence, central motion, and minimal set, are defined similarly, and many of the propositions and theorems in Sections E(1)–E(5) hold similarly for discrete flows (homeomorphisms).

F. Stability

(1) Let (X, φ) be a continuous flow on a metric space X . A point $x \in X$ is called **orbitally stable** if for any $\varepsilon > 0$ there exists a $\delta > 0$ such that $C_+(y)$ is contained in the ε -neighborhood of $C_+(x)$ for all y with $d(x, y) < \delta$ (\rightarrow 394 Stability). A nonempty set A is called **stable** if every neighborhood of A contains a positively invariant neighborhood of A . If A is compact (in particular, if A is a periodic orbit), then orbital stability and stability for A are equivalent. A nonempty set A is called **asymptotically stable** if A is stable and there exists a neighborhood V of A such that $\omega(x) \subset A$ for all $x \in V$. If A is stable and $\omega(x) \subset A$ for all $x \in X$, then A is called **globally asymptotically stable**. A point $x \in X$ is **Lyapunov stable** if for any $\varepsilon > 0$ there exists a $\delta > 0$ such that $d(\varphi_t(x), \varphi_t(y)) < \varepsilon$ for all $t \geq 0$ and y with $d(x, y) < \delta$. Lyapunov stability implies orbital stability. A point x is **uniformly Lyapunov stable** if for any $\varepsilon > 0$ there exists a $\delta > 0$ such that for $z \in C(x)$ and y with $d(y, z) < \delta$ we have $d(\varphi_t(y), \varphi_t(z)) < \varepsilon$ for all $t \geq 0$. Uniform Lyapunov stability implies Lyapunov stability. For a singular point, the notions of uniform Lyapunov stability, Lyapunov stability, orbital stability, and stability are equivalent. Assume that the phase space X is locally compact and A is a nonempty compact subset of X . Then A is asymptotically stable if and only if there exist a neighborhood N of A and a continuous real-valued function L on N such that (i) $L(x) = 0$ if $x \in A$ and $L(x) > 0$ if $x \notin A$; (ii) $L(\varphi(x, t)) < L(x)$ if $x \notin A$, $t > 0$, and $\varphi(\{x\} \times [0, t]) \subset N$.

Such a function L is called a **Lyapunov function** for A (\rightarrow 394 Stability). Assume that X is locally compact and A is nonempty, stable, and invariant. Then A is asymptotically stable if and only if there exists a neighborhood U of A such that any invariant set in U is necessarily contained in A (Ura). Let A be a nonempty closed invariant set. A is called an **attractor** if it has an open neighborhood U satisfying the following conditions: (i) U is positively invariant; (ii) For each open neighborhood V of A , there is a $T > 0$ such that $\varphi_t(U) \subset V$ for all $t \geq T$. Condition (ii) implies that $\bigcap_{t \geq 0} \varphi_t(U) = A$ and $\omega(x) \subset A$ for all $x \in U$. Thus an attractor is asymptotically stable. If A is an attractor, the **basin** of A is the union of all open neighborhoods of A satisfying (i) and (ii).

(2) Assume that the phase space X is complete. A motion φ^x ($x \in X$) is called **almost periodic** if for any $\varepsilon > 0$ there exists a relatively dense subset $\{\tau_n\}$ in \mathbf{R} such that $d(\varphi^x(t), \varphi^x(t + \tau_n)) < \varepsilon$ for all $t \in \mathbf{R}$ and τ_n (\rightarrow 18 Almost Periodic Functions). If φ^x is almost periodic, then φ^y is almost periodic for all $y \in C(x)$. If A is a compact minimal set and if φ^x is almost periodic for some x in A , then every motion φ^y , $y \in A$, is almost periodic. An almost periodic motion is recurrent. The converse is not true. But if x is recurrent and Lyapunov stable in $C(x)$ (i.e., in the restriction flow $(C(x), \varphi|_{C(x) \times \mathbf{R}})$), then φ^x is almost periodic. If x is uniformly Lyapunov stable in $C(x)$ and negatively Lagrange stable, then φ^x is almost periodic (A. A. Markov).

G. Singular Points and Closed Orbits

In this section we assume that the phase space is a * paracompact differentiable manifold of class C^∞ with metric d .

(1) Let E be a finite-dimensional real vector space and $L: E \rightarrow E$ a linear automorphism. L is called **hyperbolic** if it has no * eigenvalues of absolute value 1. If $L: E \rightarrow E$ is hyperbolic, there are unique vector subspaces E^s and E^u satisfying the following conditions: (i) $E = E^s \oplus E^u$, (ii) $L(E^s) = E^s$ and $L(E^u) = E^u$, (iii) if $\|\cdot\|$ is a * norm on E , then there exist constants $c > 0$ and $0 < \lambda < 1$ such that, for any positive integer m , $\|L^m(v)\| \leq c\lambda^m\|v\|$ when $v \in E^s$ and $\|L^{-m}(v)\| \leq c\lambda^m\|v\|$ when $v \in E^u$. The zero 0 of E is the only fixed point of a hyperbolic linear automorphism. Put $s = \dim E^s$ and $u = \dim E^u$. Then $s + u = \dim E$, and s (resp. u) is the number of eigenvalues of absolute value < 1 (resp. > 1) counted with multiplicity. A topological conjugacy class of a hyperbolic linear automorphism $L: E \rightarrow E$ is determined by s , u , and the signs of $\det(L|_{E^s})$ and $\det(L|_{E^u})$, where $\det(L|_{E^s})$ is the * determinant of the restriction

$L|E^\sigma: E^\sigma \rightarrow E^\sigma$ of L on E^σ ($\sigma = s, u$). Further investigations of topological classification of linear automorphisms have been carried out by N. H. Kuiper and J. W. Robbin.

(2) Let $f: \mathbf{R}^n \rightarrow \mathbf{R}^n$ be a C^r -diffeomorphism ($1 \leq r \leq \infty$). Assume that the origin $0 \in \mathbf{R}^n$ is a fixed point of f . Then the t differential $df_0: \mathbf{R}^n \rightarrow \mathbf{R}^n$ of f at 0 is a linear automorphism. It is given by $df_0(x) = J_0(f)x$, $x \in \mathbf{R}^n$, where $J_0(f)$ is the t Jacobian matrix of f at 0 and x is expressed as a column vector. If df_0 is hyperbolic, then f is topologically conjugate to df_0 in a sufficiently small neighborhood of 0 (P. Hartman). Assume that f is of class C^∞ , and let $\lambda_1, \dots, \lambda_n$ (possibly repeated) be the eigenvalues of df_0 . If $\lambda_i \neq \lambda_i^m$ for all $1 \leq i \leq n$ and for all nonnegative integers m_1, \dots, m_n with $2 \leq m_1 + \dots + m_n$, then in a sufficiently small neighborhood of 0, f is C^∞ -conjugate to df_0 (S. Sternberg).

(3) Let $f: M \rightarrow M$ be a C^r -diffeomorphism ($1 \leq r \leq \infty$) of a differentiable manifold M of class C^∞ . Let $p \in M$ be a fixed point of f . Then the t differential df_p of f at p is a linear automorphism of the t tangent space $T_p(M)$ of M at p . If df_p is hyperbolic, then p is called a **hyperbolic fixed point** of f . Let p be a hyperbolic fixed point of f and $T_p(M) = E^s \oplus E^u$ be the direct sum decomposition with respect to df_p . Put $W^s(p) = \{x \in M \mid f^n(x) \rightarrow p \text{ as } n \rightarrow \infty\}$ and $W^u(p) = \{x \in M \mid f^{-n}(x) \rightarrow p \text{ as } n \rightarrow \infty\}$. $W^s(p)$ and $W^u(p)$ are invariant sets and images of t injective immersions of class C^r of vector spaces E^s and E^u , respectively. At the point p , $W^s(p)$ and $W^u(p)$ are tangent to E^s and E^u , respectively [21]. We call $W^s(p)$ (resp. $W^u(p)$) the **stable** (resp. **unstable**) **manifold** of f at p . In a sufficiently small neighborhood of a hyperbolic fixed point p of f , f is topologically conjugate to its differential df_p . Therefore a hyperbolic fixed point is an **isolated fixed point** (i.e., there are no fixed points in its sufficiently small neighborhood except itself). A hyperbolic fixed point p is called a **source** if $\dim W^s(p) = 0$ and a **sink** if $\dim W^u(p) = 0$. Otherwise it is a **saddle point**. The number of topological conjugacy classes of hyperbolic fixed points on an n -dimensional manifold is 4^n .

Let $p \in M$ be a periodic point of f and m the smallest positive period of p . Replacing f by f^m , we obtain notions of hyperbolicity, stable manifold, and so on for the periodic point p . We also obtain propositions and theorems similar to those stated above for periodic points.

(4) Let A be a real $n \times n$ matrix. Consider the system of linear differential equations

$$dx/dt = Ax, \quad x \in \mathbf{R}^n. \quad (5)$$

This equation generates a C^∞ -flow (\mathbf{R}^n, φ) , and $\varphi_t: \mathbf{R}^n \rightarrow \mathbf{R}^n$ is given by $\varphi_t(x) = e^{tA}x$, where e^{tA} is

the t exponential of the matrix tA . Thus φ_t is a linear automorphism for all $t \in \mathbf{R}$. The origin $0 \in \mathbf{R}^n$ is a singular point of (\mathbf{R}^n, φ) . If none of the real parts of the eigenvalues of A are zero, we call $0 \in \mathbf{R}^n$ a **hyperbolic singular point** of (5). If $0 \in \mathbf{R}^n$ is a hyperbolic singular point of (5), then there exist two vector subspaces E^s and E^u of \mathbf{R}^n satisfying the following conditions: (i) $\mathbf{R}^n = E^s \oplus E^u$; (ii) $A(E^s) = E^s$ and $A(E^u) = E^u$; (iii) E^s and E^u are invariant sets of (\mathbf{R}^n, φ) ; (iv) there exist positive constants c and λ such that for all $t \geq 0$, $\|\varphi_t(x)\| \leq ce^{-\lambda t} \|x\|$ when $x \in E^s$ and $\|\varphi_{-t}(x)\| \leq ce^{-\lambda t} \|x\|$ when $x \in E^u$, where $\|\cdot\|$ is the norm on \mathbf{R}^n . The origin 0 is a hyperbolic singular point of (5) if and only if the time-one mapping $\varphi_1 = e^A: \mathbf{R}^n \rightarrow \mathbf{R}^n$ of φ is a hyperbolic linear automorphism. If 0 is a hyperbolic singular point of (5), the above direct sum decomposition $\mathbf{R}^n = E^s \oplus E^u$ coincides with the one with respect to φ_1 . Put $s = \dim E^s$ and $u = \dim E^u$. Then $s + u = n$, and s (resp. u) is the number of all eigenvalues of A with negative (resp. positive) real parts counted with multiplicity. Also we obtain the following properties: (i) $x \in E^s$ (resp. E^u) $\Leftrightarrow \varphi_t(x) \rightarrow 0$ as $t \rightarrow \infty$ (resp. $t \rightarrow -\infty$), (ii) $x \notin E^s$ (resp. E^u) $\Rightarrow \|\varphi_t(x)\| \rightarrow \infty$ as $t \rightarrow \infty$ (resp. $t \rightarrow -\infty$), (iii) the origin 0 is the only singular point.

Let A and B be $n \times n$ real matrices. Let $(\mathbf{R}^n, \varphi_A)$ and $(\mathbf{R}^n, \varphi_B)$ be the flows determined by the equations $dx/dt = Ax$ and $dx/dt = Bx$, respectively. Assume that $0 \in \mathbf{R}^n$ is a hyperbolic singular point for both of the equations. Let s and u (resp. s' and u') be the integers defined for φ_A (resp. φ_B) in the above paragraph. Then the following conditions are equivalent: (i) $(\mathbf{R}^n, \varphi_A)$ and $(\mathbf{R}^n, \varphi_B)$ are flow equivalent, (ii) $(\mathbf{R}^n, \varphi_A)$ and $(\mathbf{R}^n, \varphi_B)$ are topologically equivalent, (iii) $s = s'$, (iv) $u = u'$, (v) $(\varphi_A)_1$ and $(\varphi_B)_1$ are topologically conjugate. Further investigations of the phase portrait of the equation $dx/dt = Ax$ without the assumption of hyperbolicity were done by Kuiper.

(5) Let D be an open set of \mathbf{R}^n and $f: D \rightarrow \mathbf{R}^n$ a continuous mapping. Consider the system of differential equations (1), which we write down again here:

$$dx/dt = f(x), \quad x \in D. \quad (6)$$

A point $p \in D$ is a **singular point** of (6) if the trajectory through p consists of a single point p . If (6) generates a flow (D, φ) , then p is a singular point of (6) if and only if p is a singular point of (D, φ) . A point p is a singular point of (6) if and only if $f(p) = 0$.

Suppose further that f is a C^r -mapping ($1 \leq r \leq \infty$). A singular point p of (6) is called **hyperbolic** if none of the real parts of the eigenvalues of the Jacobian matrix $J_p(f)$ of f at p is zero. Let p be a singular point of (6). We assume for simplicity that $p = 0$ and (6) generates

a flow (D, φ) . Denote the Jacobian matrix of f at 0 by A , and let $(\mathbf{R}^n, \varphi_A)$ be the flow generated by the equation $dx/dt = Ax$. If 0 is a hyperbolic singular point, then in a sufficiently small neighborhood of 0, the flows (D, φ) and $(\mathbf{R}^n, \varphi_A)$ are flow equivalent and hence topologically equivalent (Hartman, D. M. Grobman). Let $\lambda_1, \dots, \lambda_n$ (possibly repeated) be the eigenvalues of A . If f is of class C^∞ and $\lambda_i \neq m_1 \lambda_1 + \dots + m_n \lambda_n$ for all $1 \leq i \leq n$ and for all nonnegative integers m_1, \dots, m_n with $2 \leq m_1 + \dots + m_n$, then in a sufficiently small neighborhood of 0, two flows (D, φ) and $(\mathbf{R}^n, \varphi_A)$ are C^∞ -equivalent (Sternberg).

(6) Let M be a paracompact differentiable manifold of class C^∞ and V a vector field of class C^r ($1 \leq r \leq \infty$) on M . For simplicity we assume that V generates a C^r -flow (M, φ) . For each point p of M , take a coordinate neighborhood (U, α) of class C^∞ around p , where U is an open neighborhood of p in M and $\alpha: U \rightarrow \mathbf{R}^n$ is a homeomorphism onto an open set D in \mathbf{R}^n . Using (U, α) , we can express the vector field V as a system of ordinary differential equations of the form (6) in D . The eigenvalues $\lambda_1, \dots, \lambda_n$ (possibly repeated) of the Jacobian matrix of f at $\alpha(p)$ are independent of the choice of local coordinates (U, α) around p . Thus $\lambda_1, \dots, \lambda_n$ are invariants of the C^r -equivalence, but they are not invariants of the topological equivalence.

A singular point p of a flow (M, φ) (or a vector field V) is called **hyperbolic** if $\alpha(p)$ is a hyperbolic singular point of the corresponding equation (6) (i.e., none of the real parts of the above eigenvalues $\lambda_1, \dots, \lambda_n$ are zero). A singular point of (M, φ) is hyperbolic if and only if it is a hyperbolic fixed point of the time-one mapping φ_1 of φ . A hyperbolic singular point p is an isolated singular point.

Let p be a hyperbolic singular point of (M, φ) and $T_p(M) = E^s \oplus E^u$ the direct sum decomposition with respect to φ_1 . Put $s = \dim E^s$ and $u = \dim E^u$. Then s (resp. u) is the number of all eigenvalues λ_i of negative (resp. positive) real parts. Put $W^s(p) = \{x \in M \mid \varphi_t(x) \rightarrow p \text{ as } t \rightarrow \infty\}$ and $W^u(p) = \{x \in M \mid \varphi_{-t}(x) \rightarrow p \text{ as } t \rightarrow \infty\}$. $W^s(p)$ and $W^u(p)$ are invariant sets and images of injective immersions of class C^r of vector spaces E^s and E^u , respectively. At the point p , $W^s(p)$ and $W^u(p)$ are tangent to E^s and E^u , respectively. We call $W^s(p)$ (resp. $W^u(p)$) the **stable** (resp. **unstable**) manifold of f at p . The stable manifold and the unstable manifold of (M, φ) at a hyperbolic singular point p coincide with those of the time-one mapping φ_1 at p . A hyperbolic singular point p is called a **source** if $\dim W^s(p) = 0$ and a **sink** if $\dim W^u(p) = 0$. Otherwise it is called a **saddle point**. If p is a source (resp. a sink), then $W^u(p)$ (resp. $W^s(p)$) is a neighborhood of p . A singular point p is a source (resp. a sink) if and

only if all real parts of the corresponding eigenvalues $\lambda_1, \dots, \lambda_n$ are positive (resp. negative).

(7) Let V be a vector field of class C^r on a C^∞ -differentiable manifold M of dimension $n \geq 2$ and (M, φ) the C^r -flow generated by V . Let C be a closed orbit of (M, φ) , p a point of C , and $T > 0$ its smallest positive period. Then p is a fixed point of the C^r -diffeomorphism $\varphi_T: M \rightarrow M$. Let $V(p) \in T_p(M)$ be the value of V at p and $(d\varphi_T)_p: T_p(M) \rightarrow T_p(M)$ the differential of φ_T at p . Then $(d\varphi_T)_p(V(p)) = V(p)$, and $V(p) \neq 0$. Therefore 1 is an eigenvalue of $(d\varphi_T)_p$. The other eigenvalues $\lambda_1, \dots, \lambda_{n-1}$ (possibly repeated) of $(d\varphi_T)_p$ do not depend on a choice of $p \in C$ and are called the **characteristic multipliers** of C . If none of the characteristic multipliers of C is of absolute value 1, we call C a **hyperbolic closed orbit**. If C is a hyperbolic closed orbit, then there exist vector subspaces E_p^s and E_p^u for each $p \in C$ satisfying the following conditions: (i) $T_p(M) = L(V(p)) \oplus E_p^s \oplus E_p^u$, where $L(V(p))$ is the 1-dimensional subspace generated by $V(p)$; (ii) $(d\varphi_t)_p(E_p^s) = E_{\varphi_t(p)}^s$ ($\sigma = s, u$) for all $t \in \mathbf{R}$, where $(d\varphi_t)_p: T_p(M) \rightarrow T_{\varphi_t(p)}(M)$. In particular, $(d\varphi_T)_p(E_p^s) = E_p^s$ ($\sigma = s, u$); (iii) $\dim E_p^s$ (resp. $\dim E_p^u$) is independent of $p \in C$ and is equal to the number of λ_i of absolute value < 1 (resp. > 1). Put $W^s(C) = \{x \in M \mid d(\varphi_t(x), C) \rightarrow 0 \text{ as } t \rightarrow \infty\}$ and $W^u(C) = \{x \in M \mid d(\varphi_{-t}(x), C) \rightarrow 0 \text{ as } t \rightarrow \infty\}$. Then $W^s(C)$ (resp. $W^u(C)$) is an invariant set and is an injectively immersed C^r -submanifold of M which is tangent to $L(V(p)) \oplus E_p^s$ (resp. $L(V(p)) \oplus E_p^u$) for each $p \in C$. $W^s(C)$ (resp. $W^u(C)$) is called the **stable** (resp. **unstable**) manifold for C .

Let p be a point of a closed orbit C . An embedded $(n-1)$ -dimensional disk D of class C^r in M containing p is called a **cross section for a closed orbit** C if V is transverse to D (i.e., $T_x(M) = L(V(x)) \oplus T_x(D)$ for each $x \in D$) and $D \cap C = \{p\}$. For a given cross section D for C , there exists a neighborhood U of p in D such that for any $x \in U$ there exists a $\tau(x) > 0$ such that $\varphi(x, \tau(x)) \in D$ and $\varphi(x, t) \notin D$ for $0 < t < \tau(x)$. A mapping $f: U \rightarrow D$, defined by $f(x) = \varphi(x, \tau(x))$, $x \in U$, is called a **Poincaré mapping** for D . The C^r -conjugacy class of the germ of a Poincaré mapping $f: V \rightarrow D$ at p is independent of the choice of $p \in C$ and the cross section D for the closed orbit C . The point p is a fixed point of f , and the eigenvalues of df_p coincide with the characteristic multipliers of C including multiplicity. Therefore C is hyperbolic if and only if $p \in C$ is a hyperbolic fixed point of f . In a sufficiently small neighborhood of C , the flow is C^r -equivalent to the suspension of f . The topological equivalence of the flow in a sufficiently small neighborhood of C is determined by the topological conjugacy class of f . The number of topological equivalence classes of hyperbolic closed orbits which appear in a

flow on an n -dimensional manifolds is $4(n-1)$ (M. C. Irwin).

(8) Let V be a vector field of class C^r ($1 \leq r \leq \infty$) on a compact C^∞ -manifold M . If M has a nonempty boundary, we assume that V points outward at all boundary points. Let p be an isolated singular point of V and denote by $i(p)$ the \dagger index of the vector field V at the singular point P . If all singular points are isolated, then the sum $\sum_p i(p)$ is independent of V and is equal to the \dagger Euler-Poincaré characteristic $\chi(M)$ of M (Poincaré, H. Hopf) (\rightarrow 153 Fixed-Point Theorems). A vector field (or a flow) is called **nonsingular** if it has no singular points. If $\chi(M) \neq 0$, then any vector field (and hence any flow) on M has a singular point. If $\chi(M) = 0$, then there exists a nonsingular vector field on M . If M is 2-dimensional and without boundary, then M admits a nonsingular vector field if and only if M is a \dagger torus or a \dagger Klein bottle.

There are many directions in which generalizations of the Poincaré-Hopf theorem can be made. For example, an index of an isolated closed orbit of a flow has been defined and investigated by F. B. Fuller.

The phase portrait near a singular point or a closed orbit which is not hyperbolic is complicated. Many results in general situations have been obtained for planar flows, but there are only a few for higher-dimensional flows.

H. Generic Properties and Structural Stability

(1) Let M be a compact C^∞ -manifold without boundary. The set $\mathcal{X}^r(M)$ of all vector fields of class C^r ($1 \leq r \leq \infty$) on M forms a real vector space in a natural way. We can give a norm $\|V\|_r$ (called a **C^r -norm**) for $V \in \mathcal{X}^r(M)$ using its expressions in a given suitable system of local coordinates of class C^∞ on M and their partial derivatives up to order r . By virtue of this norm, $\mathcal{X}^r(M)$ is a Banach space with the topology of uniform C^r -convergence (\rightarrow 168 Function Spaces). A subset of a topological space is called a **residual set** or a **Baire set** if it is the intersection of a countable number of dense open sets. A residual set in $\mathcal{X}^r(M)$ is a dense set. A proposition P concerning a vector field of class C^r is called **generic** if the set $\{V \in \mathcal{X}^r(M) | P(V)\}$ contains a residual set for any M . The following properties are generic properties: (i) All singular points and all closed orbits are hyperbolic [21, 22]; (ii) any stable manifold (of a hyperbolic singular point or a hyperbolic closed orbit) meets transversally with any unstable manifold (of a hyperbolic singular point or a hyperbolic closed orbit) at any point of their intersection [21, 22]; (iii) the set of all periodic points (i.e., the union of all

singular points and all closed orbits) is dense in the nonwandering set Ω for $V \in \mathcal{X}^1(M)$ [23]; (iv) there is no regular first integral for $v \in \mathcal{X}^1(M)$, where a **regular first integral** of a vector field V on M is a C^1 -function $f: M \rightarrow \mathbf{R}$ such that f is not constant on any open set of M and is constant along any orbit of (the flow generated by) V (R. C. Robinson).

Let V (resp. V') be an element of $\mathcal{X}^r(M)$ (resp. $\mathcal{X}^r(M')$), (M, φ) (resp. (M', φ')) the flow generated by V (resp. V'), and Ω (resp. Ω') the nonwandering set of (M, φ) (resp. (M', φ')). V and V' are called **topologically equivalent** (resp. **Ω -equivalent**) if (M, φ) and (M', φ') (resp. the restrictions $(\Omega, \varphi|_{\Omega \times \mathbf{R}})$ and $(\Omega', \varphi'|_{\Omega' \times \mathbf{R}})$) are topologically equivalent. A vector field $V \in \mathcal{X}^r(M)$ (or the flow generated by V) is called **C^r -structurally stable** (resp. **C^r - Ω -stable**) if there exists a neighborhood \mathcal{N} of V in $\mathcal{X}^r(M)$ such that any V' in \mathcal{N} is topologically equivalent (resp. Ω -equivalent) to V . If $V \in \mathcal{X}^r(M)$ is structurally stable (resp. Ω -stable), then the topological structure of the phase portrait of (the flow generated by) V in the whole space (resp. the nonwandering set) remains invariant under a sufficiently small C^r -perturbation of V . The generic properties (i)–(iv) above hold for C^1 -structurally stable vector fields (Markus, Thom, Peixoto, J. Arnaud). The generic properties (i) and (iii) above hold for C^1 - Ω -stable vector fields.

(2) Let M be a compact C^∞ -manifold without boundary. Let $F^r(M)$ be the set of all C^r -mappings of M into itself with the topology of uniform C^r -convergence. Let $\text{Diff}^r(M)$ be the subset of $F^r(M)$ consisting of all C^r -diffeomorphisms of M onto itself. Then $F^r(M)$ is a complete metric space, and $\text{Diff}^r(M)$ is open in $F^r(M)$. Thus $\text{Diff}^r(M)$ is a \dagger Baire space and also a topological group with respect to this topology. A proposition P concerning $f \in \text{Diff}^r(M)$ is called **generic** if the set $\{f \in \text{Diff}^r(M) | P(f)\}$ contains a residual set. The following properties are generic: (i) Every periodic point is hyperbolic [21]; (ii) for each pair of hyperbolic periodic points p and q , the stable manifold $W^s(p)$ intersects the unstable manifold $W^u(q)$ transversally [21]; (iii) for a C^1 -diffeomorphism $f \in \text{Diff}^1(M)$ the set of all periodic points is dense in the nonwandering set ([23], Robinson).

Let $f: M \rightarrow M$ and $g: N \rightarrow N$ be C^r -diffeomorphisms and $\Omega(f)$ and $\Omega(g)$ their nonwandering sets. f and g are called **Ω -conjugate** if $f|_{\Omega(f)}: \Omega(f) \rightarrow \Omega(f)$ and $g|_{\Omega(g)}: \Omega(g) \rightarrow \Omega(g)$ are topologically conjugate. A diffeomorphism $f \in \text{Diff}^r(M)$ is called **C^r -structurally stable** (resp. **C^r - Ω -stable**) if there exists a neighborhood \mathcal{N} of f in $\text{Diff}^r(M)$ such that any g in \mathcal{N} is topologically conjugate (resp. Ω -conjugate) to f . Generic properties (i)–

(iii) above hold for C^1 -structurally stable diffeomorphisms, and (i) and (iii) above hold for C^1 - Ω -stable diffeomorphisms.

I. Low-Dimensional Systems

(1) Let $S^1 = \{z \in \mathbb{C} \mid |z| = 1\}$ be the unit circle in the complex plane \mathbb{C} and $p: \mathbb{R} \rightarrow S^1$ the \dagger covering projection defined by $p(x) = e^{2\pi i x}$, $x \in \mathbb{R}$. Let $f: S^1 \rightarrow S^1$ be an \dagger orientation-preserving homeomorphism. Then f can be lifted to a mapping $F: \mathbb{R} \rightarrow \mathbb{R}$ satisfying the following conditions: (i) $p \circ F = f \circ p$; (ii) F is monotone increasing; (iii) $F - 1_{\mathbb{R}}$ is a periodic function of period 1, where $1_{\mathbb{R}}$ is the identity mapping of \mathbb{R} . The limit $\rho(f) = \lim_{n \rightarrow \infty} F^n(x)/n$ exists for all $x \in \mathbb{R}$, and its \dagger residue class modulo \mathbb{Z} is independent of F and x . We call $\rho(f)$ the **rotation number** of f . Let $f, g: S^1 \rightarrow S^1$ be orientation-preserving homeomorphisms. If f and g are topologically conjugate by an orientation-preserving (resp. \dagger reversing) homeomorphism, then $\rho(f) \equiv \rho(g)$ (resp. $\rho(f) = -\rho(g)$) modulo \mathbb{Z} . An orientation preserving homeomorphism $f: S^1 \rightarrow S^1$ has a periodic point of the smallest positive period s if and only if $\rho(f) = r/s$, where r and s are relatively prime integers. In this case all periodic points are of the smallest positive period s . If $\rho(f)$ is irrational, then the ω -limit set $\omega(x)$ of $x \in S^1$ is independent of x , and $E = \omega(x)$ is either \dagger perfect and \dagger nowhere dense or the whole space S^1 . If $\rho(f)$ is irrational and $E = \omega(x) = S^1$, then f is called **transitive**. If f is transitive, then it is topologically conjugate to the rotation $r_{\rho(f)}: S^1 \rightarrow S^1$ defined by $r_{\rho(f)}(e^{2\pi i x}) = e^{2\pi i(x + \rho(f))}$, $x \in \mathbb{R}$. Let $f: S^1 \rightarrow S^1$ be of class C^1 with $\rho(f)$ irrational. If its derivative f' is of \dagger bounded variation, then f is transitive (A. Denjoy). In particular, if f is of class C^2 with $\rho(f)$ irrational, then f is topologically conjugate to the rotation $r_{\rho(f)}$. However, there are C^1 -diffeomorphisms of S^1 onto itself whose nonwandering sets are not the whole space. Those C^1 -diffeomorphisms are never topologically conjugate to C^2 -diffeomorphisms. M. R. Herman gave a sufficient condition for a diffeomorphism of S^1 onto itself to be differentiably conjugate to a rotation.

A C^r -diffeomorphism $f: S^1 \rightarrow S^1$ is structurally stable if and only if $\Omega(f)$ is finite (hence $\Omega(f)$ consists of a finite number of periodic points), and all periodic points are hyperbolic. The set of all structurally stable C^r -diffeomorphisms of S^1 onto itself is a dense open set in $\text{Diff}^r(S^1)$ (Peixoto).

(2) Let D be an open set in \mathbb{R}^2 and $f: D \rightarrow \mathbb{R}^2$ a continuous mapping. We assume that for each $x \in D$ there exists a unique nonextendable solution $\varphi(x, t)$ with the initial condition

$\varphi(x, 0) = x$ defined on (a_x, b_x) for the equation $dx/dt = f(x)$, $x \in D$. Suppose that for a given point $x \in D$ there exists a compact set K in D containing the positive semiorbit $C_+(x) = \{\varphi(x, t) \mid 0 \leq t < b_x\}$ of x . Then $b_x = \infty$. Further, we assume that the ω -limit set $\omega(x)$ of x contains no singular points. Then we have either (i) $C_+(x) = \omega(x)$ and it is a closed orbit, or (ii) $C_+(x) \neq \omega(x)$ and $\omega(x)$ is a closed orbit. In case (ii), $\omega(x)$ is a \dagger simple closed curve and $C_+(x)$ is a spiral which tends the closed orbit $\omega(x)$ (Poincaré, I. Bendixson). We call such a closed orbit $\omega(x)$ a **limit cycle**. Let f_1 and f_2 be polynomials of two variables and m the maximum of degrees of f_1 and f_2 . Let $f = (f_1, f_2): \mathbb{R}^2 \rightarrow \mathbb{R}^2$ be the mapping defined by f_1 and f_2 . The equation $dx/dt = f(x)$, $x \in \mathbb{R}^2$, defined by such an f is called a polynomial system of degree m . The following is Hilbert's 16th problem: Is there a number $N(m)$ depending only on m such that the number of limit cycles for any polynomial system of degree m is bounded by $N(m)$?

Let M be a closed (i.e., compact, without boundary) C^∞ -manifold of dimension 2 and (M, φ) a C^2 -flow on M . Then a minimal set of (M, φ) is either (i) a singular point, (ii) a closed orbit, or (iii) the whole space M . For case (iii), M is a torus (Poincaré, Denjoy, C. L. Siegel, A. J. Schwartz). Let T be a 2-dimensional torus and (T, φ) a C^r -flow. Suppose that (T, φ) has a cross section Σ which is C^1 -diffeomorphic to S^1 . Let $f: \Sigma \rightarrow \Sigma$ be the Poincaré mapping for Σ . Then (T, φ) has a closed orbit if and only if the rotation number $\rho(f)$ of f is rational. If $\rho(f)$ is irrational and (T, φ) is of class C^2 , then T is a minimal set.

Let M be an orientable 2-dimensional closed C^∞ -manifold and $V \in \mathcal{X}^1(M)$. Then V is structurally stable if and only if the following conditions are satisfied: (i) There are only a finite number of singular points, all hyperbolic; (ii) There are only a finite number of closed orbits, all hyperbolic; (iii) There are no orbits which connect saddle points; (iv) The $\alpha(x)$ and $\omega(x)$ for any $x \in M$ are singular points or closed orbits (Peixoto). The above theorem was first proved by Andronov and Pontryagin for analytic vector fields on a 2-dimensional disk which are transverse to the boundary of the disk at any boundary point. The set of all structurally stable vector fields of class C^1 on M is a dense open set in $\mathcal{X}^1(M)$ (Peixoto).

J. Axiom A Systems

In this section we assume that phase spaces are closed C^∞ -manifolds with metric d and $1 \leq r \leq \infty$ unless stated otherwise.

(1) A vector field $V \in \mathcal{X}^r(M)$ (resp. a C^r -flow (M, φ)) is called a **Morse-Smale vector field** (resp. a **Morse-Smale flow**) if the following conditions are satisfied: (i) The nonwandering set is the union of a finite number of singular points and a finite number of closed orbits; (ii) The singular points and closed orbits are all hyperbolic; (iii) The stable manifolds and the unstable manifolds of the singular points and closed orbits intersect each other transversely. If $\dim M = 2$, the Morse-Smale vector fields on M are exactly the structurally stable ones discussed in Section I(2). A Morse-Smale vector field is structurally stable [25]. The set of all Morse-Smale vector fields on M is open but not dense in $\mathcal{X}^r(M)$ if $\dim M > 2$ (Palis, Smale). However, it contains a dense open subset of the set of all \dagger gradient vector fields with respect to a given \dagger Riemannian metric (Smale). In particular, any closed manifold admits Morse-Smale vector fields and hence structurally stable vector fields. For a Morse-Smale vector field, the \dagger Morse inequalities hold as they do in the \dagger calculus of variations in the large [24].

(2) A vector field $V \in \mathcal{X}^r(M)$ (or the C^r -flow (M, φ) generated by V) is called an **Anosov vector field** (or an **Anosov flow**) if the following conditions are satisfied: (i) There is a direct sum decomposition $T_x(M) = L(V(x)) \oplus E_x^s \oplus E_x^u$ of the tangent space $T_x(M)$ for each $x \in M$ which depends continuously on $x \in M$; (ii) $(d\varphi_t)_x(E_x^s) = E_{\varphi_t(x)}^s$ and $(d\varphi_t)_x(E_x^u) = E_{\varphi_t(x)}^u$ for all $x \in M$ and $t \in \mathbf{R}$; (iii) There are a Riemannian metric on M and constants $c, \lambda > 0$ such that, for all $t > 0$ and $x \in M$, $\|(d\varphi_t)_x(w)\| \leq ce^{-\lambda t} \|w\|$ when $w \in E_x^s$, and $\|(d\varphi_{-t})_x(w)\| \leq ce^{-\lambda t} \|w\|$ when $w \in E_x^u$, where $\|\cdot\|$ is the norm induced by the Riemannian metric. The suspensions of Anosov diffeomorphisms and the \dagger geodesic flows on Riemannian manifolds of negative curvature are important examples of Anosov flows (J. Hadamard [8]). There are examples of Anosov flows other than the ones stated above (M. Handel and W. P. Thurston, J. Franks and R. F. Williams). The following have been proved by Anosov [8]: (i) An Anosov flow is structurally stable; (ii) there are countably many closed orbits for an Anosov flow; (iii) if there exists a **smooth invariant measure** (i.e., an \dagger invariant measure which has a \dagger smooth density with respect to the measure associated with the Riemannian metric), then the set of all closed orbits is dense in M . If we assume further that the flow is of class C^2 , then it is \dagger ergodic; (iv) the set of all Anosov vector fields is open in $\mathcal{X}^r(M)$; (v) $\{E_x^s\}, \{E_x^u\}$ ($x \in M$) define \dagger foliations on M , which are called **Anosov foliations**.

(3) A vector field $V \in \mathcal{X}^r(M)$ (or the C^r -flow (M, φ) generated by V) is called an **Axiom A**

vector field (or an **Axiom A flow**) if the following conditions are satisfied: A(a) The nonwandering set consists of a finite set F of singular points, all hyperbolic, and the closure Λ of the union of closed orbits, and $F \cap \Lambda = \emptyset$; A(b) The conditions (i)–(iii) in the definition of Anosov flow in which we replace the terms “ $x \in M$ ” by “ $x \in \Lambda$.” For each $x \in M$, put $W^s(x) = \{y \in M \mid d(\varphi_t(x), \varphi_t(y)) \rightarrow 0 \text{ as } t \rightarrow \infty\}$ and $W^u(x) = \{y \in M \mid d(\varphi_{-t}(x), \varphi_{-t}(y)) \rightarrow 0 \text{ as } t \rightarrow \infty\}$. We call $W^s(x)$ (resp. $W^u(x)$) the **stable** (resp. **unstable**) manifold of V at x . For a subset A of M , put $W^\sigma(A) = \bigcup_{x \in A} W^\sigma(x)$ ($\sigma = s, u$). For $x \in M$, put $W^{w\sigma}(x) = W^\sigma(C(x))$ ($\sigma = s, u$), where $C(x)$ is the orbit of x . If the flow satisfies Axiom A, then $W^s(x)$, $W^u(x)$, $W^{ws}(x)$, and $W^{wu}(x)$ are injectively immersed submanifolds for all $x \in M$ (M. W. Hirsch and C. C. Pugh). If $x \in M$ is a hyperbolic singular point, then $W^s(x)$ and $W^u(x)$ defined above coincide with those defined before. If $C(x)$ is a hyperbolic closed orbit, then $W^s(C(x))$ and $W^u(C(x))$ defined above coincide with those defined before.

For an Axiom A flow, there is a decomposition of the nonwandering set $\Omega = \Omega_1 \cup \dots \cup \Omega_m$ (disjoint union), where each Ω_i is closed, invariant, and **transitive** (i.e., has a dense orbit), and $M = \bigcup_{i=1}^m W^s(\Omega_i) = \bigcup_{i=1}^m W^u(\Omega_i)$ (disjoint union) [7]. This decomposition is called the **spectral decomposition** of Ω , and each Ω_i is called a **basic set**. Let $\Omega = \Omega_1 \cup \dots \cup \Omega_m$ be the spectral decomposition of the nonwandering set for an Axiom A flow. Denote $\Omega_i \leq \Omega_j$ if $W^s(\Omega_i) \cap W^u(\Omega_j) \neq \emptyset$. A sequence of basic sets $\Omega_{i_0}, \Omega_{i_1}, \dots, \Omega_{i_k}$ ($k > 1$) is called a **cycle** if $\Omega_{i_0} \leq \Omega_{i_1} \leq \dots \leq \Omega_{i_k}, \Omega_{i_0} = \Omega_{i_k}$, and otherwise $\Omega_{i_p} \not\leq \Omega_{i_q}$ for $p \neq q$. An Axiom A flow which has no cycles in the above sense is said to satisfy the **no cycle condition**. The **Ω -stability theorem**:

An Axiom A flow with the no cycle condition is Ω -stable [27]. **Ω -explosion**: If an Axiom A flow has a cycle, then it is not Ω -stable (Palis). An Axiom A flow is said to satisfy the **strong transversality condition** if $W^{ws}(x)$ and $W^{wu}(x)$ intersect transversely at any $x \in M$. An Axiom A flow with the strong transversality condition satisfies the no cycle condition [7]. The **structural stability theorem**: An Axiom A flow of class C^1 with the strong transversality condition is structurally stable [29, 31]. Morse-Smale flows and Anosov flows are Axiom A flows with the strong transversality condition. There are Axiom A flows other than Morse-Smale flows and Anosov flows that satisfy the strong transversality condition [7]. **Stability conjecture**: A C^r -flow is structurally stable (resp. Ω -stable) if and only if it is an Axiom A flow with the strong transversality condition (resp. the no cycle condition). S. Newhouse, V. A. Pliss, Robinson, R. Mañé, S. D. Liao,

and A. Sannami have made important contributions to the study of the stability conjecture.

Neither the set of all Axiom A flows nor the set of all Ω -stable flows nor the set of structurally stable flows is dense in $\mathcal{X}^r(M)$ if $\dim M > 2$ (R. Abraham and Smale, Newhouse). However, the set of all structurally stable flows is dense in $\mathcal{X}^r(M)$ in the C^0 topology (M. Shub, M. M. C. de Oliverira).

(4) A diffeomorphism $f \in \text{Diff}^r(M)$ is called a **Morse-Smale diffeomorphism** if the following conditions are satisfied: (i) The nonwandering set Ω is a finite set, and hence it consists of periodic points; (ii) all periodic points are hyperbolic; (iii) for each pair $p, q \in \Omega$, $W^s(p)$ intersects $W^u(q)$ transversally. The Morse-Smale diffeomorphisms on the unit circle S^1 are exactly the structurally stable ones described in Section I(1). A Morse-Smale diffeomorphism is structurally stable [25]. The set of all Morse-Smale diffeomorphisms on M is open but not dense in $\text{Diff}^r(M)$ if $\dim M \geq 2$ (Palis, Smale). However, it contains a dense open subset of the set of all time-one mappings of the flows generated by gradient vector fields. In particular, any closed manifold admits Morse-Smale diffeomorphisms and hence structurally stable diffeomorphisms. For a Morse-Smale diffeomorphism, the Morse inequalities hold [24].

Let Λ be a closed invariant set of $f \in \text{Diff}^r(M)$. Λ is called **hyperbolic** if the following conditions are satisfied: (i) There is a splitting $T_x(M) = E_x^s \oplus E_x^u$ of the tangent space $T_x(M)$ for each $x \in \Lambda$, which depends continuously on $x \in \Lambda$; (ii) $df_x(E_x^s) = E_{f(x)}^s$ and $df_x(E_x^u) = E_{f(x)}^u$ for all $x \in \Lambda$; (iii) There is a Riemannian metric on M and constants $c > 0$, $0 < \lambda < 1$ such that, for any integer $m > 0$ and $x \in \Lambda$, $\|df_x^m(w)\| \leq c\lambda^m\|w\|$ when $w \in E_x^s$ and $\|df_x^{-m}(w)\| \leq c\lambda^m\|w\|$ when $w \in E_x^u$. A diffeomorphism $f \in \text{Diff}^r(M)$ is called an **Anosov diffeomorphism** if M itself is hyperbolic for f . Manifolds which admit Anosov diffeomorphisms are restricted (Hirsch, K. Shiraiwa). Examples of Anosov diffeomorphisms are given as follows: Let $L: \mathbf{R}^n \rightarrow \mathbf{R}^n$ be a hyperbolic linear automorphism with $L(\mathbf{Z}^n) = \mathbf{Z}^n$, where \mathbf{Z}^n is the discrete subgroup of \mathbf{R}^n consisting of all elements with integral coordinates. Then L induces an automorphism $f: T^n \rightarrow T^n$ of the n -dimensional torus $T^n = \mathbf{R}^n/\mathbf{Z}^n$, which is an Anosov diffeomorphism. There are similar constructions using hyperbolic automorphisms of simply connected nilpotent Lie groups and their uniform discrete subgroups (Smale). A homeomorphism $h: X \rightarrow X$ of a metric space X is called **expansive** if there is a constant $\varepsilon > 0$ such that $x, y \in X$ and $d(h^n(x), h^n(y)) < \varepsilon$ for all $n \in \mathbf{Z}$ imply $x = y$. An Anosov diffeomorphism is expansive. For Anosov diffeomorphisms,

theorems similar to those stated in Section J(2) hold. Franks, Newhouse, A. Manning, and J. N. Mather obtained important results concerning Anosov diffeomorphisms.

A diffeomorphism $f \in \text{Diff}^r(M)$ is called an **Axiom A diffeomorphism** if the following conditions are satisfied: A(a) The nonwandering set Ω is hyperbolic; A(b) the set of all periodic points is dense in Ω . There are examples that satisfy Axiom A(a) but not Axiom A(b) (A. Dankner, M. Kurata). For $x \in M$, put $W^s(x) = \{y \in M \mid d(f^n(x), f^n(y)) \rightarrow 0 \text{ as } n \rightarrow \infty\}$ and $W^u(x) = \{y \in M \mid d(f^{-n}(x), f^{-n}(y)) \rightarrow 0 \text{ as } n \rightarrow \infty\}$. We call $W^s(x)$ (resp. $W^u(x)$) the **stable** (resp. **unstable**) manifold of f at x . For a subset A of M , put $W^\sigma(A) = \bigcup_{x \in A} W^\sigma(x)$ ($\sigma = s, u$). If f is an Axiom A diffeomorphism, $W^s(x)$ and $W^u(x)$ are injectively immersed submanifolds of M . If x is a hyperbolic periodic point, $W^s(x)$ and $W^u(x)$ defined here coincide with those defined before. For Axiom A diffeomorphisms, notions such as spectral decomposition, basic sets, the strong transversality condition, and the no cycle condition are defined similarly, and theorems similar to those stated in Section J(3) hold.

Let $h: X \rightarrow X$ be a homeomorphism of a metric space X and $\alpha, \beta > 0$. A sequence $\{x_i\}_{i \in \mathbf{Z}}$ of points in X is an **α -pseudo-orbit** if $d(h(x_i), x_{i+1}) < \alpha$ for all $i \in \mathbf{Z}$. We say that $\{x_i\}_{i \in \mathbf{Z}}$ is **β -shadowed** (or **β -traced**) by a point $x \in X$ if $d(h^i(x), x_i) \leq \beta$ for all $i \in \mathbf{Z}$. We say that h has the **pseudo-orbit tracing property** if for any $\beta > 0$ there exists an $\alpha > 0$ so that any α -pseudo-orbit is β -shadowed by some point. If f is an Axiom A diffeomorphism, then $f|_{\Omega(f)}: \Omega(f) \rightarrow \Omega(f)$ has the pseudo-orbit tracing property (Bowen). Axiom A diffeomorphisms with the strong transversality condition (in particular, Anosov diffeomorphisms) have the pseudo-orbit tracing property (Bowen, K. Sawada, K. Kato, A. Morimoto).

(5) Let S be a discrete topological space with n elements ($n \geq 2$) and $\Sigma(S) = \prod_{i \in \mathbf{Z}} S_i$ the doubly infinite product of copies S_i of S with the product topology. A point $x = (x_i)_{i \in \mathbf{Z}}$ of $\Sigma(S)$ is a doubly infinite sequence of points in S . $\Sigma(S)$ is a totally disconnected, perfect, compact, metrizable space (i.e., a Cantor set). Let $\sigma: \Sigma(S) \rightarrow \Sigma(S)$ be a mapping defined by $\sigma(x) = y$, $x = (x_i)$, $y = (y_i)$, $y_i = x_{i+1}$ ($i \in \mathbf{Z}$). Then σ is a homeomorphism of $\Sigma(S)$ and is called the **shift automorphism** with n symbols.

Define a diffeomorphism $f: S^2 \rightarrow S^2$ of the 2-dimensional sphere S^2 as follows. We consider S^2 as $\mathbf{R}^2 \cup \{\infty\}$. Let U be a region of \mathbf{R}^2 consisting of the rectangle $R (= ABCD)$ and an upper and a lower cap as shown in Fig. 1. f maps U into itself as in Fig. 1 ($f(A) = A'$, $f(B) = B'$, $f(C) = C'$, $f(D) = D'$, and so on). Here, $R \cap f(R) = P \cup Q$ is the union of two rectangles,

$P'=f^{-1}(P)$ and $Q'=f^{-1}(Q)$ are rectangles, and f is affine on each of P' and Q' (stretching in the vertical direction and contracting in the horizontal direction). The lower cap is contracted into itself, and every point in it tends to a sink x_0 . The upper cap is mapped into the lower one and stays there. The point ∞ is the only source, and $\lim_{n\rightarrow\infty} f^{-n}(x)=\infty$ for all $x\in\mathbb{R}^2-U$. Thus the nonwandering set of f consists of a sink x_0 , a source ∞ , and $\Lambda=\bigcap_{n\in\mathbb{Z}} f^n(R)$. The mapping f constructed here is called the **horseshoe diffeomorphism**. It is an Axiom A diffeomorphism with the strong transversality condition (and hence structurally stable). The restriction $f|_\Lambda$ of f on a basic set Λ is topologically conjugate to the shift automorphism with two symbols. It is neither a Morse-Smale diffeomorphism nor an Anosov diffeomorphism [7].

Fig. 1

A restriction of a shift automorphism on a closed invariant set is called a **subshift**. Let $A=(A_{ij})$ be an $n\times n$ matrix with (i,j) -component $A_{ij}=0$ or 1 for all $i,j=1,\dots,n$. It is **irreducible** if for each i,j there is a positive integer m such that A^m has a nonzero (i,j) -component. Assume that A is irreducible and $S=\{1,\dots,n\}$. Put $\Sigma_A=\{x=(x_i)\in\Sigma(S)|A_{x_i,x_{i+1}}=1\text{ for all }i\in\mathbb{Z}\}$. Then Σ_A is a closed invariant set of $\Sigma(S)$. The restriction $\sigma_A=\sigma|_{\Sigma_A}:\Sigma_A\rightarrow\Sigma_A$ is called a **subshift of finite type** or a **Markov subshift**, and A is called the **transition matrix**. A topological classification of the subshifts of finite type has been investigated by Williams.

Let $f\in\text{Diff}^r(M)$ be an Axiom A diffeomorphism and Λ its basic set. Bowen constructed a \dagger Markov partition for $f|_\Lambda$ by generalizing the Sinai construction for Anosov diffeomorphisms. The Markov partition connects $f|_\Lambda$ with a suitable subshift of finite type and is applied to the study of Axiom A diffeomorphisms, especially to the ergodic theory of Axiom A diffeomorphisms (Bowen, Ruelle). A similar theory for flows was developed by Bowen, Ruelle, and M. E. Ratner.

(6) Let $x\in M$ be a hyperbolic fixed point of

$f\in\text{Diff}^r(M)$. A point $p\in W^s(x)\cap W^u(x)$ ($p\neq x$) is called a **homoclinic point**. If $W^s(x)$ and $W^u(x)$ intersect transversally at a homoclinic point p , then p is called a **transversal homoclinic point**. In a neighborhood of a transversal homoclinic point, there is a closed invariant set Λ of f^m for some positive integer m such that $f^m|_\Lambda$ is topologically conjugate to the shift automorphism with two symbols (Smale). There are generalizations of this theorem for semiflows by F. R. Marotto, Shiraiwa, and Kurata.

K. Topological Entropy and Zeta Functions

(1) The notion of topological entropy was first defined by R. L. Adler, A. G. Konheim, and M. H. McAndrew as an analog to measure-theoretic entropy. Let X be a compact topological space and α an open covering of X . Let $N(\alpha)$ be the minimum number of members of a subcovering of α . Let $f:X\rightarrow X$ be a continuous mapping and α an open covering of X . Then $\lim_{n\rightarrow\infty} (1/n)\log N(\alpha\vee f^{-1}\alpha\vee\dots\vee f^{n-1}\alpha)$ exists, where $\alpha\vee f^{-1}\alpha\vee\dots\vee f^{n-1}\alpha$ is the open covering $\{A_0\cap f^{-1}(A_1)\cap\dots\cap f^{n-1}(A_{n-1})|A_0,A_1,\dots,A_{n-1}\in\alpha\}$. We denote the above limit by $h(f,\alpha)$ and call it the **topological entropy of f with respect to α** . The **topological entropy $h(f)$** of f is defined as the $\sup h(f,\alpha)$, where the supremum is taken over all open coverings α of X . Now assume that X is a compact metric space. For an open covering α of X , put $\text{diam}\alpha=\sup\{\text{diam} A|A\in\alpha\}$, where $\text{diam} A$ is the diameter of A . If $\{\alpha_n\}_{n\geq 1}$ is a sequence of open coverings of X such that $\text{diam}\alpha_n\rightarrow 0$ as $n\rightarrow\infty$, then $h(f,\alpha_n)\rightarrow h(f)$ as $n\rightarrow\infty$. The topological entropy of the shift automorphism with n symbols is equal to $\log n$. Let $L:\mathbb{R}^n\rightarrow\mathbb{R}^n$ be a linear mapping with $L(\mathbb{Z}^n)\subset L(\mathbb{Z}^n)$ and $\lambda_1,\dots,\lambda_n$ its eigenvalues. Let $f:T^n\rightarrow T^n$ be the induced endomorphism of the n -dimensional torus $T^n=\mathbb{R}^n/\mathbb{Z}^n$. Then the topological entropy is given by $h(f)=\sum_{|\lambda_i|>1}\log|\lambda_i|$.

Let $f:X\rightarrow X$ be a continuous mapping and $M(f)$ the set of all $\dagger f$ -invariant probability measures on the Borel sets of X . For each $\mu\in M(f)$, denote by $h_\mu(f)$ the (measure-theoretic) entropy of f with respect to μ . Then $h(f)=\sup\{h_\mu(f)|\mu\in M(f)\}$ (E. I. Dinaburg, T. N. T. Goodman, L. W. Goodwyn). The following properties hold: (i) If $f:X\rightarrow X$ is a homeomorphism, then $h(f^n)=|n|h(f)$ for all $n\in\mathbb{Z}$. (ii) If (X,φ) is a continuous flow, then $h(\varphi_t)=|t|h(\varphi_1)$ for all $t\in\mathbb{R}$. (iii) Let $f_i:X_i\rightarrow X_i$ ($i=1,2$) be continuous. Then $h(f_1\times f_2)=h(f_1)+h(f_2)$. (iv) Let $f_i:X_i\rightarrow X_i$ ($i=1,2$) be continuous. If there is a continuous mapping $g:X_1\rightarrow X_2$ such that $g(X_1)=X_2$ and $g\circ f_1=f_2\circ g$, then $h(f_1)\geq h(f_2)$. In particular, if f_1 and f_2 are topologically conjugate, then $h(f_1)=h(f_2)$.

$h(f_2)$. (v) If $f: X \rightarrow X$ is a homeomorphism and Ω is the nonwandering set of f , then $h(f) = h(f|_{\Omega})$. In particular, Ω -conjugate homeomorphisms have the same topological entropy (Bowen). (vi) If $f: M \rightarrow M$ is an Axiom A diffeomorphism of a closed C^∞ -manifold M , then $h(f) = \limsup_{n \rightarrow \infty} (1/n) \log N_n(f)$, where $N_n(f)$ is the number of all periodic points of period n . And $h(f) = 0$ if and only if the nonwandering set is finite (Bowen).

Bowen gave alternative definitions of the topological entropy and generalized it for uniformly continuous mappings of (not necessarily compact) metric spaces. If $f: M \rightarrow M$ is a C^1 -mapping of an n -dimensional Riemannian manifold M , then $h(f) \leq \max\{0, n \log \sup\{\|df_x\| \mid x \in M\}\}$, where $\|df_x\|$ is the norm of $df_x: T_x(M) \rightarrow T_{f(x)}(M)$, and hence $h(f)$ is finite (Bowen, S. Ito).

(2) Let $f: M \rightarrow M$ be a continuous mapping of a closed C^∞ -manifold M and $f_*: H_*(M) \rightarrow H_*(M)$ (resp. $f_{*1}: H_1(M) \rightarrow H_1(M)$) the \dagger induced homomorphism if f on the \dagger homology group $H_*(M)$ (resp. the \dagger first homology group $H_1(M)$) with coefficients in \mathbf{R} . The **spectral radius** $s(L)$ of a linear mapping $L: E \rightarrow E$ of a real vector space E is the maximum of the absolute values of the eigenvalues of L . The following **entropy conjecture** is still open: If $f: M \rightarrow M$ is a C^1 -diffeomorphism (C^1 -mapping), then $h(f) \geq \log s(f_*)$. Concerning the entropy conjecture, the following are known: (i) The conjecture holds for a dense open set of $\text{Diff}^r(M)$ in the C^0 -topology (Shub); (ii) for any continuous mapping f , $h(f) \geq \log s(f_{*1})$ (Manning); (iii) the conjecture fails for a homeomorphism (Pugh); (iv) the conjecture holds for an Axiom A diffeomorphism with the no cycle condition (Shub and Williams); (v) the conjecture holds for any continuous mapping of the n -dimensional torus (M. Misiurewicz, F. Przytycki); (vi) for a C^1 -mapping $f: M \rightarrow M$, $h(f) \geq \log |\deg f|$, where $\deg f$ is the \dagger mapping degree of f (Misiurewicz, Przytycki).

(3) M. Artin and B. Mazur first defined the zeta function of a diffeomorphism by analogy to \dagger Weil's zeta function. Let $f: X \rightarrow X$ be a homeomorphism of a compact metric space X . Assume that the number $N_m = N_m(f)$ of all periodic points of period m is finite for all m . Put $\zeta(t) = \exp(\sum_{m=1}^{\infty} N_m t^m / m)$ and call it the **zeta function** of f . For any closed C^∞ -manifold M , there is a dense set E of $\text{Diff}^r(M)$ such that $\tilde{N}_m(f) \leq ck^m$ for $f \in E$, where $\tilde{N}_m(f)$ is the number of isolated periodic points of period m and c and k are positive constants depending only on f (Artin, Mazur). Hence, for such $f \in E$, the series $\exp(\sum_{m=1}^{\infty} \tilde{N}_m(f) t^m / m)$ has a positive radius of convergence. Originally, Artin and Mazur called this the zeta function of f .

Let $\sigma_A: \Sigma_A \rightarrow \Sigma_A$ be a subshift of finite type with transition matrix A ; then $\zeta(t) = 1/\det(E - tA)$, where E is the unit matrix (Bowen and O. E. Lanford III). The zeta function of an Axiom A diffeomorphism has a positive radius of convergence and is a rational function (K. Meyer, J. Guckenheimer, Manning).

Let (M, φ) be a nonsingular C^r -flow on a closed C^∞ -manifold M . Let Γ be the set of all closed orbits and $l(\gamma)$ the smallest positive period of $\gamma \in \Gamma$. Smale defined the **zeta function** of (M, φ) by $Z(s) = \prod_{\gamma \in \Gamma} \prod_{k=0}^{\infty} (1 - [\exp l(\gamma)]^{-s-k})$. If (M, φ) is the geodesic flow on a surface of constant negative curvature, $Z(s)$ reduces to the \dagger Selberg zeta function.

There are generalizations and modifications of the notion of zeta function by Ruelle and Franks.

L. Classical Dynamical Systems

(1) Let M be a C^∞ -manifold without boundary. A C^r -flow (M, φ) or a C^r -diffeomorphism $f: M \rightarrow M$ with a smooth invariant measure is called a **classical dynamical system**. Most important classical dynamical systems are Hamiltonian or Lagrangian systems. In the modern formulation, a **Hamiltonian system** consists of M , a **symplectic form** ω on M (i.e., a \dagger nondegenerate \dagger closed 2-form), and the vector field X_H on M defined by a C^{r+1} -function $H: M \rightarrow \mathbf{R}$. We call X_H the **Hamiltonian vector field** with **energy function** H . Let (M, ω, X_H) be a Hamiltonian system. Then the following hold: (i) M is of even dimension and there is a system of local coordinates $(q^1, \dots, q^n, p_1, \dots, p_n)$ such that $\omega = \sum_{i=1}^n dq^i \wedge dp_i$ (J. G. Darboux). In these coordinates X_H is expressed by \dagger Hamilton's equations $dq^i/dt = \partial H / \partial p_i$, $dp_i/dt = -\partial H / \partial q^i$, $i = 1, \dots, n$; (ii) the smooth measure defined by the \dagger volume element $\Omega = ((-1)^{n(n-1)/2}/n!) \omega^n$ is an invariant measure for the flow generated by X_H (J. Liouville); (iii) the energy function H is constant along any trajectory of X_H . Especially, $H^{-1}(e)$ ($e \in \mathbf{R}$) is an invariant set for each e and is called an **energy surface**. Energy surfaces are submanifolds of codimension one for almost all $e \in \mathbf{R}$.

Important examples of Hamiltonian systems are given as follows. Let Q be an n -dimensional manifold and $T^*(Q)$ the \dagger cotangent bundle of Q . Then $T^*(Q)$ has a canonical symplectic form ω_0 . We call Q a **configuration space** and $T^*(Q)$ a **momentum phase space**. For any C^{r+1} -function H on $T^*(Q)$, we have a Hamiltonian system $(T^*(Q), \omega_0, X_H)$ in which X_H is of class C^r . The Hamiltonian formalism is translated into Lagrangian formalism by using the \dagger tangent bundle $T(Q)$ instead of $T^*(Q)$. $T(Q)$ is called a **velocity phase space**.

For a given differentiable function L on $T(Q)$, the **energy function** E on $T(Q)$ and the **Lagrangian vector field** X_E on $T(Q)$ are constructed. If L satisfies a certain condition, there is a system of local coordinates $(q^1, \dots, q^n, \dot{q}^1, \dots, \dot{q}^n)$ such that X_E is expressed in these coordinates by the \dagger Euler-Lagrange equations $dq^i/dt = \dot{q}^i$, $d/dt(\partial L/\partial \dot{q}^i) = \partial L/\partial q^i$, $i = 1, \dots, n$. The projection of an integral curve (i.e., an orbit) of X_E into Q is called a base integral curve. Under a suitable condition, the base integral curve of a Lagrangian (or a Hamiltonian) system is the geodesic of the Jacobi metric on Q up to a reparametrization, and the restriction of the flow generated by X_X on an energy surface is the geodesic flow described below.

(2) Let M be a \dagger complete Riemannian manifold of class C^∞ and $S(M) = \{v \in T(M) \mid \|v\| = 1\}$. Let $\pi: S(M) \rightarrow M$ be the projection defined by $\pi(v) = x$ for $v \in T_x(M)$. Then $S(M)$ is a \dagger sphere bundle over M , which is called the **unit tangent sphere bundle** over M . Each $v \in S(M)$ determines a unique \dagger geodesic $C_v: \mathbf{R} \rightarrow M$ such that $C_v(0) = \pi(v)$ and the \dagger tangent vector $C'_v(0)$ to C_v at $t = 0$ is equal to v . Let v_t be the tangent vector $C'_v(t)$ to C_v at t for $t \in \mathbf{R}$. Then $\|v_t\| = 1$ and $\pi(v_t) = C_v(t)$ for all $t \in \mathbf{R}$. Define a mapping $\varphi: S(M) \times \mathbf{R} \rightarrow S(M)$ by $\varphi(v, t) = v_t$. Then $(S(M), \varphi)$ is a C^∞ -flow, which is called the **geodesic flow** on M . By the classical Liouville theorem, a geodesic flow has a smooth invariant measure.

(3) Let $T^n = \mathbf{R}^n/\mathbf{Z}^n$ be the n -dimensional torus and $\omega_1, \dots, \omega_n$ real constants. Define a mapping $\varphi: T^n \times \mathbf{R} \rightarrow T^n$ by $\varphi([x_1, \dots, x_n], t) = [x_1 + \omega_1 t, \dots, x_n + \omega_n t]$, where $[x_1, \dots, x_n] \in \mathbf{R}^n/\mathbf{Z}^n = T^n$ is the residue class of $(x_1, \dots, x_n) \in \mathbf{R}^n$ modulo \mathbf{Z}^n . Then (T^n, φ) is a C^∞ -flow. We call it the **translation flow with frequencies** $\omega_1, \dots, \omega_n$. If $\omega_1, \dots, \omega_n$ are linearly independent over \mathbf{Z} , they are called **independent**. Every orbit of the translation flow is dense if and only if its frequencies are independent (Poincaré, H. Weyl). A translational flow with independent frequencies is called **quasiperiodic**.

Let (M, ω, X_H) be a Hamiltonian system on a $2n$ -dimensional manifold M . Under a certain condition, there exist an open set U of M and a diffeomorphism $f: U \rightarrow T^n \times \mathbf{R}^n$ such that the following holds: Identify U with $T^n \times \mathbf{R}^n$ by f , and let $(q^1, \dots, q^n, p_1, \dots, p_n)$ be the coordinates of $T^n \times \mathbf{R}^n$. Then the energy function H is independent of $q = (q^1, \dots, q^n)$ so that Hamilton's equations becomes $dq^i/dt = \partial H/\partial p_i$, $dp_i/dt = -\partial H/\partial q^i = 0$ for $i = 1, \dots, n$. Therefore the solutions are given by $q^i(t) = (\partial H/\partial p_i(c))t + q^i(0)$ modulo \mathbf{Z} , $p_i(t) = p_i(0) = c_i$, $i = 1, \dots, n$, where $c = (c_1, \dots, c_n)$. Therefore $N_c = f^{-1}(T^n \times \{c\})$ is an **invariant torus** (i.e., an invariant set diffeomorphic to T^n) of (the flow generated by) X_H for all $c \in \mathbf{R}^n$, and the restriction flow on

N_c is the translational flow with frequencies $\omega_1 = \partial H/\partial p_1(c), \dots, \omega_n = \partial H/\partial p_n(c)$ (Arnold). Assume further that the Hessian $\det(\partial^2 H/\partial p_i \partial p_j)$ does not vanish at c and $\omega_1, \dots, \omega_n$ are independent. Let \tilde{H} be an energy function obtained by adding a sufficiently small perturbation to H . Then for almost all c' near c , there exists an invariant torus \tilde{N} of $X_{\tilde{H}}$ near N_c such that the restriction flow on \tilde{N} is differentially equivalent to the translational flow with the same frequencies (Kolmogorov, Arnold, Moser).

(4) Generic properties for Hamiltonian systems were investigated by M. Buchner, Markus, Meyer, Pugh, Robinson, Takens, and Newhouse.

M. Bifurcation

(1) Consider a differential equation with a parameter. For example, let X be a domain of \mathbf{R}^n , $J = (-1, 1)$, and $f: J \times X \rightarrow \mathbf{R}^n$ a C^r -mapping. For each $\mu \in J$, define $f_\mu: X \rightarrow \mathbf{R}^n$ by $f_\mu(x) = f(\mu, x)$, $x \in X$. Consider the differential equation

$$dx/dt = f_\mu(x), \quad x \in X \text{ and } \mu \in J. \tag{7}$$

As μ varies, the topological structure of the phase portrait of (7) may change. Suppose that there exists $\mu_0 \in J$ such that the topological structure of the phase portrait of (7) changes at $\mu = \mu_0$ but remains the same when $\mu_0 - \varepsilon < \mu < \mu_0$ or $\mu_0 < \mu < \mu_0 + \varepsilon$ for some $\varepsilon > 0$. Then μ_0 is called a **bifurcation point** of (7).

Hopf bifurcation: Assume that $X = \mathbf{R}^2$ and the origin $0 \in \mathbf{R}^2$ is a singular point of (7) for all $\mu \in J$. Assume further that the Jacobian matrix of f_μ at $0 \in \mathbf{R}^2$ has two distinct complex conjugate eigenvalues $\lambda(\mu)$ and $\bar{\lambda}(\mu)$ such that the real part $\text{Re } \lambda(\mu)$ of $\lambda(\mu)$ is positive when $\mu > 0$, zero when $\mu = 0$, and negative when $\mu < 0$. Then $0 \in \mathbf{R}^2$ is a sink for $\mu < 0$ and a source for $\mu > 0$. Now assume further that $d/d\mu(\text{Re } \lambda(\mu))|_{\mu=0}$ is positive and $0 \in \mathbf{R}^2$ is a "vague attractor." Then $0 \in J$ is a bifurcation point, and there exists an asymptotically stable closed orbit for (7) near and around $0 \in \mathbf{R}^2$ which depends continuously on μ for $\mu > 0$ [37]. Thus a sink of (7) ($\mu < 0$) changes to a source and an asymptotically stable closed orbit ($\mu > 0$) when μ changes its sign. The Hopf bifurcation theorem can be generalized to a higher-dimensional case, and there is a diffeomorphism version of the theorem.

(2) Bifurcations in more general settings have been investigated by many mathematicians, including Thom, Arnold, R. J. Sacker, G. R. Sell, D. H. Sattinger, G. Iooss, Ruelle, and Takens. Generic bifurcations of dynamical systems have been investigated by J. Soto-

mayer, Meyer, P. Brunovský, and others; bifurcations of Morse-Smale systems by Newhouse, Palis, Peixoto, and S. Matsumoto; and bifurcations of Axiom A diffeomorphisms by Newhouse and Palis.

N. Miscellaneous Topics

(1) Let S^3 be the 3-dimensional sphere and $V \in \mathcal{X}^1(S^3)$. H. Seifert proved that if V is sufficiently close (in C^0 topology) to a nonsingular vector field tangent to the fibers of the 1 Hopf fibration $S^3 \rightarrow S^2$, then V has a closed orbit. He conjectured that every nonsingular vector field $V \in \mathcal{X}^1(S^3)$ had a closed orbit. (**Seifert conjecture**; \rightarrow 154 Foliations D). If a nonsingular vector field $V \in \mathcal{X}^1(S^3)$ is transverse to a codimension 1 foliation of class C^2 , then it has a closed orbit (S. P. Novikov). Let M be a 3-dimensional C^∞ -manifold. Then there exists a nonsingular vector field $V \in \mathcal{X}^1(M)$ with no closed orbit in any 1 homotopy class of a nonsingular vector field on M (P. A. Schweitzer). Thus the Seifert conjecture fails for a vector field of class C^1 , but the conjecture for a vector field of class C^r ($r \geq 2$) is an open problem. Related work has been done by Fuller, H. Chu, and A. Weinstein.

(2) Let M be a closed connected C^∞ -manifold. A C^r -flow (M, φ) (resp. $f \in \text{Diff}^r(M)$) is a **minimal flow** (resp. a **minimal diffeomorphism**) if M itself is a minimal set. If M admits a 1 locally free S^1 -action of class C^∞ , then it admits a minimal C^∞ -diffeomorphism, and if M admits a locally free special (in particular, a 1 free) T^2 -action of class C^∞ , then it admits a minimal C^∞ -flow (A. Fathi, Herman, A. B. Katok). Open problems: What are the topological properties of the manifolds admitting minimal flows? Does S^3 admit a minimal flow?

(3) E. N. Lorenz studied numerical solutions of the following nonlinear equations in \mathbf{R}^3 which arose from the convection equation: $dx/dt = -\sigma x + \sigma y$, $dy/dt = -xz + rx - y$, $dz/dt = xy/bz$. When $\sigma = 10$, $r = 28$, and $b = 8/3$, he found irregular behavior in this dynamical system. R. M. May studied numerical solutions of the following difference equation in connection with the growth of biological populations with nonoverlapping generations: $x_{n+1} = ax_n(1 - x_n)$, $x_n \in [0, 1]$ ($1 < a < 4$). He found that the dynamical structure of the above difference equation was delicate and complicated. Y. Ueda and H. Kawakami also found similar phenomena in their numerical study of Duffing's equation of the type $d^2x/dt^2 + k dx/dt + x^3 = B \cos t$. The phenomena observed in these investigations were called **chaos**, which exhibits **strange attractors**.

These investigations have attracted the

attention of many mathematicians and scientists. For 1-dimensional semidynamical systems such as May's equation, T. Y. Li, J. A. Yorke, A. N. Sharkovskii, J. W. Milnor, Thurston, and many others have obtained notable results, while for Lorenz's equation we have results by Ruelle, Guckenheimer, Williams, Sinai, and many others. Chaos arising from discretization of differential equations has been studied by M. Yamaguti, S. Ushiki, and others (\rightarrow 433 Turbulence and Chaos).

127 (XIX.8) Dynamic Programming

A. General Remarks

There are two types of multistage [†]decision processes. In one of them, an outcome of the whole process is determined at the final stage without any consideration of the outcome for each intermediate stage. The [†]extensive form of a [†]game is of this type. In the other type, an outcome is assigned at each stage of a multistage decision process. The theory of **dynamic programming**, dealing with this latter type, has been developed by R. Bellman and others since 1950 and is now one of the fundamental branches of mathematical programming, along with the theories of linear and nonlinear programming. The following examples illustrate some features of multistage decision processes.

Multistage allocation process. We are given a quantity $x > 0$ that can be divided into two parts y and $(x - y)$. From y we obtain a return $g(y)$, and from $(x - y)$ a return $h(x - y)$. In so doing, we expend a certain amount of our original resources and are left with a new quantity, $ay + b(x - y)$, $0 < a, b < 1$, with which the process is continued. How do we proceed so as to maximize the total return obtained in a finite or unbounded number of stages?

Multistage choice process. Suppose that we possess two gold mines A and B , the first of which contains an amount x of gold, while the second contains an amount y . In addition, we have a single gold mining machine with the property that if used to mine gold in the mine A , there is a probability P_1 that it will mine a fraction r_1 of the gold there and remain in working order, and a probability $1 - P_1$ that it will mine no gold and be damaged beyond repair. Similarly, the mine B has associated

with it the corresponding probabilities P_2 and $1 - P_2$ and fraction r_2 . How do we proceed in order to maximize the total amount of gold before the machine is defunct?

These two processes have the following features in common: (1) In each case we have a physical system characterized in any state by a small set of parameters, the **state variables**. (2) In each state of either process we have a choice of a number of **decisions**. (3) The effect of a decision is a transformation of the state variables. (4) The past history of the system is of no importance in determining future actions (*Markov property). (5) The purpose of the process is to maximize some function of the state variables.

A **policy** is a rule for making decisions that yields an allowable sequence of decisions; an **optimal policy** is a policy that maximizes a preassigned function of the final state variables. A convenient term for this preassigned function of the final state variables is **criterion function**. One of the characteristic features of Bellman's methodology of dynamic programming is the appeal to the **principle of optimality**: An optimal policy has the property that whatever the initial state and initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision.

In the multistage allocation process the state variables are x (the quantity of resources) and z (the return obtained up to the current stage). The decision at any stage consists of an allocation of a quantity $0 \leq y \leq x$. This decision has the effect of transforming x into $ay + b(x - y)$ and z into $z + g(y) + h(x - y)$. The purpose of the process is to maximize the final value of z . Denote by $f_N(x)$ the N -stage return obtained starting from an initial state x and using an optimal policy. Then we have

$$f_1(x) = \max_{0 \leq y \leq x} [g(y) + h(x - y)],$$

$$f_n(x) = \max_{0 \leq y \leq x} [g(y) + h(x - y) + f_{n-1}(ay + b(x - y))], \quad n \geq 2.$$

This recurrence relation yields a method for obtaining the sequence $\{f_n(x)\}$ inductively.

In the stochastic gold-mining process, the state variables are x and y (the present level of the two mines) and z (the amount of gold mined to date). The decision at any stage consists of a choice of A and B . If A is chosen, (x, y) goes into $((1 - r_1)x, y)$ and z into $z + r_1x$, and if B is chosen, (x, y) goes into $(x, (1 - r_2)y)$ and z into $z + r_2y$. The purpose of the process is to maximize the expected value of z obtained before the machine becomes defunct.

Denote by $f(x, y)$ the expected amount of gold obtained using an optimal sequence of

choice. Then we have

$$f(x, y) = \max \left[\begin{array}{l} p_1 \{r_1x + f((1 - r_1)x, y)\} \\ p_2 \{r_2y + f(x, (1 - r_2)y)\} \end{array} \right].$$

The optimal policy can be described in the following way. We choose A or B according as $p_1r_1x/(1 - p_1)$ is greater or less than $p_2r_2y/(1 - p_2)$. We can choose either A or B if equality holds. After an operation according to such a choice, the machine may become defunct and terminate the process. If the machine is usable, then we can apply our policy to a new combination of the amounts of gold in A and B .

B. Discrete Deterministic Processes

By a deterministic process we mean a process in which the outcome of a decision is uniquely determined by the decision. We assume that the state of the system, apart from time dependence, is described in any stage by an M -dimensional vector p constrained to lie within some region D . Let $T = \{T_q\}$ (where q runs over a set S) be a set of transformations with the property that $p \in D$ implies that $T_q(p) \in D$ for all $q \in S$, i.e., any transformation T_q carries D into itself. The term "discrete" signifies here that we have a process consisting of a finite or denumerably infinite number of stages. A policy, for the finite process which we consider first, consists of a selection of N transformations in order, $P = (T_1, T_2, \dots, T_N)$, yielding successively the sequence of states $p_i = T_i(p_{i-1})$ ($i = 2, 3, \dots, N$) with $p_1 = T_1(p)$. These transformations are to be chosen to maximize a given function R of the final state p_N . Observe that the maximum value of $R(p_N)$, as determined by an optimal policy, will be a function of the initial vector p and the number N of stages only. Let us then define our basic auxiliary functions $f_N(p) = \max R(p_N) =$ the N -stage return obtained starting from an initial state p and using an optimal policy. This sequence is defined for $N = 1, 2, \dots$, and $p \in D$. The essential uses of the principle of optimality can be observed from the following two features. The first is the use of the **embedding principle**. The original process is embedded in a family of similar processes. In place of attempting to determine the characteristics of an optimal policy for an isolated process, we attempt to deduce the common properties of the set of optimal policies possessed by the members of the family. The second feature is the derivation of recurrence relations by which the functional equations connecting the members of the sequence $\{f_k(p)\}$ are established. Assume that we choose some transformation T_q as a result of our first decision, obtaining in this way a new state vector $T_q(p)$. The **maximum return**

from the following $k-1$ stages is, by definition, $f_{k-1}(T_q(p))$. It follows that, if we wish to maximize the total k -stage return, q must now be chosen to maximize this $(k-1)$ -stage return. The result is the basic recurrence relation $f_k(p) = \max_{q \in S} f_{k-1}(T_q(p))$, for $k \geq 2$, with $f_1(p) = \max_{q \in S} R(T_q(p))$. For the case of an unbounded process, the sequence $\{f_k(p)\}$ is replaced by a single function $f(p)$, the total return obtained by using an optimal policy starting from state p , and the recurrence relation is replaced by the functional equation $f(p) = \max_q f(T_q(p))$.

C. Discrete Stochastic Processes

We again consider a discrete process, but one in which the transformations are stochastic rather than deterministic. The initial vector p is transformed into a stochastic vector z with an associated distribution function $dG_q(p, z)$ dependent on p and the choice of q . We assume that z is known after the decision has been made and before the next decision is to be made. We agree to measure the value of a policy in terms of some average value of the function of the final state. Let us call this expected value the **return**. Beginning with the case of a finite process, we define $f_k(p)$ as before. The expected return as a result of the initial choice of T_q is therefore

$$\int_{z \in D} f_{k-1}(z) dG_q(p, z).$$

Consequently, the recurrence relation for the sequence $\{f_k(p)\}$ is

$$f_k(p) = \max_{q \in S} \int_{z \in D} f_{k-1}(z) dG_q(p, z), \quad k \geq 2,$$

with $f_1(p) = \max_{q \in S} \int_{z \in D} R(z) dG_q(p, z)$. Considering the unbounded process, we obtain the functional relation

$$f(p) = \max_{q \in S} \int_{z \in D} f(z) dG_q(p, z).$$

D. Continuous Deterministic Processes

A number of interesting processes require that decisions be made at each point of a continuum, such as a time interval. The simplest examples of processes of this character are provided by the calculus of variations. Let us denote by $f(p; T)$ the return obtained over a time interval $[0, T]$ starting from the initial state p and employing an optimal policy. Although we consider the process as one consisting of choices made at each point t on $[0, T]$, it is better to begin with the concept of choosing policies (functions) over intervals, and then pass to the limit as these intervals shrink to points. Let d be an allowable deci-

sion made over the interval $[0, S]$, and let p_d be the state at S starting from the initial state p and employing d . The application of the principle of optimality suggests that

$$f(p; S+T) = \sup_D f(p_d, T), \quad (1)$$

where the supremum is taken over the set D of all allowable decisions d .

The limiting form of (1) as $S \rightarrow 0$ is a nonlinear partial differential equation (Bellman partial differential equation). This expression is important for use in actual analysis. For numerical purposes, S is kept nonzero but small. R. Bellman showed that it is possible to avoid many of the quite difficult rigorous details involved in this limiting procedure if we are interested only in the computational solution of variational processes.

E. Markovian Decision Processes

Consider a physical system which at any of the times $t=0, \Delta, 2\Delta, \dots$ must lie in one of the states S_1, S_2, \dots, S_N . Let $y_i(n)$ be the probability that the system is in S_i at times $n\Delta$, and let P_{ij} be the probability that the system is in state S_j at $t+\Delta$ if it is in state S_i at time t . We suppose that the transition probabilities P_{ij} are independent of t . We assume that the P_{ij} depend on a parameter q , which may be a vector, and that at each stage of the process q is to be chosen so as to maximize the probability that the system is in the state S_1 . We obtain the nonlinear system

$$\begin{aligned} y_1(n+1) &= \max_q \sum_{j=1}^N p_{1j}(q) y_j(n) \\ &= \sum_{i=1}^N y_i(n) p_{i1}(q^*); \end{aligned}$$

$$y_i(n+1) = \sum_{j=1}^N p_{ij}(q^*) y_j(n), \quad i=2, 3, \dots, N,$$

where $q^* = q^*(n)$ in the remaining $N-1$ equations is one of the values of q that maximize $y_1(n+1)$. There are similar processes that can be considered as continuous analogs of this type of decision process. These are called **Markovian decision processes** and were discussed by Bellman. There is, however, another type of Markovian decision process in which a reward is given at each stage. For each state S_i of the system there are k alternatives $1, 2, 3, \dots, k$. If we choose the alternative h among these k alternatives, then the transition probabilities p_{ij}^h ($j=1, 2, \dots, n$) are determined, and a reward r_{ij}^h is associated with each state S_j . Let us denote by $v_i(n)$ the total expected return obtained at the n th stage by appealing to an optimal policy when the initial state is S_i . Then the principle of optimality in the theory

of dynamic programming yields

$$v_i(n+1) = \max_h \left(\sum_{j=1}^N p_{ij}^h(r_{ij}^h + v_j(n)) \right).$$

A policy-iteration method involving a value-determination operation with a policy-improvement routine was given by R. A. Howard [4].

F. Dynamic Programming and the Calculus of Variations

Problems in the calculus of variations can be viewed as multistage decision problems of a continuous type. It can be shown that the dynamic-programming approach yields formal derivations of classical necessary conditions for the calculus of variations. Let us consider the problem of minimizing the functional

$$J(y) = \int_a^b f(x, y(x), y'(x)) dx,$$

where the function y is subject to $y(a) = c$.

We embed this problem within the family of problems generated by allowing a and c to be parameters with the ranges of variation $-\infty < a < b$, $-\infty < c < \infty$. Now we define the optimal value function $S(a, c) = \min_y J(y)$. Then the principle of optimality yields the functional equation

$$S(a, c) = \min \left(\int_a^{a+\Delta} f(x, y, y') dx + S(a+\Delta, c(y)) \right),$$

where the minimization is taken over all functions defined over $[a, a+\Delta]$ with $y(a) = c$ and $c(y) = y(a+\Delta)$. Then, writing $v = y'(a)$, we get

$$-\frac{\partial S}{\partial a} = \min_v \left(f(a, c, v) + v \frac{\partial S}{\partial c} \right).$$

This yields the Euler equation, the Legendre condition, the Weierstrass condition, and the Erdman corner conditions. Furthermore, it can be shown that the functional equation characterization yields the Hamilton-Jacobi partial differential equation of classical mechanics.

The dynamic-programming approach can be applied to more general problems in the calculus of variations.

G. Dynamic Programming and the Maximum Principle

In general, the method of dynamic programming carries a more universal character than the maximum principle of optimal control theory. However, in contrast to the latter, this

method does not have a rigorous logical foundation. V. G. Boltyanskii [6] has presented a justification of the dynamic programming method.

Let $f_i(x, u)$ ($i=0, 1, \dots, n$) be defined for $x \in V \subset \mathbf{R}^n$ and $u \in U \subset \mathbf{R}^r$, where V is an open set, and continuously differentiable on $V \times U$. Suppose that two points x^0 and x^1 are given in V . Among all the piecewise continuous controls $u(t) = (u_1(t), \dots, u_r(t)) \in U$ which transfer the phase point moving in accordance with

$$\frac{dx_i}{dt} = f_i(x, u(t)), \quad i=1, \dots, n,$$

from $x^0 = x(t_0)$ to $x^1 = x(t_1)$, find the control $u(t)$ for which the functional

$$J = \int_{t_0}^{t_1} f_0(x(t), u(t)) dt$$

takes the smallest value.

A continuous function $\omega(x) = \omega(x_1, \dots, x_n)$ is called a **Bellman function** relative to a point $a \in V$ if it possesses the following properties: (1) $\omega(a) = 0$; (2) there exists a set M (the singular set of $\omega(x)$), which is closed in V and does not contain interior points, such that the function $\omega(x)$ is continuously differentiable on the set $V - M$ and satisfies the condition

$$\sup_{u \in U} \left(\sum_{i=1}^n \frac{\partial \omega}{\partial x_i} f_i(x, u) - f_0(x, u) \right) = 0, \quad x \in V - M.$$

The following theorem gives a sufficient optimality condition.

Theorem: Assume that for $dx/dt = f(x, u(t))$ given in a region $V \subset \mathbf{R}^n$ there exists a Bellman function $\omega(x)$ relative to the point $a \in V$ with a piecewise smooth singular set. Assume, furthermore, that for any point $x^0 \in V$ there exists a control $u(t)$ which transfers the phase point from $x^0 = x(t_0)$ to $a = x(t_1)$ and satisfies the relation

$$\int_{t_0}^{t_1} f_0(x(t), u(t)) dt = -\omega(x^0).$$

Then any such control $u(t)$ is optimal in V .

Recently, Vinter and Levis [7] obtained the following general result in this connection. The sufficient condition is given in terms of a solution to the Bellman partial differential equation. It is shown that if this equation is modified so that it is actually an inequality, and if this inequality is required to be satisfied in a limiting sense only, then the condition is also necessary for optimality.

H. Characteristic Features of Dynamic Programming

The characteristic features of the dynamic-programming approach can be summarized in

the following five points: (1) the advantage of lower dimensionality in comparison with the enumeration approach; (2) the possibility of finding maxima and/or minima of functions defined over restricted domains for which differential calculus may not work well; (3) the availability of numerical solutions in recursive form; (4) the possibility of formulating certain problems to which classical methods do not apply; and (5) the applicability of the method to most types of problems in mathematical programming, such as inventory and production control, optimal searching, and some optimal and adaptive control processes.

E

128 (XVIII.15) Econometrics

A. General Remarks

The term **econometrics** can be interpreted in various ways. In its widest sense, it means the application of mathematical methods to economic problems and includes mathematical economics, †mathematical programming, etc. However, here we use it to mean statistical methods applied to economic analysis.

The object of econometrics is to provide methods to analyze relationships between economic variables. We classify these methods into four categories according to the types of relationships involved: (1) Analysis of causal relations: If a set of variables X_1, \dots, X_n affects an economic variable Y , we can estimate the direction and extent of those effects on Y . (2) Analysis of equilibrium: When a set of economic variables Y_1, \dots, Y_m is determined through a market equilibrium mechanism, we can analyze the structure of relationships that determines the equilibrium. (3) Analysis of correlation: When a set of economic variables is affected simultaneously by some (unknown) common factors, we can analyze the correlation structure of the variables. (4) Analysis of time interdependence: A process of development in time of a set of economic variables can be analyzed.

There are two types of economic data: (a) **macroeconomic data**, representing quantities and variables related to a national economy as a whole, usually based on national census; and (b) **microeconomic data**, representing information about the economic behavior of individual persons, households, and firms. Macroeconomic data are usually given as a set of time series (\rightarrow 421 Time Series Analysis A), while microeconomic data are obtained mainly through statistical surveys and are given as **cross-sectional data**. These two types of data, related to macroeconomic theory and microeconomic theory, respectively, require different approaches; and sometimes information obtained from both types of data has to be combined; obtaining macroeconomic information from microeconomic data is called aggregation.

B. Regression Analysis

The most common technique for the first category of problems is †regression analysis, which is applied to both microeconomic and macroeconomic analysis. However, there are

problems peculiar to economic analysis, where a factor can seldom be controlled; and usually there are too many highly related independent variables. In such cases, if all possible independent variables are taken into the model, the accuracy of the †estimators of the coefficients becomes extremely poor. Such a phenomenon, called **multicollinearity**, brings up the problem of selection of independent variables (\rightarrow 403 Statistical Models), to which no satisfactory solution has been given. Also, assumptions about the error terms may be dubious, the error terms may be correlated, or the variances may be different. If the †variance-covariance matrix of the errors is given, the †generalized least squares method can be applied, but usually such a matrix is not available.

C. Systems of Simultaneous Equations

The second category of problems is peculiar to economic analysis and applies mainly to macroeconomic data. Suppose that $\mathbf{Y} = (Y_1, \dots, Y_G)'$ is a vector consisting of G economic variables, among which there exist G relationships that determine the equilibrium levels of the variables. We also suppose that there exist K variables $\mathbf{Z} = (Z_1, \dots, Z_K)'$ that are independent of the economic relations but affect the equilibrium. The variables \mathbf{Y} are called **endogenous variables**, and the \mathbf{Z} are called **exogenous variables**. If we assume linear relationships among them, we have an expression such as

$$\mathbf{Y} = B\mathbf{Y} + \Gamma\mathbf{Z} + \mathbf{u}, \quad (1)$$

where B and Γ are matrices with constant coefficients and \mathbf{u} is a vector of **disturbances** or errors. (1) is called the **linear structural equation system** and is a system of simultaneous equations. By solving the equations formally, we get the so-called **reduced form**

$$\mathbf{Y} = \Pi\mathbf{Z} + \mathbf{v}, \quad (2)$$

where $\Pi = (I - B)^{-1}\Gamma$, $\mathbf{v} = (I - B)^{-1}\mathbf{u}$. The relation of \mathbf{Y} to \mathbf{Z} is determined through the reduced form (2), and if we have enough data on \mathbf{Y} and \mathbf{Z} we can estimate Π . The problem of **identification** is to decide whether we can determine the unknown parameters in B and Γ uniquely from the parameters in the reduced form. A necessary condition for the parameters in one of the equations in (1) to be identifiable is that the number of unknown parameters (or, since known constants in the system are usually set equal to zero, the number of variables appearing in the equation) not be greater than $K + 1$. If it is exactly equal to $K + 1$, the equation is said to be **just identified**,

and if it is less than $K + 1$, the equation is said to be **overidentified**.

If all the equations in the system are just identified, for arbitrary Π there exist unique B and Γ that satisfy $\Pi = (I - B)^{-1} \Gamma$. Therefore, if we denote the least squares estimator of Π by $\hat{\Pi}$, we can estimate B and Γ from the equation $(I - \hat{B})\hat{\Pi} = \hat{\Gamma}$. This procedure is called the **indirect least squares method** and is equivalent to the maximum likelihood method if we assume normality for u .

When some of the equations are overidentified, the estimation problem becomes complicated. Three kinds of procedures have been proposed: (1) full system methods, (2) single equation methods, and (3) subsystem methods. In full system methods all the parameters are considered simultaneously, and if normality is assumed, the maximum likelihood estimator can be obtained by minimizing $[(Y - \Pi Z)'(Y - \Pi Z)]$. Since it is usually difficult to compute the maximum likelihood estimator, a simpler, but asymptotically equivalent, **three-stage least squares method** has been proposed. The single equation methods and the subsystem methods take into consideration only the information about the parameters in one equation or in a subset of the equations, and estimate the parameters in each equation separately. There is a single equation method, called the **limited information maximum likelihood method**, based on the maximum likelihood approach, and also a **two-stage least squares method**, which estimates Π first by least squares, computes $\hat{Y} = \hat{\Pi}Z$, and then applies the least squares method to the model $Y = B\hat{Y} + \Gamma Z + \tilde{u}$.

These two and also some others are asymptotically equivalent. Among asymptotically equivalent classes of estimators corresponding to different information structures it has been established that the maximum likelihood estimators have asymptotically higher-order efficiency [5] (\rightarrow 399 Statistical Estimation) than other estimators, and Monte Carlo and numerical studies show that they are in most cases better than others if properly adjusted for the biases.

In many simultaneous equation models which have been applied to actual macroeconomic data, the values of endogenous variables obtained in the past appear on the right-hand sides of equations (1). Such variables are called **lagged variables**, and they can be treated, at least in the asymptotic theory of inference, as though they were exogenous. Hence exogenous variables and lagged endogenous variables are jointly called **predetermined variables**. When many lagged variables

appear over many time periods and when some structure among the coefficients of those lagged variables can be assumed, such a model is called a distributed lag model.

Sometimes it is necessary to include some nonlinear equations in the simultaneous equation model. Such nonlinear simultaneous equation models are difficult to deal with, partly because the solution of the equation may not be unique, and in practical applications ad hoc procedures are applied to obtain estimates of the parameters.

D. Multivariate and Time Series Analysis

Problems in the third category can be approached by multivariate analysis techniques. Sometimes principal component analysis and canonical correlation analysis have been applied to analyze the variations of a large amount of data. However, the practical meaning of the results obtained is often dubious.

The fourth category is the problem of time series analysis. Sophisticated theories of stochastic processes have little relevance for economic time series, because usually the time series do not satisfy such conditions as being stationary or having the Markov property, etc. Recently, however, autoregressive moving average (ARMA) and multivariate ARMA models [4] have been applied to macroeconomic data, especially for the purpose of prediction and for determining the direction of causal relations (\rightarrow 421 Time Series Analysis). Traditionally, fluctuations of economic time series have been thought to consist of trend, cyclic variation, seasonal variation, and error. Various ad hoc techniques have been used to separate or eliminate such components, but the theoretical treatment of such problems is far from satisfactory.

129 (XXI.21) Einstein, Albert

Albert Einstein (March 14, 1879–April 18, 1955) was born of Jewish parents in the city of Ulm in southern Germany. He became a Swiss citizen soon after graduating from the Eidgenössische Technische Hochschule of Zürich in 1900. Afterward, he obtained a position as examiner of patents at Bern, and while at that post, he published his theories on light quanta, †special relativity, and †Brownian motion. After briefly holding professorships at the University of Zürich and the University of Prague, he became a professor at the University of Berlin in 1913. His general theory of relativity was announced in 1916, and in 1921 he won the Nobel Prize in physics for his contributions to theoretical physics. To escape Nazi persecution, he fled to the United States in 1933, and until his retirement in 1945 he was a professor at the Institute for Advanced Study at Princeton. He advised President Roosevelt of the feasibility of constructing the atomic bomb, but after World War II, along with others who had been connected with the bomb, he was active in promoting the nuclear disarmament movement and the establishment of a world government.

The theory of relativity raises fundamental epistemological problems concerning time, space, and matter. The results of the general theory were verified in 1919 by observations of the solar eclipse.

Through his latter years, Einstein continued to work on †unified field theory and on the generalization of relativity theory.

130 (XX.16) Electromagnetism

A. Maxwell's Equations

Mathematical formulation of electromagnetics leads to †initial value and †boundary value problems for Maxwell's equations according to the geometric nature of the medium. **Max-**

well's equations for a vacuum are written in the form

$$\begin{aligned}\epsilon_0 \partial \mathbf{E} / \partial t &= \text{rot } \mathbf{H} - \mathbf{J}_e, & \epsilon_0 \text{div } \mathbf{E} &= \rho_e, \\ \mu_0 \partial \mathbf{H} / \partial t &= -\text{rot } \mathbf{E} - \mathbf{J}_m, & \mu_0 \text{div } \mathbf{H} &= \rho_m,\end{aligned}\quad (1)$$

where \mathbf{E} and \mathbf{H} are the **electric** and **magnetic field** vectors, ρ_e and ρ_m the electric and magnetic charge densities, \mathbf{J}_e and \mathbf{J}_m the electric and magnetic current densities, ϵ_0 and μ_0 constants, and the quantity $1/\sqrt{\epsilon_0 \mu_0} = c$ the speed of light in vacuum (2.99797×10^8 m/s). Charge and current densities must satisfy the **equations of continuity**

$$\begin{aligned}\partial \rho_e / \partial t + \text{div } \mathbf{J}_e &= 0, \\ \partial \rho_m / \partial t + \text{div } \mathbf{J}_m &= 0.\end{aligned}\quad (2)$$

Following upon the observation that, apparently, $\rho_m = 0$ and $\mathbf{J}_m = 0$ in nature, we henceforth set them equal to zero. This causes an asymmetry between the electric and magnetic quantities. On the other hand, the proposition " $\rho_m = 0$ and $\mathbf{J}_m = 0$ " cannot be deduced from the classical theory itself.

In the presence of matter, additional charge and current appear due to the **electric** and **magnetic polarization** \mathbf{P} and \mathbf{M} of the material. Therefore, in this case, it is necessary to make the following substitutions in (1):

$$\begin{aligned}\rho_e &\rightarrow \rho = \rho_e - \text{div } \mathbf{P}, \\ \mathbf{J}_e &\rightarrow \mathbf{J} = \mathbf{J}_e + \partial \mathbf{P} / \partial t + \text{rot } \mathbf{M}, \\ \mathbf{H} &\rightarrow \mathbf{H} + \mathbf{M}.\end{aligned}\quad (3)$$

Moreover, if we define the **electric flux density** (or **electric displacement**) \mathbf{D} and the **magnetic flux density** (or **magnetic induction**) \mathbf{B} by

$$\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P}, \quad \mathbf{B} = \mu_0 (\mathbf{H} + \mathbf{M}), \quad (4)$$

then Maxwell's equations (1) are transformed into

$$\begin{aligned}\partial \mathbf{D} / \partial t &= \text{rot } \mathbf{H} - \mathbf{J}_e, & \text{div } \mathbf{D} &= \rho_e, \\ \partial \mathbf{B} / \partial t &= -\text{rot } \mathbf{E}, & \text{div } \mathbf{B} &= 0.\end{aligned}\quad (5)$$

In the electromagnetic field in a vacuum there is energy with a density

$$u = (\epsilon_0/2) \mathbf{E}^2 + (\mu_0/2) \mathbf{B}^2, \quad (6)$$

and energy flux with a density expressed by the **Poynting vector**

$$\mathbf{S} = \mathbf{E} \times \mathbf{H}. \quad (7)$$

Between these quantities the following relation holds:

$$\partial u / \partial t + \text{div } \mathbf{S} = 0. \quad (8)$$

An electric charge q moving with velocity \mathbf{v} in an electromagnetic field is subject to the **Lorentz force**

$$\mathbf{F} = q\mathbf{E} + q\mathbf{v} \times \mathbf{B}. \quad (9)$$

This force can be interpreted as being caused by the **Maxwell stress tensor**

$$T_{ik} = (\epsilon_0/2)(-E_i E_k + 2\delta_{ik} E^2) + (\mu_0/2)(-H_i H_k + 2\delta_{ik} H^2). \quad (10)$$

By introducing the **scalar potential** V and the **vector potential** \mathbf{A} , we can express the field vectors as

$$\mathbf{B} = \text{rot } \mathbf{A}, \quad \mathbf{E} = -\text{grad } V - \partial \mathbf{A} / \partial t. \quad (11)$$

Furthermore, if we impose an auxiliary condition (**Lorentz condition**)

$$\text{div } \mathbf{A} + \epsilon_0 \mu_0 \partial V / \partial t = 0, \quad (12)$$

then we obtain from (1) the wave equations

$$\square V = -\rho_e / \epsilon_0, \quad \square \mathbf{A} = -\mu_0 \mathbf{J}_e, \quad (13)$$

where $\square \equiv \Delta - \epsilon_0 \mu_0 \partial^2 / \partial t^2$ is called the **d'Alembertian** and is sometimes written as \diamond^2 . From (13) we conclude that the electromagnetic field can propagate in a vacuum as a wave with speed $c = 1/\sqrt{\epsilon_0 \mu_0}$. In \dagger quantum theory the potentials V and \mathbf{A} are regarded as being more fundamental than \mathbf{E} and \mathbf{H} themselves. However, they are not uniquely determined, in the sense that the **gauge transformation**

$$V \rightarrow V + \partial \psi / \partial t, \quad \mathbf{A} \rightarrow \mathbf{A} - \text{grad } \psi \quad (14)$$

with an arbitrary function ψ of the space and time variables does not affect the fields.

Maxwell's equations are invariant under the \dagger Lorentz transformation. Therefore they can be written in 4-dimensional tensor form (\rightarrow 359 Relativity C).

Maxwell's equations can be regarded as the \dagger wave equations for \dagger bosons with spin 1 (\dagger photons). The equations of quantum electrodynamics are obtained if we regard the field quantities as quantum-mechanical variables (q -numbers) and then perform \dagger second quantization.

B. Concrete Problems

In solving Maxwell's equations concretely, we usually make additional assumptions for polarizations, electric current, and field vectors

$$\mathbf{P} = \chi_e \mathbf{E}, \quad \mathbf{M} = \chi_m \mathbf{H}, \quad \mathbf{J}_c = \sigma \mathbf{E}, \quad (15)$$

where χ_e , χ_m , and σ are called the **electric susceptibility**, **magnetic susceptibility**, and **conductivity**, respectively. Then we have

$$\mathbf{D} = \epsilon \mathbf{E}, \quad \mathbf{B} = \mu \mathbf{H}, \quad (16)$$

where $\epsilon = \epsilon_0 + \chi_e$ is the **dielectric constant** and $\mu = \mu_0(1 + \chi_m)$ is the **magnetic permeability**. Therefore the equations (5) become identical to (1) if ϵ_0 and μ_0 are replaced by ϵ and μ , respectively. (ρ_m and \mathbf{J}_m are set equal to zero.)

Some cases of practical importance are given below.

(1) **Electrostatics**. If the fields are time-independent and there is no electric current, then \mathbf{E} and \mathbf{H} are mutually independent. The static electric field is calculated from the solution of the boundary value problem of the \dagger Poisson equation $\Delta V = -\rho_e/\epsilon$. Specifically, V takes a constant value in each conductor.

(2) **Magnetostatics**. For zero electric current, the problem of magnetostatics is solved in the same way as in electrostatics. For the case of nonvanishing stationary electric current, the problem is reduced to that of solving

$$\Delta \mathbf{A} = -\mu \mathbf{J}_e, \quad \text{div } \mathbf{A} = 0. \quad (17)$$

(3) **Electric current in a conductor**. A stationary electric current in a conductor is governed by the equation of continuity $\text{div } \mathbf{J} = 0$, **Ohm's law** $\mathbf{J} = \sigma \mathbf{E}$, and a special case of Maxwell's equation $\text{rot } \mathbf{E} = 0$. The electric current produces heat (**Joule heat**) proportional to $\mathbf{J} \cdot \mathbf{E}$ per unit volume per unit time (**Joule's law**). For certain substances, the **specific resistance** σ^{-1} suddenly becomes negligibly small below a critical temperature. This is called **superconductivity**.

(4) **Quasistationary electric circuit**. The problem appearing most often in electrical engineering is that of a quasistationary circuit. Its characteristic feature is that the electric currents exist only in the circuit elements (inductors, capacitors, and resistors) and in the lines connecting them. The current (both \mathbf{J}_e and $\partial \mathbf{D} / \partial t$) can be neglected in all other parts of the system. (This could be compared to the situation in dynamics where we consider systems of material points or of rigid bodies having a finite number of degrees of freedom, although every material body is essentially a continuum.) The system network is constructed as a \dagger linear graph with the circuit elements as its branches. Topological \dagger network theory deals with the relation between the structure of the linear graph and the electrical characteristics of the network, whereas function-theoretic network theory deals with the relation between current and voltage at each part of the network. In the latter theory, current and voltage are considered as functions of the frequency of the sinusoidal alternating voltage applied to some point of the network. Together these constitute a unique theoretical system in engineering mathematics for designing system networks (\rightarrow 282 Networks).

(5) **Theory of electromagnetic waves**. The theory of electromagnetic waves deals with the case where the changes of all field quantities are proportional to $e^{i\omega t}$, and in addition the frequency ω is so large that the term $\partial \mathbf{D} / \partial t$ in

(5) is of the same order as or larger than \mathbf{J}_e . In such a situation the electromagnetic field behaves like a wave.

Problems of various types arise depending on the geometry of the conducting and dielectric substances, on the type of the energy source, etc. Important problems are: (i) radiation of a wave from a point source into free space; (ii) scattering of a plane wave by small bodies or cylinders; (iii) diffraction of a wave through holes in a conducting plate; (iv) reflection and refraction of a wave at the boundary between different media; (v) wave propagation along a conducting tube (wave guide); and (vi) resonance of the electromagnetic field in a cavity surrounded by a conducting substance. Theoretical treatment similar to that for ordinary networks is possible for microwave circuits consisting of wave guides, cavities, etc.

(6) **Wave guides.** For electromagnetic waves with a harmonic time dependence $e^{-i\omega t}$ propagating inside a hollow tube of uniform cross section extending in the z -direction with perfectly conducting walls (called a **wave guide**), the Maxwell equations become

$$\begin{aligned}\operatorname{rot} \mathbf{E} &= i\omega \mathbf{B}, & \operatorname{div} \mathbf{B} &= 0, \\ \operatorname{rot} \mathbf{B} &= -i\mu\epsilon\omega \mathbf{E}, & \operatorname{div} \mathbf{E} &= 0,\end{aligned}\quad (18)$$

with the boundary condition

$$\mathbf{n} \times \mathbf{E} = 0, \quad \mathbf{n} \cdot \mathbf{B} = 0,$$

where \mathbf{n} is a unit normal at the boundary surface. A further reduction is gained by Fourier analysis in the z -variable. For harmonic z -dependence e^{ikz} , the transverse components $\mathbf{E}_t = (\mathbf{e}_z \times \mathbf{E}) \times \mathbf{e}_z$ and $\mathbf{B}_t = (\mathbf{e}_z \times \mathbf{B}) \times \mathbf{e}_z$ are determined from the z -components $E_z = \mathbf{e}_z \cdot \mathbf{E}$ and $H_z = \mathbf{e}_z \cdot \mathbf{H}$ by the following part of the Maxwell equations:

$$\begin{aligned}ikE_t + i\omega\mathbf{e}_z \times \mathbf{B}_t &= \operatorname{grad}_t E_z, \\ ik\mathbf{B}_t - i\mu\epsilon\omega\mathbf{e}_z \times \mathbf{E}_t &= \operatorname{grad}_t B_z\end{aligned}\quad (19)$$

(where grad_t is the transverse components of the gradient), up to the solutions for $E_z = B_z = 0$, called **transverse electromagnetic (TEM) waves**, for which $k = \omega\sqrt{\mu\epsilon}$, $\mathbf{B}_t = \pm\sqrt{\mu\epsilon}\mathbf{e}_z \times \mathbf{E}_t$, and \mathbf{E}_t is a solution of the electrostatic problem in two dimensions $\operatorname{rot} \mathbf{E}_t = 0$, $\operatorname{div} \mathbf{E}_t = 0$. To have $\mathbf{E}_t \neq 0$ for the TEM solution, it is necessary to have two or more surfaces, such as a coaxial cable (region between two concentric cylinders) or a parallel-wire transmission line. Nonzero longitudinal components E_z and B_z are determined from the 2-dimensional equations

$$\left[\left(\frac{\partial}{\partial x} \right)^2 + \left(\frac{\partial}{\partial y} \right)^2 + (\mu\epsilon\omega^2 - k^2) \right] \begin{Bmatrix} E_z \\ B_z \end{Bmatrix} = 0 \quad (20)$$

with boundary conditions $E_z = 0$ and $\partial B_z / \partial n = 0$ on the wall, where $(\partial / \partial n)$ denotes the partial derivative in the normal direction. The solutions with $B_z = 0$ are called **transverse magnetic (TM) waves** (or **electric (E) waves**) and those with $E_z = 0$ **transverse electric (TE) waves** (or **magnetic (M) waves**); for each of these cases the equations determine an eigen-wave number k for a given angular frequency ω (typically in a waveguide situation) or eigenfrequency $\nu = \omega / (2\pi)$ for a given wavelength $\lambda = 2\pi / k$ (typically in a resonant cavity situation).

131 (X.8) Elementary Functions

A. Definition

A function of a finite number of real or complex variables that is algebraic, exponential, logarithmic, trigonometric, or inverse trigonometric, or the composite of a finite number of these, is called an **elementary function**. Elementary functions comprise the most common type of function in elementary calculus.

J. Liouville [1] defined the elementary functions as follows: An algebraic function of a finite number of complex variables is called an elementary function of class 0. Then e^z and $\log z$ are called elementary functions of class 1. Inductively, we define elementary functions of class n under the assumption that elementary functions of class at most $n - 1$ have already

been defined. Let $g(t)$ and $g_j(w_1, \dots, w_n)$ ($1 \leq j \leq m$) be elementary functions of class at most 1 and $f(z_1, \dots, z_m)$ be an elementary function of class at most $n-1$. Then the composite functions $g(f(z_1, \dots, z_m))$ and $f(g_1(w_1, \dots, w_n), \dots, g_m(w_1, \dots, w_n))$ (and only such functions) are called the elementary functions of class at most n . An elementary function of class at most n and not of class at most $n-1$ is called an **elementary function of class n** . A function that is an elementary function of class n for some integer n is called an **elementary function**. In this article, we explain the properties of the most common elementary functions.

B. Exponential and Logarithmic Functions of a Real Variable

Let $a > 0, a \neq 1$. A function $f(x)$ of a real variable satisfying the functional relation

$$f(x+y) = f(x)f(y), \quad f(1) = a, \tag{1}$$

satisfies $f(n) = a^n$ for positive integers n and $f(-n) = 1/a^n$ for negative integers $-n$. In general, $f(n/m) = \sqrt[m]{a^n}$ for every rational number $r = n/m$. If we assume that $f(x)$ is continuous, then there is a unique strictly monotone function $f(x)$ defined in $(-\infty, \infty)$ whose range is $(0, \infty)$. The function $f(x)$ is called the **exponential function with the base a** and is denoted by a^x , read “ a to the power x ” and also called a **power of a with exponent x** . Its inverse function is called the **logarithmic function to the base a** , and is denoted by $\log_a x$. The specific value $\log_a x$ is called the **logarithm of x to the base a** . If $g(x) = \log_a x$, we have

$$g(xy) = g(x) + g(y), \quad g(a) = 1. \tag{2}$$

Hence we have $xy = f(g(x) + g(y))$. Therefore we can reduce multiplication to addition by using a numerical table for the logarithmic function.

C. Logarithmic Computation

The logarithm to the base 10 is called the **common logarithm**. If two numbers x, y expressed in the decimal system differ only in the position of the decimal point (i.e., $y = x \cdot 10^n$ for an integer n), they share the same fractional parts in their common logarithms. The integral part of the common logarithm is called the **characteristic**, and the fractional part is called the **mantissa**. (We note that the word “mantissa” is also frequently used for the fractional part a in the floating point representation $x = a \cdot 10^n, 10^{-1} \leq a < 1$, or $1 \leq a < 10$.) The

common logarithms of integers have been computed and published in tables.

D. Derivatives of Exponential and Logarithmic Functions

The function $f(x) = a^x$ is differentiable, and $f'(x) = k_a f(x)$, where k_a is a constant determined by the base a . If we take the base a to be

$$e = \lim_{v \rightarrow \infty} \left(1 + \frac{1}{v}\right)^v = \sum_{v=0}^{\infty} \frac{1}{v!} = 2.71828 \dots,$$

then we have $k_e = 1$. The number $\sum(1/v!)$ is usually called **Napier’s number** and is denoted by e after L. Euler (his letter to C. Goldbach of 1731; → Appendix B, Table 6). In 1873, C. Hermite proved that e is a transcendental number. We sometimes denote e^x by **exp x** ; the term **exponential function** usually means the function $\exp x$. The function e^x is invariant under differentiation, and conversely, a function invariant under differentiation necessarily has the form Ce^x . The logarithm to the base e is called the **Napierian logarithm (or natural logarithm)**, and we usually denote it by **log x** without explicitly naming the base e (sometimes it is denoted by $\ln x$). The derivative of $\log x$ is $1/x$, hence we have the integral representation

$$\log x = \int_1^x \frac{dx}{x}. \tag{3}$$

The constant factor k_a in the derivative of a^x is equal to $\log a$. The graphs of $y = e^x$ and $y = \log x$ are shown in Fig. 1. The functions e^x and $\log(1+x)$ are expanded in the following Taylor series at $x=0$:

$$e^x = \sum_{v=0}^{\infty} \frac{x^v}{v!}, \tag{4}$$

$$\log(1+x) = \sum_{v=1}^{\infty} (-1)^{v+1} \frac{x^v}{v}. \tag{5}$$

The power series in the right-hand sides of (4) and (5) are called the **exponential series** and the **logarithmic series**, respectively. The radii of convergence of (4) and (5) are ∞ and 1, respectively.

Fig. 1

E. Trigonometric and Inverse Trigonometric Functions of a Real Variable

The trigonometric functions of a real variable x are the functions $\sin x$, $\cos x$ (\rightarrow 432 Trigonometry) and the functions $\tan x = \sin x / \cos x$, $\cot x = \cos x / \sin x$, $\sec x = 1 / \cos x$, and $\operatorname{cosec} x = 1 / \sin x$ derived from $\sin x$ and $\cos x$. The derivatives of $\sin x$ and $\cos x$ are $\cos x$ and $-\sin x$, respectively. They have the following Taylor expansions at $x=0$:

$$\sin x = \sum_{v=0}^{\infty} \frac{(-1)^v}{(2v+1)!} x^{2v+1}, \quad (6)$$

$$\cos x = \sum_{v=0}^{\infty} \frac{(-1)^v}{(2v)!} x^{2v}. \quad (7)$$

The radii of convergence of (6) and (7) are both ∞ .

The inverse functions of $\sin x$, $\cos x$, and $\tan x$ are the **inverse trigonometric functions** and are denoted by $\arcsin x$, $\arccos x$, and $\arctan x$, respectively. (Instead of this notation, $\sin^{-1} x$, $\cos^{-1} x$, and $\tan^{-1} x$ are also used). These functions are infinitely multiple-valued, as shown in Fig. 2. But if we restrict their ranges within the part shown by solid lines in Fig. 2, they are considered single-valued functions. To be more precise, we restrict the range as follows: $-\pi/2 \leq \arcsin x \leq \pi/2$, $0 \leq \arccos x \leq \pi$, $-\pi/2 < \arctan x < \pi/2$.

Fig. 2

The functions having these ranges are called the **principal values** and are sometimes denoted by $\operatorname{Arcsin} x$, $\operatorname{Arccos} x$, and $\operatorname{Arctan} x$, respectively. The derivatives of these functions are $(1-x^2)^{-1/2}$, $-(1-x^2)^{-1/2}$, $(1+x^2)^{-1}$, respectively (\rightarrow Appendix A, Table 9.I; for the Taylor or Laurent expansions of $\tan x$, $\cot x$, $\sec x$, $\operatorname{cosec} x$, $\arcsin x$, $\arccos x$, $\arctan x$, etc., \rightarrow Appendix A, Table 10.IV).

F. Hyperbolic Functions

Let P be a point on the branch of the hyperbola $x^2 - y^2 = 1$, $x > 0$, and let O be the origin and A the vertex $(1, 0)$ of the hyperbola. Denote by $\theta/2$ the area of the domain surrounded by the line segments OA , OP , and the arc \widehat{AP}

of the hyperbola. Then we define the coordinates of P to be $(\cosh \theta, \sinh \theta)$ as functions of θ . We have

$$\begin{aligned} \cosh x &= (e^x + e^{-x})/2, \\ \sinh x &= (e^x - e^{-x})/2, \end{aligned} \quad (8)$$

called the **hyperbolic cosine** and **hyperbolic sine**, respectively. As in the case of trigonometric functions, we define the **hyperbolic tangent** by $\tanh x = \sinh x / \cosh x$, the **hyperbolic cotangent** by $\coth x = \cosh x / \sinh x$, the **hyperbolic secant** by $\operatorname{sech} x = 1 / \cosh x$, and the **hyperbolic cosecant** by $\operatorname{cosech} x = 1 / \sinh x$. They are called the **hyperbolic functions**. The graphs of $\sinh x$ and $\cosh x$ are shown in Fig. 3. The trigonometric functions are sometimes called **circular functions**.

Fig. 3

We now introduce the **Gudermannian** (or **Gudermann function**):

$$\theta = \operatorname{gd} u = 2 \arctan e^u - \pi/2,$$

$$u = \operatorname{gd}^{-1} \theta = \log |\tan \theta + \sec \theta| = \frac{1}{2} \log \frac{1 + \sin \theta}{1 - \sin \theta}.$$

Then the hyperbolic functions can be expressed in terms of the trigonometric functions. For example,

$$\sinh u = \tan \theta, \quad \cosh u = \sec \theta, \quad \tanh u = \sin \theta.$$

G. Elementary Functions of a Complex Variable (\rightarrow Appendix A, Table 10)

(1) **Exponential function.** The power series (4) converges for all finite values if we replace x by the complex variable z and gives an entire function of z with an essential singularity at the point at infinity. This is the exponential function e^z of a complex variable z . It satisfies the **addition formula** (1), $e^{z_1+z_2} = e^{z_1} e^{z_2}$, and it is also the analytic continuation of the exponential function of a real variable. For a purely imaginary number $z = iy$, we have the **Euler formula**

$$e^{iy} = \cos y + i \sin y. \quad (9)$$

The function $w = e^z$ gives a conformal mapping from the z -plane to the w -plane, as shown in Fig. 4, which maps the imaginary axis of

the z -plane onto the unit circle of the w -plane ($w = u + iv$). For $z = x + iy$ (x, y are real numbers), we have $e^z = e^x e^{iy}$; hence e^z is a simply periodic function with fundamental period $2\pi i$.

Fig. 4

(2) **Logarithmic function.** The logarithmic function $\log z$ of a complex variable z is the inverse function of e^z . It is an infinitely multiple-valued analytic function that has logarithmic singularities at $z = 0$ and $z = \infty$. All possible values are expressed by $\log z + 2n\pi i$ (n is an arbitrary integer), where we select a suitable value $\log z$. The **principal value** of $\log z$ is usually taken as $\log r + i\theta$, where $z = re^{i\theta}$ ($r = |z|$, θ is the argument of z) and $0 \leq \theta < 2\pi$. (Sometimes the range of the argument is taken as $-\pi < \theta \leq \pi$.) The principal value of $\log z$ is sometimes denoted by **Log** z . The power series (5) gives one of its functional elements. The integral representation (3) holds for a complex variable z . The multivalency of $\log z$ results from the selection of a contour of integration; the integral of $1/z$ around the origin is $2\pi i$, which is the increment of $\log z$.

(3) **Power.** The exponential function a^z for an arbitrary complex number a is defined to be $\exp(z \log a)$. Similarly, z^a is defined to be $\exp(a \log z)$. The function z^a is an algebraic function if and only if a is rational. In other cases, the function z^a is an elementary function of class 2.

(4) **Trigonometric functions, inverse trigonometric functions, hyperbolic functions.** The trigonometric, inverse trigonometric, and hyperbolic functions of a complex variable are defined by the analytic continuations of the corresponding functions of a real variable. For example, $\sin z$ and $\cos z$ are defined by the power series (6) and (7), respectively. They are entire functions whose zero points are $n\pi$ and $(n - \frac{1}{2})\pi$ (n is an integer), respectively. They are also represented by Weierstrass's infinite product (\rightarrow Appendix A, Table 10.VI).

The functions $\tan z$, $\cot z$, $\sec z$, and $\operatorname{cosec} z$ are meromorphic functions of z on the complex z -plane, and they are expressed by Mittag-Leffler partial fractions (\rightarrow Appendix A, Tables 10.IV, 10.V). As can be shown from

(8) and (9), we have

$$\begin{aligned} \cos z &= (e^{iz} + e^{-iz})/2, & \sin z &= (e^{iz} - e^{-iz})/2i, \\ \cosh z &= \cos iz, & \sinh z &= (\sin iz)/i. \end{aligned} \quad (10)$$

Each of these formulas (10) is called an **Euler formula**. For a complex variable, the trigonometric and hyperbolic functions are composites of exponential functions, the inverse trigonometric functions are composites of logarithmic functions, and all of them are elementary functions of class 1. The definition of elementary functions by Liouville described in Section A refers, of course, to the functions of a complex variable. We remark that the inverse function of an elementary function is not necessarily an elementary function. For example, the inverse function of $y = x - a \sin x$ is not an elementary function (\rightarrow 309 Orbit Determination B).

The derivative of an elementary function is also an elementary function. However, the primitive function of an elementary function is not necessarily an elementary function. The primitive function of a rational function or an algebraic function of genus 0 is again an elementary function. Similar properties hold for rational functions of trigonometric functions. Liouville [1] carried through a deep investigation of the situation where the integral of an elementary function is also an elementary function.

132 (XX.31) Elementary Particles

A. Introduction

The word “atom” is derived from the Greek word for indivisible. It turns out that an atom

is divisible into its constituent nucleus and electrons. The nucleus, in turn, consists of protons and neutrons (together called nucleons). Photons (quanta of electromagnetic waves), electrons, protons, and neutrons (denoted by γ , e , p , and n , respectively), along with many other subsequently discovered sub-nuclear particles, are called **elementary particles**, while nuclei, atoms, and molecules are the **composite particles** composed of these elementary particles.

States of a particle form an irreducible (unitary) representation of the proper inhomogeneous Lorentz group with positive energy (or a finite direct sum of such representations). Thus a **mass** ($m \geq 0$) and a **spin** ($j = 0, \frac{1}{2}, 1, \dots$) are assigned to each particle (\rightarrow 258 Lorentz Group). For example, e , p , and n have spin $\frac{1}{2}$ and nonzero masses, while γ has spin 1 and zero mass.

Many elementary particles are unstable, decaying into other particles. The average **lifetime** is denoted by τ and its inverse is called the **half-width**. The time in which half of many samples of the same particle decays is called the **half-life**, given by $\tau \log 2$. For example, electrons, protons, and photons are supposed to be stable (or at least to have very long lifetimes), while a neutron decays into a proton, an electron, and a neutrino ν (β -decay) with a lifetime of about 15 minutes.

From the study of the relativistic equations (Dirac equations) for wave functions of an electron, P. A. M. Dirac predicted the existence of particles with the same mass as the electron, but of opposite electric charge (Dirac's hole theory, 1930). These were discovered in 1932 and called positrons. Every elementary particle is now believed to be associated with an **anti-particle** characterized by the opposite sign of the particle's additive quantum numbers, the two being connected by the \dagger PCT theorem. Hence the positron is the antiparticle of the electron. The antiproton, theoretically expected for a long time and experimentally found in 1955, is the antiparticle of the proton. Antiprotons, antineutrons, and positrons are constituents of antimatter. The particles whose additive quantum numbers are all invariant under change of sign, such as photons (γ), neutral pions (π^0), etc., seem to be antiparticles of themselves and are said to be self-conjugate.

Elementary particles have four distinct types of interaction: gravitational, weak, electromagnetic, and strong, in increasing order of interaction strength. Gravitational and electromagnetic interactions were recognized in earlier centuries because these interactions are of long range. A. Einstein put forward the idea of a light quantum or photon as a lump of electromagnetic energy behaving like a par-

ticle. Whether a corresponding quantum (graviton) exists for gravitational interactions is a question related to the existence of gravitational waves themselves, and is not yet settled.

The nuclear force is an example of a strong interaction and is studied to elucidate nuclear structure and to derive the cross sections of various collision processes involving nuclei. H. Yukawa predicted in 1935 the existence of a particle associated with the nuclear force, just as photons are associated with the electromagnetic interaction. Its mass was predicted, from the range of the nuclear force, to be about 200 times the electron mass, which is intermediate between the masses of electrons and nucleons, and hence the particle was named a mesotron or a meson. These were found in cosmic rays in 1947 and, in fact, it was found that the mesons relevant to the nuclear force (now called pions and denoted by π^+ , π^- , π^0 according to their electric charge) decay into other kinds of particles called muons (denoted by μ^+ , μ^-) with a charged-pion lifetime of 2.6×10^{-8} sec ($\pi^\pm \rightarrow \mu^\pm + \nu(\bar{\nu})$; the neutral pion π^0 decays, over a shorter lifetime, into photons). The muons then decay into electrons and neutrinos ($\mu^\pm \rightarrow e^\pm + \nu + \bar{\nu}$, $\bar{\nu}$ indicating antineutrinos) with muon lifetimes of about 2.2×10^{-6} sec. Weak interactions are relevant to these decays as well as to the β -decay of the nucleus and the neutron. Since 1962 electron neutrinos ν_e and muon neutrinos ν_μ have been distinguished in these decays, so that electron and muon numbers may be conserved.

Since 1949, many new particles (unstable under weak interactions) have been gradually found in cosmic rays; these are called strange particles. Some of the early ones are hyperons (Λ , Σ , Ξ), of spin $\frac{1}{2}$, and kaons (K , \bar{K}), of spin 0. For such strange particles, the strangeness quantum number, which is preserved in the strong interaction, has been introduced, and the **Nakano–Nishijima–Gell-Mann formula** concerning this number is known to hold. This says that $Q = I_3 + \frac{1}{2}(B + S)$ for each elementary particle, where Q is the electric charge in units of that of the positron, I_3 is the third component of the isospin, B is the baryon number, and S is the strangeness.

Quantum-mechanical wave functions for a system of identical particles seem to be either totally symmetric (Bose statistics) or totally antisymmetric (Fermi statistics) under permutations of particles. Accordingly, particles are either **bosons** (or Bose particles) or **fermions** (or Fermi particles). All bosons seems to have integer spins and all fermions half-odd-integer spins. This is the **connection of spin and statistics** and follows from certain axioms in quantum field theory (\rightarrow 150 Field Theory). There

has been some discussion on intermediate statistics (parabosons and parafermions).

B. Families of Elementary Particles

Elementary particles are classified into families of leptons, photons, and hadrons.

The family of leptons now consists of electrons (e), muons (μ), and tau-leptons (τ), their accompanying neutrinos (ν_e, ν_μ, ν_τ), and their antiparticles; τ was discovered in the late 1970s. Experimentally, ν_τ is not well established nor has the possibility $\nu_\tau = \nu_e$ yet been excluded. Leptons have spin $\frac{1}{2}$. They are characterized by having no strong interactions.

The family of photons consists of photons and the recently discovered intermediary weak vector bosons. Gluons (\rightarrow Section C (4)), if they exist, also belong to this family.

The family of hadrons has a large number of members which are either **mesons** or **baryons**, the former being bosons and the latter fermions. We now have, in addition to pions and kaons, many resonant mesons (unstable under strong interaction) such as ρ -mesons and ω -mesons. At present we have, in all, more than 20 species of mesons. This number does not count spin, charge, and antiparticle degrees of freedom. The baryon subfamily includes nucleons, hyperons, and excited states, now consisting of more than 30 species, again not counting spin, charge, and antiparticle degrees of freedom. We have nucleonic resonances with spin as high as $11/2$.

Hadrons are now well understood as composites of subhadronic constituents called quarks (and antiquarks), although free quarks have not been observed. (Hence the problem of quark confinement has been discussed extensively.) Mesons are systems made up of a quark and an antiquark. Baryons are systems made up of three quarks. Therefore, at our present level of knowledge, the elementary particles might be leptons, photons, and quarks (and the corresponding antiparticles).

C. Methods in the Theory of Elementary Particles

(1) **†Quantum Field Theory.** Application of the ideas of quantum mechanics to electromagnetic fields and their interaction with electrons resulted in the formulation of **quantum electrodynamics** (and more generally quantum field theory). Application of quantum-mechanical perturbation theory to quantum electrodynamics with the fine-structure constant $\alpha = e^2/(\hbar c)$ (about $1/137$) as an expansion parameter resulted in divergent expressions—

the so-called divergence difficulties. The **ultra-violet divergence** comes from integration over high momenta (of virtual particles), and the **infrared divergence** is due to the zero mass of photons. It was later found that the ultraviolet divergence can be combined with a small number of parameters of the theory (i.e., electron mass, (possibly nonzero) photon mass, and electromagnetic coupling constant e) into a revised set of constants (called the renormalized masses and coupling constant), which are then equated to the observed finite values of these constants—a procedure called renormalization. Physically, this renormalization is pictured to be effected by virtual photons (and electron-positron pairs) surrounding (bare) electrons and photons. The infrared divergence is supposed to be a reflection of the fact that electrons can be accompanied by infinitely many photons with negligibly small total energy (a situation made possible by the zero mass of photons); this cannot be experimentally analyzed (and is indistinguishable from a single electron).

The relativistically covariant formulation of the renormalized perturbation theory of quantum electrodynamics proposed by S. Tomonaga, J. S. Schwinger, and R. P. Feynman (independently and in different forms), and in particular the Feynman rules and Feynman diagrams that lead to the Feynman integrals (\rightarrow 146 Feynman Integrals), made possible detailed theoretical computations, and the computed values (such as the Lamb shift of hydrogen and the anomalous magnetic moment of an electron) fit marvelously well with observed values—an achievement considered a great success of quantum electrodynamics. F. J. Dyson more or less showed that the renormalization procedure really absorbs all the divergences in all orders of the perturbation expansion in terms of renormalized constants, though there were later refinements and elaborations of the proof. This work also leads to the division of quantum field theories into two classes: **renormalizable** theories, where (infinitely many) ultraviolet divergences can be absorbed into a finite number of constants by renormalized perturbation theory, and **unrenormalizable** theories. The question of whether perturbation series converge in some sense is an unsolved question of quantum electrodynamics.

In quantum field theory, the central role is played by quantum fields, which are operator-valued generalized functions of a space-time point. Particle interpretations of any state at infinite past and infinite future are obtained in the theory from the asymptotic behavior of the fields (\dagger asymptotic fields) at time $-\infty$ and time $+\infty$, and from their relation, expressed by the

\dagger S-matrix, describing how particles scatter by collision. Thus any model of quantum fields makes, in principle, a prediction about what particles appear and how they behave (asymptotically) in mutual collisions.

After the success of quantum electrodynamics, the perturbation theory of quantum fields was applied to systems of pions and nucleons; this proved to be unsuccessful, possibly due to the lack of an appropriate expansion parameter. This has led some people to study the mathematically rigorous consequences of quantum field theories; these mathematical consequences do not require any perturbation calculation, simply following from a small number of mathematically formulated axioms believed to be satisfied by a large class of quantum field theories. This approach, referred to as \dagger axiomatic quantum field theory, has yielded a few physically meaningful consequences of general nature: analyticity of some S -matrix elements, the \dagger PCT theorem, and the connection of spin and statistics (\rightarrow Section A).

While the axiomatic approach provides a general framework, the \dagger constructive field theory developed later provides examples of quantum field theories that fit into such a framework. Because of its concrete nature, it can make statements about detailed properties of the model, such as the (non-)existence of composite particles, the establishment of perturbation theory as an asymptotic expansion, and phase-transitions phenomena and the related broken symmetry as the coupling constant varies. It has, however, been successful for only 2 and 3 space-time dimensions.

(2) Analytic S -Matrix Approach. Due to the failure of the perturbation approach in quantum field theory, a new approach was developed based on assumptions about the analyticity properties of the S -matrix elements. The assumed analyticity properties were surmised from examination of Feynman integrals and of nonrelativistic potential scattering, and partially follow from axiomatic field theory. In this approach, the information that scattering amplitudes, or S -matrix elements, possess certain analytic properties with respect to energies, scattering angles, and so on is expressed by means of integral representations. For example, the forward two-body scattering amplitude $f(s)$ as a function of $s=(\text{energy in the center of mass system})^2$ is written as

$$f(s) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{\text{Im } f(s')}{s' - s} ds'. \quad (1)$$

$\text{Im } f(s)$ is related to the total cross section by the optical theorem, which is a statement of

the unitarity of the S -matrix. Hence equation (1), called a **dispersion relation**, gives a relation among observable quantities. An integral representation for the general two-body scattering amplitude $f(s, t, u)$ (2 incoming and 2 outgoing particles) has been proposed by S. Mandelstam and is called the **Mandelstam representation**, where $s=(p_1 + p_2)^2$, $t=(p_1 + p_3)^2$, and $u=(p_1 + p_4)^2$ (squares in a Minkowski metric) and p_1, p_2, p_3, p_4 are the 4-momenta of the incoming and outgoing particles, with sign reversed for the latter. (Some relations hold among variables: $p_i^2 = m_i^2$ with m_i the mass, $\sum p_i = 0$, $s + t + u = \sum m_i^2$.) Under the interchange of incoming and outgoing particles, the corresponding f 's are related by analytic continuation. This is called the **crossing symmetry**. The study of the S -matrix directly from its analyticity and unitarity is called the **S -matrix approach** (\rightarrow 386 S -Matrices).

The analyticity of the two-body scattering amplitude f as a function of the angular momentum l with a fixed s was investigated by T. Regge for nonrelativistic potential scattering, and later the idea was applied to the S -matrix approach. The poles $l=l(s)$ of f (f is considered to be a function of l for each fixed s) are called **Regge poles**. Regge trajectories $l=l(s)$ for variable $s \leq 0$ have been shown to play important roles in the high-energy behavior of scattering amplitudes for small values of the variable t (four-momentum-transfer squared).

An approximate expression of S -matrix elements, with Regge poles and satisfying the crossing symmetry, was introduced by G. Veneziano and is called the **Veneziano model**. It has developed into the so-called **dual resonance model** (dual in the sense that s -channel poles are dual to t -channel poles) and has subsequently evolved into the **string model** of hadrons, according to which hadrons are viewed as systems composed of strings joining quarks (and antiquarks).

(3) Group-Theoretical Approach. In connection with the symmetry properties shown by the spectra and reaction patterns of hadrons, a group-theoretical approach has been developed. For example, the similarity of the behavior of neutrons and protons in nuclei, apart from the difference in their electromagnetic properties, was formulated as isospin invariance (under the group $SU(2)$). The symmetry properties are sometimes understood in terms of new additive quantum numbers that are conserved or nearly conserved, and these properties are made more concrete in the final stage by the introduction of fundamental constituents carrying these quantum numbers.

Based on the canonical formalism of quantum field theory, (Noether) currents, as

quantum-mechanical generators of the symmetry, are introduced in association with conserved quantum numbers. The commutation relation of these currents, referred to as a **current algebra**, shows the structure of a Lie algebra expressing the symmetry of the Lagrangian of the system of hadrons; for example, $SU(3) \times SU(3)$ for three species (flavors) of massless quarks (the first factor for vector currents and the second for axial-vector currents). The approach showed remarkable success when combined with the hypothesis of the **partially conserved axial-vector currents** (PCAC), which requires the divergence of the axial-vector currents to be proportional to the pseudoscalar meson fields.

Even if a theory has a symmetry under a group G in its formulation, a vacuum state of the theory might not have a symmetry under G . If that occurs, we speak of **spontaneously broken symmetry**. Under some assumptions, a particle of zero mass (which is connected to the vacuum by the current for the spontaneously broken symmetry) is associated with the spontaneously broken symmetry. This statement is called **Goldstone's theorem**, and the relevant particle of zero mass is called the **Nambu-Goldstone boson**. The PCAC hypothesis is believed to be connected with the spontaneous breakdown of the axial $SU(3)$ symmetry with pions, kaons, and eta-mesons as Nambu-Goldstone bosons. This approach produced the **Adler-Weisberger sum rule**, which relates the weak axial-vector coupling constants to pion-nucleon scattering cross sections.

A group-theoretical attempt to treat fermions and bosons on an equal footing resulted in the introduction of super Lie algebras (Z_2 -graded Lie algebras). The basic new ingredient in this approach is a special class of generators roughly interpreted as the square root of the four-momentum, whose anticommutators (instead of commutators) are linear combinations of ordinary generators. A supermultiplet, which is an irreducible representation of a super Lie algebra, consists of both fermions and bosons. Extensions to local super Lie algebras (and also incorporation of gravitons into the framework) have been tried, with no realistic model emerging so far.

(4) Non-Abelian Gauge Field Theory. Recently, quantum field theory has been revived as non-Abelian gauge theory, resulting in what are considered to be successful qualitative and semiquantitative predictions. The quantization of the theory was at first carried out in terms of the Feynman path integral, where fictitious particles, called **Faddeev-Popov ghosts**, appear through the precise definition of the functional measure of the path integral. The canonical

quantization has also been formulated with the explicit introduction of Faddeev-Popov ghosts from the beginning. Non-Abelian gauge field theory exhibits the very important property of asymptotic freedom, which states that the interaction at asymptotically high energies, or at very short distances, approaches that of free (noninteracting) theory. This property is required for the description of hadronic systems made of quarks in view of the experimental observation of the scaling behavior of deep inelastic inclusive structure functions. Thus gauge theory is believed to describe the dynamics of systems of quarks in hadrons. It is called **quantum chromodynamics**, and the quantum of the gauge field is called the gluon. The recent development of gauge field theory has been accompanied by many technical refinements of quantum field theory, which include the methods of dimensional regularization and renormalization groups.

Dimensional regularization starts with Feynman integrals defined for n -dimensional momenta with $n \neq 4$, in order to give meaning to integrals divergent for $n = 4$. Then Feynman integrals have poles at $n = 4$, which are absorbed into the unrenormalized constants by means of the renormalization procedure. This method is particularly suited for non-Abelian gauge theory, since it is the regularization method that keeps gauge invariance at each step of the calculation.

The renormalization-group equation has been known for a long time. It results from the requirement that physical quantities should be dimensionally covariant under renormalization of constants in the theory. The renormalization-group equation is usually written as a differential equation for a Green's function, expressing the fact that a change of scale of momenta is balanced by changing coupling constants and masses. Further refinements are due to C. G. Callan, K. Symanzik, S. Weinberg, and G. 't Hooft.

D. Models of Elementary Particles

Hadrons are now considered to be made of more fundamental constituents; at present, at least 15 species of subhadronic, fermionic constituents (quarks) have been proposed. Attempts to understand subhadronic structure have a long history, the main landmarks of which include the Fermi-Yang model (where π -mesons are supposed to be made of protons and neutrons), the **Sakata model** (where all hadrons are supposed to be made of protons, neutrons, and Λ -hyperons), and a variety of quark models developed from the **eightfold way** of M. Gell-Mann and Y. Ne'eman (new

assignments of representations of $SU(3)$ to particles somewhat different from the Sakata model; for example, the octet representation for mesons and low-lying baryons, and the decuplet for excited baryons). Originally, quarks were supposed to come in 3 species (u -quarks, d -quarks, s -quarks), each carrying its own quantum number, now called the flavor quantum number. Then it was suggested that each flavored quark has three additional degrees of freedom, i.e., three new quantum numbers (called color quantum numbers) in order to account for experimental data: (1) the spin-statistics problem of baryonic ground state wave functions, (2) the decay rate of $\pi \rightarrow 2\gamma$, (3) the Drell ratio (= total cross section for $\{e^- + e^+ \rightarrow \text{anything}\}$, divided by the cross section for $e^- + e^+ \rightarrow \mu^- + \mu^+$). Recently, two new flavor degrees of freedom besides the old 3 flavors (u, d, s) have been discovered, the carriers of which are c -quarks and b -quarks, c being the constituents of J/ψ -particles, b of Y -particles. The combination of 5 flavors and 3 colors results in 15 quarks, as stated earlier.

The so-called standard model is a quantum field theory based on a local, non-Abelian gauge group $SU(3) \times SU(2) \times U(1)$. The group $SU(3)$ is called the color $SU(3)$ group, which is supposed to be strictly unbroken and expresses the invariance of the theory under the local $SU(3)$ transformation of the three color degrees of freedom. Quarks having spin $\frac{1}{2}$ transform as its 3-dimensional fundamental representation, and the vector gauge bosons transforming as its 8-dimensional regular representation are **gluons**. This part of the theory is **quantum chromodynamics (QCD)**. The remaining part of the theory, based on the local gauge group $SU(2) \times U(1)$, is called the **Glashow-Weinberg-Salam model** or its hadronic extension **quantum flavor dynamics (QFD)**, and unifies the electromagnetic and the weak interactions. This gauge group is supposed to be spontaneously broken with the only unbroken subgroup $U(1)$ corresponding to the electromagnetic gauge transformation. The underlying mechanism for the spontaneous breakdown of the gauge group $SU(2) \times U(1)$ is not well understood, but conventionally it is assumed to occur through the so-called **Higgs mechanism**. This is a mechanism proposed by P. W. Higgs, whereby the Goldstone boson acquires a nonzero mass if the broken symmetry occurs in the presence of an associated massless vector field (called a gauge vector field), which also becomes associated with massive bosons. The gauge vector bosons are identified with photons (γ) (unbroken symmetry and hence massless) and weak intermediary bosons (broken symmetry and hence massive), usually denoted by W and Z . Quarks

and leptons transform under the group $SU(2)$ as doublet or singlet representations. The renormalizability of the spontaneously broken gauge field theory has been established by 't Hooft. Major predictions of the Glashow-Weinberg-Salam model, including the existence of the gauge bosons W and Z , have been borne out experimentally.

Grand unified models attempt to unify QCD and QFD, employing a larger Lie group containing $SU(3) \times SU(2) \times U(1)$ as a subgroup. The most popular ones are those based on the groups $SU(5)$, $SO(10)$ and on some of the exceptional groups. Super grand unified models attempt to unify QCD, QFD, and the gravitational interaction, with super Lie groups as a possible basis. Recently, there have been attempts to search for subquark structures.

133 (XIV.9) Ellipsoidal Harmonics

A. Ellipsoidal Coordinates

If $a > b > c$, then for any given $(x, y, z) \in \mathbf{R}^3$, the three roots of the cubic equation in θ

$$F(\theta) = \frac{x^2}{a^2 + \theta} + \frac{y^2}{b^2 + \theta} + \frac{z^2}{c^2 + \theta} - 1 = 0$$

are real and lie in the intervals $\theta > -c^2$, $-c^2 > \theta > -b^2$, and $-b^2 > \theta > -a^2$. Denoting these three roots by λ , μ , and ν (they are labeled so as to satisfy the inequalities $\lambda > -c^2 > \mu > -b^2 > \nu > -a^2$), $F(\lambda) = 0$, $F(\mu) = 0$, and $F(\nu) = 0$ represent an ellipsoid, a hyperboloid of one sheet, and a hyperboloid of two sheets, respectively. They are confocal with the ellipsoid

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} - 1 = 0,$$

pass through the point (x, y, z) , and mutually intersect orthogonally.

The quantities λ , μ , ν are called the **ellipsoidal coordinates** of the point (x, y, z) . Rectangular coordinates (x, y, z) are expressed in terms of ellipsoidal coordinates (λ, μ, ν) by the formula

$$x^2 = \frac{(a^2 + \lambda)(a^2 + \mu)(a^2 + \nu)}{(a^2 - b^2)(a^2 - c^2)}, \quad (1)$$

and two others obtained from (1) by cyclic permutations of (a, b, c) and (x, y, z) .

B. Ellipsoidal Harmonics

When a \dagger harmonic function ψ of three real variables is constant on the surface $\lambda = \text{constant}$, $\mu = \text{constant}$, or $\nu = \text{constant}$ in ellipsoidal coordinates, the function ψ is called an **ellipsoidal harmonic**. A solution of Laplace's equation $\Delta\psi = 0$ in the form $\psi = \Lambda(\lambda)M(\mu)N(\nu)$ can be obtained by the method of separation of variables. The equation $\Delta\psi = 0$ is written in the form

$$\sum (\mu - \nu) \Delta_\lambda \frac{\partial}{\partial \lambda} \left(\Delta_\lambda \frac{\partial \psi}{\partial \lambda} \right) = 0,$$

where the summation is taken over the even permutations of (λ, μ, ν) , and

$$\Delta_\lambda = \sqrt{(a^2 + \lambda)(b^2 + \lambda)(c^2 + \lambda)}.$$

The ordinary differential equation

$$4\Delta_\lambda \frac{d}{d\lambda} \left(\Delta_\lambda \frac{d\Lambda}{d\lambda} \right) = (K\lambda + C)\Lambda \quad (2)$$

is satisfied by Λ and also by M and N if we replace λ by μ and ν , respectively. Equation (2) is called **Lamé's differential equation**, with K and C the separation constants.

Let $K = n(n+1)$ for $n = 0, 1, 2, \dots$. Then equation (2), for a suitable value (the eigenvalue) of C , has a solution that is a polynomial in λ or a polynomial multiplied by one, two, or three of $\sqrt{a^2 + \lambda}$, $\sqrt{b^2 + \lambda}$, and $\sqrt{c^2 + \lambda}$.

Among these solutions $2n+1$ are linearly independent. We denote these solutions by $\Lambda = f_n^m(\lambda)$ ($m = 1, 2, \dots, 2n+1$). They are essentially equivalent to the Lamé functions, to be defined at the end of this section. To be precise, by setting

$$\lambda + (a^2 + b^2 + c^2)/3 = \xi,$$

$$C = B + n(n+1)(a^2 + b^2 + c^2)/3,$$

$$e_1 = (b^2 + c^2 - 2a^2)/3, \dots, \quad e_1 + e_2 + e_3 = 0,$$

we have

$$\begin{aligned} \frac{d^2 \Lambda}{d\xi^2} + \left(\frac{1/2}{\xi - e_1} + \frac{1/2}{\xi - e_2} + \frac{1/2}{\xi - e_3} \right) \frac{d\Lambda}{d\xi} \\ = \frac{n(n+1)\xi + B}{4(\xi - e_1)(\xi - e_2)(\xi - e_3)} \Lambda. \end{aligned} \quad (3)$$

This can also be written in the form

$$\frac{d^2 \Lambda}{du^2} = (n(n+1)\wp(u) + B)\Lambda \quad (4)$$

by the change of variable $\xi = \wp(u)$ with the Weierstrass \wp -function.

The differential equation (3) has $\xi = e_1, e_2, e_3, \infty$ as \dagger regular singular points. A solution of (3) that is a polynomial in ξ or a polynomial multiplied by one, two, or three of $\sqrt{\xi - e_1}$, $\sqrt{\xi - e_2}$, and $\sqrt{\xi - e_3}$ is called a **Lamé function of the first kind**.

C. Classification of Lamé Functions

The $2n+1$ linearly independent solutions $f_n^m(\lambda)$ of (2) are classified into the following four families. If n is an even number $2p$, then $p+1$ solutions $f_n^m(\lambda)$ among the $2n+1$ solutions are polynomials in λ of degree p , and the other $3p$ functions are polynomials in λ of degree $p-1$ multiplied by

$$\sqrt{(b^2 + \lambda)(c^2 + \lambda)}, \quad \sqrt{(c^2 + \lambda)(a^2 + \lambda)},$$

or

$$\sqrt{(a^2 + \lambda)(b^2 + \lambda)}.$$

Since all these polynomials are products with real factors of degree 1, the solutions belonging

to the first family are of the type

$$f_n^m(\lambda) = (\lambda - \theta_1)(\lambda - \theta_2) \dots (\lambda - \theta_{n/2}), \quad (5)$$

while solutions of the latter kinds are of the type

$$f_n^m(\lambda) = \left\{ \begin{array}{l} \sqrt{(b^2 + \lambda)(c^2 + \lambda)} \\ \sqrt{(c^2 + \lambda)(a^2 + \lambda)} \\ \sqrt{(a^2 + \lambda)(b^2 + \lambda)} \end{array} \right\} \times (\lambda - \theta_1)(\lambda - \theta_2) \dots (\lambda - \theta_{n/2-1}). \quad (6)$$

The functions (5) and (6) are called **Lamé functions of the first species and of the third species**, respectively. On the other hand, if n is an odd number $2p + 1$, then $3(p + 1)$ solutions among the $2n + 1$ functions $f_n^m(\lambda)$ are of the type

$$f_n^m(\lambda) = \left\{ \begin{array}{l} \sqrt{a^2 + \lambda} \\ \sqrt{b^2 + \lambda} \\ \sqrt{c^2 + \lambda} \end{array} \right\} \times (\lambda - \theta_1)(\lambda - \theta_2) \dots (\lambda - \theta_{(n-1)/2}), \quad (7)$$

and the other p functions are of the type

$$f_n^m(\lambda) = \sqrt{(a^2 + \lambda)(b^2 + \lambda)(c^2 + \lambda)} \times (\lambda - \theta_1)(\lambda - \theta_2) \dots (\lambda - \theta_{(n-3)/2}). \quad (8)$$

The functions (7) and (8) are called **Lamé functions of the second species and of the fourth species**, respectively. Hence in either case we have $2n + 1$ linearly independent Lamé functions.

When n is even, we obtain an ellipsoidal harmonic

$$\psi_n^m = \prod_{p=1}^{n/2} (\lambda - \theta_p)(\mu - \theta_p)(v - \theta_p)$$

by multiplying $f_n^m(\lambda)$, $f_n^m(\mu)$, and $f_n^m(v)$ belonging to the first family. Also, in this case, by setting

$$\Theta_p = \frac{x^2}{a^2 + \theta_p} + \frac{y^2}{b^2 + \theta_p} + \frac{z^2}{c^2 + \theta_p} - 1 \\ = \frac{(\lambda - \theta_p)(\mu - \theta_p)(v - \theta_p)}{(a^2 + \theta_p)(b^2 + \theta_p)(c^2 + \theta_p)}$$

we have

$$\psi_n^m = \Theta_1 \Theta_2 \dots \Theta_{n/2} \quad (9)$$

up to constant coefficients. Utilizing Lamé functions of the third species (instead of functions of the first species) and formula (1), we find that

$$\psi_n^m = (yz \text{ or } zx \text{ or } xy) \times \Theta_1 \Theta_2 \dots \Theta_{n/2-1}. \quad (10)$$

For even n , every ellipsoidal harmonic expressible in terms of polynomials in x , y , z of degree n can be written as a linear combination of the functions (9) and (10), which are

called the **ellipsoidal harmonics of the first and of the third species**, respectively. Similarly for odd n , the **ellipsoidal harmonics of the second and of the fourth species**

$$\psi_n^m = (x \text{ or } y \text{ or } z) \Theta_1 \Theta_2 \dots \Theta_{(n-1)/2}, \quad (11)$$

$$\psi_n^m = xyz \Theta_1 \Theta_2 \dots \Theta_{(n-3)/2} \quad (12)$$

are composed of the Lamé functions of the second and fourth species, respectively.

For odd n , these forms are a complete system of ellipsoidal harmonics that are linearly independent and expressible in terms of polynomials in x , y , z of degree n .

The zeros $\xi_1, \xi_2, \dots, \xi_p$ of the Lamé functions are real, and $\xi_i \neq \xi_j$ ($i \neq j$). They never coincide with any one of e_1, e_2 , and e_3 . If $e_1 > e_2 > e_3$, then ξ_1, \dots, ξ_p all lie between e_1 and e_3 . If m is an integer such that $0 \leq m \leq p$, we have one and only one Lamé function (with the species given) with m of its zeros lying between e_1 and e_2 and the remaining $p - m$ zeros between e_2 and e_3 (**Stieltjes's theorem**). In this way, a complete system of linearly independent Lamé functions of the specified type may be obtained, since m assumes $p + 1$ different values. When the constant B appearing in the differential equation (3) takes specific values so that the equation has Lamé functions of the first kind as its solution, (3) also yields a solution Λ such that $\Lambda \rightarrow \xi^{-(n+1)/2}$ as $\xi \rightarrow \infty$. This function Λ is called the **Lamé function of the second kind**.

D. Ellipsoids of Revolution (Spheroids)

When the fundamental ellipsoid is a spheroid

$$\frac{x^2 + y^2}{a^2} + \frac{z^2}{c^2} = 1,$$

it is convenient to use the **spheroidal coordinates** (ξ, η, φ) given by

$$x = l \sqrt{(\xi^2 - 1)(1 - \eta^2)} \cos \varphi, \\ y = l \sqrt{(\xi^2 - 1)(1 - \eta^2)} \sin \varphi, \\ z = l \xi \eta, \quad l = \sqrt{c^2 - a^2} \quad (13)$$

for $a^2 < c^2$ (prolate) and

$$x = l \sqrt{(\xi^2 + 1)(1 - \eta^2)} \cos \varphi, \\ y = l \sqrt{(\xi^2 + 1)(1 - \eta^2)} \sin \varphi, \\ z = l \xi \eta, \quad l = \sqrt{a^2 - c^2} \quad (14)$$

for $a^2 > c^2$ (oblate). The solutions of Laplace's equation, which are regular at all finite points, are given by

$$\psi = P_n^m(\xi) P_n^m(\eta) \cos m \varphi$$

in the prolate case, and

$$\psi = P_n^m(i\xi) P_n^m(\eta) \cos m \varphi$$

in the oblate case. Here P_n^m is the †associated Legendre function of the first kind. Solutions which are regular outside a finite ellipsoid can be composed of the †associated Legendre functions of the second kind, $Q_n^m(\xi)$ or $Q_n^m(i\xi)$ instead of $P_n^m(\xi)$ or $P_n^m(i\xi)$, respectively.

E. Spheroidal Wave Functions

Transforming the †Helmholtz equation in prolate spheroidal coordinates (13), we have

$$\frac{1}{(\xi^2-\eta^2)}\left\{\frac{\partial}{\partial\xi}\left((\xi^2-1)\frac{\partial\Psi}{\partial\xi}\right)+\frac{\partial}{\partial\eta}\left((1-\eta^2)\frac{\partial\Psi}{\partial\eta}\right)+\left(\frac{1}{\xi^2-1}+\frac{1}{1-\eta^2}\right)\frac{\partial^2\Psi}{\partial\varphi^2}\right\}+\kappa^2\Psi=0,\quad \kappa=kl. \tag{15}$$

By separating variables in the form $\Psi=X(\xi)Y(\eta)\cos m\varphi$, we have the equations

$$\frac{d}{d\xi}\left((1-\xi^2)\frac{dX}{d\xi}\right)+\left(\lambda-\kappa^2\xi^2-\frac{m^2}{1-\xi^2}\right)X=0, \tag{16a}$$

$$\frac{d}{d\eta}\left((1-\eta^2)\frac{dY}{d\eta}\right)+\left(\lambda-\kappa^2\eta^2-\frac{m^2}{1-\eta^2}\right)Y=0, \tag{16b}$$

which X and Y , respectively, must satisfy. The only difference between equations (16a) and (16b) arises from the fact that the domain of (16a) is given by $1<\xi$ whereas the domain of (16b) is given by $-1<\eta<1$. For the oblate spheroid, utilizing formula (14) we have

$$\frac{1}{(\xi^2+\eta^2)}\left\{\frac{\partial}{\partial\xi}\left((\xi^2+1)\frac{\partial\Psi}{\partial\xi}\right)+\frac{\partial}{\partial\eta}\left((1-\eta^2)\frac{\partial\Psi}{\partial\eta}\right)+\left(\frac{1}{1-\eta^2}-\frac{1}{\xi^2+1}\right)\frac{\partial^2\Psi}{\partial\varphi^2}\right\}+\kappa^2\Psi=0. \tag{17}$$

By separating variables as before, $Y(\eta)$ satisfies the same equation as (16b), while $X(\xi)$ satisfies equation (16a) with ξ replaced by $i\xi$. All these equations are of the type

$$\frac{d}{dz}\left((1-z^2)\frac{du}{dz}\right)+\left(\lambda-\kappa^2z^2-\frac{m^2}{1-z^2}\right)u=0. \tag{18}$$

A solution of (18) is known as a **spheroidal wave function**. The equation (18) has ± 1 as regular singular points and ∞ as an irregular singular point of class 1. Hence spheroidal wave functions behave like †Legendre functions in the interval $[-1, 1]$ and like †Bessel functions in the neighborhood of ∞ .

F. The Functions $pe_n^m(x)$ and $qe_n^m(x)$

When we write a solution of (18), it is customary to write x instead of z when z is contained in the interval $[-1, 1]$. We denote solutions of

(18) which are regular on the whole domain $-1\leq x\leq 1$ by $pe_n^m(x)$, and the corresponding eigenvalues by $\lambda_{n,m}$ (assuming the boundary condition stated in this paragraph concerning singularities). In particular, when $\kappa\rightarrow 0$, equation (18) reduces to †Legendre's associated differential equation, the eigenvalues of λ become $n(n+1)$ (n is a positive integer), and the corresponding eigenfunctions become the associated Legendre functions of the first kind:

$$P_n^m(x)=(1-x^2)^{m/2}\frac{d^m P_n}{dx^m}. \tag{19}$$

Hence $pe_n^m(x)$ is a solution which tends to a constant multiple of $P_n^m(x)$ as $\kappa\rightarrow 0$. Using a system of orthogonal functions $P_n^m(x)$, we can expand $pe_n^m(x)$ as

$$pe_n^m(x)=\sum_{l\geq m}A_{n,l}^mP_l^m(x), \tag{20}$$

$|l-n|=\text{even number.}$

The coefficients A satisfy a recurrence formula

$$\begin{aligned} &\left(\lambda_{n,m}-l(l+1)+\kappa^2\frac{2l^2+2l-1-2m^2}{(2l-1)(2l+3)}\right)A_{n,l}^m \\ &- \kappa^2\frac{(l-m-1)(l-m)}{(2l-3)(2l-1)}A_{n,l-2}^m \\ &- \kappa^2\frac{(l+m+1)(l+m+2)}{(2l+3)(2l+5)}A_{n,l+2}^m=0. \end{aligned} \tag{21}$$

The functions $pe_n^m(x)$ and $pe_l^m(x)$ are orthogonal in the domain $-1< x < 1$.

Another solution of (18) exists which corresponds to the same eigenvalue $\lambda_{n,m}$, is independent of $pe_n^m(x)$, and has the opposite parity:

$$\begin{aligned} qe_n^m(x) &= \sum_{l\geq -m, l-n=\text{even}}A_{n,l}^mQ_l^m(x) \\ &+ \sum_{j\geq m, j-n=\text{odd}}B_{n,j}^mP_j^m(x), \end{aligned} \tag{22}$$

where the $A_{n,l}^m$ are the same as in (20) and are determined by the recurrence formula (21), while for $j\geq m+2$, the $B_{n,j}^m$ satisfy the recurrence formula

$$\begin{aligned} &\left(\lambda_{n,m}-j(j+1)+\kappa^2\frac{2j^2+2j-1-2m^2}{(2j-1)(2j+3)}\right)B_{n,j}^m \\ &+ \kappa^2\frac{(j-m-1)(j-m)}{(2j-3)(2j-1)}B_{n,j-2}^m \\ &+ \kappa^2\frac{(j+m+1)(j+m+2)}{(2j+3)(2j+5)}B_{n,j+2}^m=0. \end{aligned} \tag{23}$$

Since the associated Legendre function of the second kind

$$Q_l^m(x)=(1-x^2)^{m/2}\frac{d^m Q_l}{dx^m}$$

is of the form

$$Q_l^m(x)=P_l^m(x)\log\sqrt{(1+x)/(1-x)}+(1-x^2)^{-m/2}\times(\text{a polynomial in } x)$$

for $l \geq m$, the $q e_n^m(x)$ have $x = \pm 1$ as singular points.

By expressing the solution of equation (18) in integral form we find that $p e_n^m(x)$ satisfies an integral equation

$$i^{n-m} v_{n,m} p e_n^m(x) = \int_{-1}^1 (1-x^2)^{m/2} (1-\xi^2)^{m/2} e^{ikx\xi} p e_n^m(\xi) d\xi, \quad (24)$$

where the coefficient $v_{n,m}$ is related to $P_n^m(0)$ or $P_n^{m'}(0)$.

In order to extend the domain of definition of $p e_n^m(x)$ and $q e_n^m(x)$ beyond the interval $[-1, 1]$, we adopt, in the domain G obtained by deleting the interval $[-1, 1]$ from the complex plane, the Heine-Hobson definition of the associated Legendre function,

$$P_n^m(z) = (z^2 - 1)^{m/2} d^m P_n / dz^m, \quad (25)$$

instead of N. M. Ferrers's definition (19), and construct a solution of (18) in G :

$$p e_n^m(z) = \sum_{l \geq m} A_{n,l}^m P_l^m(z),$$

$$|l - n| = \text{even number}, \quad (26)$$

which is like (20) and again satisfies the integral equation (24). From this we can obtain the expansion formula

$$p e_n^m(z) = \frac{\sqrt{2\pi} (z^2 - 1)^{m/2}}{v_{n,m} (\kappa z)^m} \times \sum_{l \geq m} (-1)^{(l-n)/2} \frac{(l+m)!}{(l-m)!} A_{n,l}^m \frac{J_{l+1/2}(\kappa z)}{\kappa z},$$

$$|l - n| = \text{even number}. \quad (27)$$

Multiplying this by a constant, we define

$$j e_n^m(z) = \sqrt{\frac{\pi}{2}} \frac{(z^2 - 1)^{m/2}}{z^m} \times \sum_{l \geq m} (-1)^{(l-n)/2} F_{n,l}^m \frac{J_{l+1/2}(\kappa z)}{\sqrt{\kappa z}} \bigg/ \sum_{l \geq m} F_{n,l}^m,$$

$$F_{n,l}^m = \frac{(l+m)!}{(l-m)!} A_{n,l}^m.$$

This expression asymptotically assumes the form

$$j e_n^m(z) \sim \sin(\kappa z - n\pi/2) / \kappa z$$

for $|z| \gg 1$. In a similar manner we find a solution

$$n e_n^m(z) = -\sqrt{\frac{\pi}{2}} \frac{(z^2 - 1)^{m/2}}{z^m} \times \sum_{l \geq m} (-1)^{(l-n)/2} F_{n,l}^m \frac{N_{l+1/2}(\kappa z)}{\sqrt{\kappa z}} \bigg/ \sum_{l \geq m} F_{n,l}^m$$

having the asymptotic form

$$n e_n^m(z) \sim \cos(\kappa z - n\pi/2) / \kappa z.$$

Disregarding a constant factor, this coincides with the function defined by (22) with $Q_n^m(z) = (z^2 - 1)^{m/2} d^m Q_n / dz^m$ in place of the associated Legendre function of the second kind.

134 (XIV.3) Elliptic Functions

A. Elliptic Integrals

Let $\varphi(z)$ be a polynomial in z of degree 3 or 4 with complex coefficients and $R(z, w)$ a rational function in z and w . Then $R(z, \sqrt{\varphi(z)})$ is called an **elliptic irrational function**. An integral of the type $\int R dz$ is called an **elliptic integral**. The origin of the name comes from the integral that appears in calculating the arc length of an ellipse. Any elliptic integral can be expressed by a suitable change of variables as a sum of elementary functions and elliptic integrals of the following three kinds:

$$\int \frac{dz}{\sqrt{(1-z^2)(1-k^2 z^2)}},$$

$$\int \sqrt{\frac{1-k^2 z^2}{1-z^2}} dz,$$

and

$$\int \frac{dz}{(1-a^2 z^2) \sqrt{(1-z^2)(1-k^2 z^2)}}$$

(\rightarrow Appendix A, Table 16.I). These three kinds of integrals are called **elliptic integrals of the first, second, and third kind**, respectively, in **Legendre-Jacobi standard form**. This classifica-

tion corresponds to that of \dagger Abelian integrals. The constant k is called the **modulus** of these elliptic integrals, and a is called the **parameter**. Let the four zeros of $\varphi(z)$ be $\alpha_1, \alpha_2, \alpha_3, \alpha_4$ (we take one of them as ∞ when $\varphi(z)$ is of degree 3). The \dagger Riemann surface \mathfrak{R} corresponding to the elliptic irrational function has the zeros $\alpha_1, \alpha_2, \alpha_3, \alpha_4$ as \dagger branch points with degree of ramification 1, and is of two sheets and of \dagger genus 1. If the integrand does not have a pole with a \dagger residue, then the integral is multivalued only because the value (called the **periodicity modulus**) of the integral taken along the normal section (basis of the homology group) is not equal to zero.

B. Elliptic Integrals of the First Kind

When R is a function without singularities other than branch points, only the topological structure of R gives rise to the multivaluedness of the integral of R . The standard form is

$$\begin{aligned} \int_0^z \frac{dz}{\sqrt{(1-z^2)(1-k^2z^2)}} \\ = \int_0^\varphi \frac{d\varphi}{\sqrt{1-k^2\sin^2\varphi}} = w = F(k, \varphi), \end{aligned} \quad (1)$$

where $z = \sin \varphi$. This integral is the inverse function of $\operatorname{sn} w$ (\rightarrow Section J). The periodicity moduli are $2iK'$ and $4K$, where

$$\begin{aligned} K = K(k) &= \int_0^1 \frac{dz}{\sqrt{(1-z^2)(1-k^2z^2)}} \\ &= \int_0^{\pi/2} \frac{d\varphi}{\sqrt{1-k^2\sin^2\varphi}} = F\left(k, \frac{\pi}{2}\right), \end{aligned}$$

$$K' = K(k'), \quad k'^2 = 1 - k^2.$$

We call $K(k)$ a **complete elliptic integral of the first kind** and $F(k, \varphi)$ an **incomplete elliptic integral of the first kind** (\rightarrow Appendix A, Table 16). Setting

$$\sin \varphi_1 = \frac{(1+k')\sin \varphi \cos \varphi}{\sqrt{1-k^2\sin^2\varphi}}, \quad k_1 = \frac{1-k'}{1+k'}, \quad (2)$$

we have the relation

$$F(k, \varphi) = (1+k_1)F(k_1, \varphi_1)/2,$$

which is called **Landen's transformation**. Since $k_1 < k$ when $0 < k < 1$, this transformation reduces the calculation of elliptic integrals to those with smaller values of k . For two given positive numbers a and b , put $a_0 = a$, $b_0 = b$, and $a_{n+1} = (a_n + b_n)/2$, $b_{n+1} = \sqrt{a_n b_n}$. Then the sequences $\{a_n\}$ and $\{b_n\}$ converge rapidly to the common limit, which is called the **arithmetic-geometric mean** of a and b , and is denoted by $\operatorname{ag}(a, b)$. The complete

elliptic integral satisfies the relation $K(k) = \pi/[2\operatorname{ag}(1, \sqrt{1-k^2})]$.

C. Elliptic Integrals of the Second Kind

When R has poles with residue zero, its integral has no singularities other than poles.

The standard form is

$$\begin{aligned} F(z) &= \int_0^z \sqrt{\frac{1-k^2z^2}{1-z^2}} dz \\ &= \int_0^\varphi \sqrt{1-k^2\sin^2\varphi} d\varphi = E(k, \varphi), \end{aligned} \quad (3)$$

where $z = \sin \varphi$. We have

$$F(z) = \int_0^u \operatorname{dn}^2 u du = \frac{\Theta'(u)}{\Theta(u)} + \frac{E}{K} u$$

if we set $z = \operatorname{sn} u$. Here, Θ is Jacobi's theta function, and

$$\Theta(u) = \mathfrak{g}_4\left(\frac{u}{2K}, \frac{iK'}{K}\right),$$

where \mathfrak{g}_4 is a theta function to be described in Section I and K, K' are the same as in the case of elliptic integrals of the first kind. The quantity

$$\begin{aligned} E &= \int_0^1 \sqrt{\frac{1-k^2z^2}{1-z^2}} dz \\ &= \int_0^{\pi/2} \sqrt{1-k^2\sin^2\varphi} d\varphi = E\left(k, \frac{\pi}{2}\right) \end{aligned}$$

is called a **complete elliptic integral of the second kind**.

D. Elliptic Integrals of the Third Kind

When R has poles with nonzero residue its integral has logarithmic singularities. In this case, residues also contribute to multivaluedness of the integral. The standard form is

$$\begin{aligned} F(z) &= \int_0^z \frac{dz}{(1-a^2z^2)\sqrt{(1-z^2)(1-k^2z^2)}} \\ &= \int_0^\varphi \frac{d\varphi}{(1-a^2\sin^2\varphi)\sqrt{1-k^2\sin^2\varphi}}, \end{aligned}$$

and it is expressed as

$$F(z) = \frac{\operatorname{sn} \alpha}{\operatorname{cn} \alpha \operatorname{dn} \alpha} \left(\frac{1}{2} \log \frac{\Theta(u-\alpha)}{\Theta(u+\alpha)} + u \frac{\Theta'(u)}{\Theta(u)} \right) + u$$

if we set $z = \operatorname{sn} u$ and $a^2 = k^2 \operatorname{sn}^2 \alpha$ (\rightarrow Appendix A, Table 16).

E. Elliptic Functions and Periodic Functions

Historically the elliptic function was first introduced as the inverse function of the elliptic

integral. However, since it has been realized that elliptic functions are characterized as functions with double periodicity, it is now customary to define them as doubly periodic functions.

If $f(x)$, defined on a linear space X , satisfies the relation $f(x + \omega) = f(x)$ for some $\omega \in X$ and all $x \in X$, the number ω is called a **period** of $f(x)$, and $f(x)$ with a period other than zero is called a **periodic function**. The set P of all periods of $f(x)$ forms an additive group contained in X . If a basis $\omega_1, \dots, \omega_n$ of the additive group P exists, its members are called **fundamental periods** of $f(x)$.

Any continuous, nonconstant, periodic function of a real variable has only one positive fundamental period and is called a **simply periodic function**. The trigonometric functions are typical examples: $\sin x$ and $\cos x$ have the fundamental period 2π ; $\tan x$ and $\cot x$ have the fundamental period π (\rightarrow 159 Fourier Series).

A single-valued nonconstant meromorphic function of n complex variables cannot have more than $2n$ fundamental periods that are linearly independent on the real number field. A function of one complex variable with two fundamental periods is called a **doubly periodic function**.

Let ω, ω' be the fundamental periods of a doubly periodic function. For a given number a , the parallelogram with vertices $a, a + \omega, a + \omega', a + \omega + \omega'$ is called the **fundamental period parallelogram**. The complex plane is covered with a network of congruent parallelograms, called **period parallelograms**, obtained by translating the fundamental period parallelogram through $m\omega + n\omega'$ ($m, n = 0, \pm 1, \pm 2, \dots$).

A doubly periodic function $f(u)$ meromorphic on the complex plane is called an **elliptic function**. For simplicity, we usually denote the fundamental periods of an elliptic function by $2\omega_1$ and $2\omega_3$, and introduce ω_2 defined by the relation $\omega_1 + \omega_2 + \omega_3 = 0$. The first, and therefore also higher, derivatives of any elliptic function are elliptic functions with the same periods. The set of all elliptic functions with the same periods forms a field. The number of poles in a period parallelogram is finite. The sum of the orders of the poles is called the **order** of the elliptic function. An elliptic function with no poles in a period parallelogram is merely a constant (**Liouville's first theorem**). The sum of the residues of an elliptic function at its poles in any period parallelogram is zero (**Liouville's second theorem**). Hence there can be no elliptic function of order 1. An elliptic function of order n assumes any value n times in a period parallelogram (**Liouville's third theorem**). The sum of the zeros minus the

sum of the poles is a period (**Liouville's fourth theorem**).

F. Weierstrass's Elliptic Functions

Weierstrass defined

$$\wp(u) = \frac{1}{u^2} + \sum' \left(\frac{1}{(u - \Omega)^2} - \frac{1}{\Omega^2} \right)$$

as the simplest kind of elliptic function. Here $\Omega = 2m\omega_1 + 2n\omega_3$, with m, n integers. The summation \sum' extends over all integral values (positive, negative, and zero) of m and n , except for $m = n = 0$. $\wp(u)$ is an elliptic function of order 2 with periods $2\omega_1$ and $2\omega_3$, called a **Weierstrass \wp -function**. The following functions $\zeta(u)$ and $\sigma(u)$ are called the **Weierstrass zeta** and **sigma functions**, respectively:

$$\zeta(u) = \frac{1}{u} + \sum' \left(\frac{1}{u - \Omega} + \frac{u}{\Omega^2} + \frac{1}{\Omega} \right)$$

and

$$\sigma(u) = u \prod' \left(\left(1 - \frac{u}{\Omega} \right) \exp \left(\frac{u}{\Omega} + \frac{u^2}{\Omega^2} \right) \right).$$

These have quasiperiodicity, expressed by

$$\zeta(u + 2\omega_i) = \zeta(u) + 2\eta_i, \quad (4)$$

$$\sigma(u + 2\omega_i) = -e^{2\eta_i(u + \omega_i)} \sigma(u), \quad (5)$$

$$\eta_1 + \eta_2 + \eta_3 = 0, \quad \eta_i = \zeta(\omega_i), \quad i = 1, 2, 3;$$

and they satisfy the relations

$$\wp(u) = -\zeta'(u) \quad (6)$$

and

$$\zeta(u) = \frac{d \log \sigma(u)}{du} = \frac{\sigma'(u)}{\sigma(u)}. \quad (7)$$

The function $\wp(u)$ is an even function of u , and $\zeta(u)$ and $\sigma(u)$ are odd functions of u . By considering the integral $\int \zeta(u) du$ once around the boundary of a fundamental period parallelogram, we have

$$\left. \begin{aligned} \eta_1 \omega_3 - \eta_3 \omega_1 \\ \eta_2 \omega_1 - \eta_1 \omega_2 \\ \eta_3 \omega_2 - \eta_2 \omega_3 \end{aligned} \right\} = \pm \frac{\pi}{2} i, \quad \text{Im} \left(\frac{\omega_3}{\omega_1} \right) \geq 0, \quad (8)$$

which is called the **Legendre relation**.

The derivative

$$\wp'(u) = -2 \sum 1/(u - \Omega)^3$$

of a \wp -function is an elliptic function of order 3 and bears the following relation to $\wp(u)$:

$$\begin{aligned} (\wp'(u))^2 &= 4(\wp(u))^3 - g_2 \wp(u) - g_3 \\ &= 4(\wp(u) - e_1)(\wp(u) - e_2)(\wp(u) - e_3), \end{aligned}$$

$$g_2 = 60 \sum' 1/\Omega^4, \quad g_3 = 140 \sum' 1/\Omega^6,$$

$$e_i = \wp(\omega_i), \quad i = 1, 2, 3. \quad (9)$$

By differentiating this relation successively, we see that $\wp^{(n)}(u)$ is expressed as a polynomial in $\wp(u)$ if n is an even number and as a product of polynomials in $\wp(u)$ and $\wp'(u)$ if n is an odd number.

In particular, writing $\wp(u) = z$ in (9) we find that the \wp -function is the inverse function of the elliptic integral

$$u = \int_{\infty}^z \frac{dz}{\sqrt{4z^3 - g_2z - g_3}}$$

(→ Appendix A, Table 16.IV).

Any elliptic function can be expressed in terms of Weierstrass's functions. Specifically, let the poles of $f(u)$ and their orders be a_1, a_2, \dots, a_m and h_1, h_2, \dots, h_m , respectively, and let the principal part in the expansion of $f(u)$ near the pole a_k be

$$\sum_{j=1}^{h_k} \frac{A_{kj}}{(u-a_k)^j}, \quad k = 1, 2, \dots, m. \quad (10)$$

Then we obtain

$$f(u) = C + \sum_{k=1}^m \left(A_{k1} \zeta(u-a_k) + \sum_{j=1}^{h_k} \frac{(-1)^j A_{kj}}{(j-1)!} \wp^{(j-2)}(u-a_k) \right), \quad (11)$$

where C is a constant depending on $f(u)$. This can be reduced to

$$f(u) = A + B\wp'(u)$$

by using the addition theorems (→ Appendix A, Table 16) for \wp and zeta functions, where A and B are rational functions of $D(u)$. Therefore, given two elliptic functions with the same periods, after expressing them as rational functions of \wp and \wp' in the above form and eliminating \wp and \wp' , we obtain an algebraic equation with constant coefficients. In particular, for any elliptic function $f(u)$ we obtain an algebraic differential equation of the first order by using this method, with $f'(u)$ an elliptic function with the same periods. Furthermore, the functions $f(u+v)$, $f(u)$, and $f(v)$ satisfy an algebraic equation. Thus for any elliptic function an algebraic addition theorem holds.

G. Elliptic Functions of the Second Kind

As an extension of the definition of elliptic functions, if a meromorphic function f satisfies the relations

$$f(u+2\omega_1) = \mu_1 f(u), \quad f(u+2\omega_3) = \mu_3 f(u) \quad (12)$$

(μ_1 and μ_3 are constants) with the fundamental periods $2\omega_1, 2\omega_3$, we call $f(u)$ an **elliptic function of the second kind**. What we have called

simply an elliptic function can now be called an **elliptic function of the first kind**. For constants ρ and v , the function

$$f(u) = e^{\rho u} \sigma(u-v) / \sigma(u) \quad (13)$$

is an example of an elliptic function of the second kind. In this case

$$\mu_i = e^{2\rho\omega_i - 2v\eta_i}, \quad i = 1, 2. \quad (14)$$

Furthermore, for given constants μ_1 and μ_3 , any elliptic function of the second kind is expressed as the product of an elliptic function of the first kind and the function (13) with ρ and v determined by (14).

H. Elliptic Functions of the Third Kind

If a meromorphic function f satisfies

$$f(u+2\omega_i) = e^{a_i u + b_i} f(u), \quad i = 1, 3 \quad (15)$$

(a_i and b_i are constants) with periods $2\omega_1, 2\omega_3$, we call it an **elliptic function of the third kind** (→ 3 Abelian Varieties I).

The Weierstrass sigma function $\sigma(u)$ is an example of an elliptic function of the third kind. The functions σ_1, σ_2 , and σ_3 , defined by the equations

$$\sigma_i(u) = -\frac{e^{\eta_i u} \sigma(u-\omega_i)}{\sigma(\omega_i)}, \quad i = 1, 2, 3, \quad (16)$$

are also elliptic functions of the third kind. In the case of elliptic functions of the second and third kinds, $2\omega_1$ and $2\omega_3$ are not periods in the strict sense defined earlier, but are conveniently referred to as the periods. The functions σ_i ($i = 1, 2, 3$) are called **cosigma functions**.

I. Theta Functions

The **theta functions**, or more strictly, **elliptic theta functions**, are defined by

$$\vartheta_1(v, \tau) = 2 \sum_{n=0}^{\infty} (-1)^n q^{(n+1/2)^2} \sin(2n+1)\pi v,$$

$$\vartheta_2(v, \tau) = 2 \sum_{n=0}^{\infty} q^{(n+1/2)^2} \cos(2n+1)\pi v,$$

$$\vartheta_3(v, \tau) = 1 + 2 \sum_{n=1}^{\infty} q^{n^2} \cos 2n\pi v,$$

$$\vartheta_4(v, \tau) = 1 + 2 \sum_{n=1}^{\infty} (-1)^n q^{n^2} \cos 2n\pi v, \quad (17)$$

where $q = e^{i\pi\tau}$, $\text{Im } \tau > 0$. We call (17) the **q -expansion formulas** of the theta functions, and we sometimes write ϑ_0 in place of ϑ_4 . A theta function is an elliptic function of the third kind with periods 1 and τ . Any elliptic function can be expressed as a quotient of theta functions (→ Appendix A, Table 16 for specific exam-

ples). The q -expansion formula is quite suitable for numerical computation because of its rapid convergence; its terms decrease as the n^2 powers of q as $n \rightarrow \infty$.

An elliptic function with the fundamental periods $2\omega_1$ and $2\omega_3$ can also be viewed as having the periods $2\omega'_1 = 2\omega_3$, $2\omega'_3 = -2\omega_1$. Consequently, theta functions formed with the parameter $\tau = \omega_3/\omega_1$ can be expressed in terms of the parameter $\tau' = \omega'_3/\omega'_1 = -\omega_1/\omega_3 = -1/\tau$, and we have

$$\begin{aligned}\vartheta_1(v, \tau) &= iA\vartheta_1(v/\tau, -1/\tau), \\ \vartheta_2(v, \tau) &= A\vartheta_4(v/\tau, -1/\tau), \\ \vartheta_3(v, \tau) &= A\vartheta_3(v/\tau, -1/\tau), \\ \vartheta_4(v, \tau) &= A\vartheta_2(v/\tau, -1/\tau), \\ A &= \sqrt{i/\tau} \exp(-\pi i v^2/\tau).\end{aligned}\quad (18)$$

These are called **Jacobi's imaginary transformations**. If $\text{Im}(-1/\tau) \gg 1$, then $|q| \approx 1$, and therefore the series in the q -expansion formula converges slowly. However, by an imaginary transformation we get $\text{Im}(\tau) \gg 1$ and $|q| \approx 0$, so that computations become much easier.

Each of the theta functions satisfies, as a function of two variables u and τ , the following partial differential equation of the heat-conduction type:

$$\partial^2 \vartheta(u, \tau) / \partial u^2 = 4\pi i \partial \vartheta(u, \tau) / \partial \tau \quad (19)$$

(\rightarrow Appendix A, Table 16.II).

J. Jacobi's Elliptic Functions

C. G. J. Jacobi defined elliptic integrals as inverse functions of elliptic integrals of the first kind in the Legendre-Jacobi standard form (1). They are, in the above notation,

$$\text{sn } w = \sqrt{e_1 - e_3} \frac{\sigma(u)}{\sigma_3(u)} = \frac{\vartheta_3(0)\vartheta_1(v)}{\vartheta_2(0)\vartheta_4(v)}, \quad (20)$$

$$\text{cn } w = \frac{\sigma_1(u)}{\sigma_3(u)} = \frac{\vartheta_4(0)\vartheta_2(v)}{\vartheta_2(0)\vartheta_4(v)}, \quad (21)$$

$$\text{dn } w = \frac{\sigma_2(u)}{\sigma_3(u)} = \frac{\vartheta_4(0)\vartheta_3(v)}{\vartheta_3(0)\vartheta_4(v)}, \quad (22)$$

where $w = \sqrt{e_1 - e_3} u$ and $v = u/2\omega_1$.

These functions satisfy the relations

$$\text{sn}^2 w + \text{cn}^2 w = 1, \quad k^2 \text{sn}^2 w + \text{dn}^2 w = 1, \quad (23)$$

where

$$k^2 = \frac{e_2 - e_3}{e_1 - e_3} = \frac{(\vartheta_2(0))^4}{(\vartheta_4(0))^4}. \quad (24)$$

The constants k and $k' = \sqrt{1 - k^2}$ are called the **modulus** and the **complementary mod-**

ulus, respectively. Furthermore, the relation $d \text{sn } w / dw = \text{cn } w \text{dn } w$ holds. The function $z = \text{sn } w$ is the inverse function of the elliptic integral (1) (\rightarrow Appendix A, Table 16.III).

135 (II.3) Equivalence Relations

A. General Remarks

Suppose that we are given a relation R between elements of a set X such that for any elements x and y of X , either xRy or its negation holds. The relation R is called an **equivalence relation** (on X) if it satisfies the following three conditions: (1) xRx , (2) xRy implies yRx , and (3) xRy and yRz imply xRz . Conditions (1), (2), and (3) are called the **reflexive**, **symmetric**, and **transitive laws**, respectively. Together, they are called the **equivalence properties**. Condition (1) can be replaced by the following: (1') For each x there exists an x' such that xRx' . The relation " x is equal to y " is an equivalence relation. If xRy means that x and y are in X , then R is also an equivalence relation. An equivalence relation is often denoted by the symbol \sim . The relations of congruence and similarity between figures are equivalence relations. If X is the set of integers and $x \equiv y$ means that $x - y$ is even, then the relation \equiv is an equivalence relation.

B. Equivalence Classes and Quotient Sets

Let R be an equivalence relation. “ xRy ” is read: “ x and y are **equivalent**” (or “ x is **equivalent to** y ”). The subset of X consisting of all elements equivalent to an element a is called the **equivalence class** of a . By (1), (2), and (3), each equivalence class is nonempty, the equivalence class of a contains a , and different equivalence classes do not overlap. Namely, X is decomposed into a disjoint union of equivalence classes. This partition is called the **classification** of X with respect to R . For example, the set of integers is classified into the equivalence class of even numbers and that of odd numbers by the relation \equiv . Conversely, since the relation “ x and y belong to the same member of a partition” is an equivalence relation, we can regard any partition as a classification. An element chosen from an equivalence class is called a **representative** of the equivalence class. In the example we can take 0 and 1 as the representatives of equivalence classes of even and odd numbers, respectively.

X/R denotes the set of equivalence classes of X with respect to R , and is called the **quotient set** of X with respect to R . The mapping $p: X \rightarrow X/R$ that carries x in X into the equivalence class of x is called **canonical surjection** (or **projection**). The idea of equivalence relations can be generalized to deal with the case when X is a \dagger class.

C. Stronger and Weaker Equivalence Relations

Let R and S be two equivalence relations on X . If xRy always implies xSy , then we say that R is **stronger** than S , S is **weaker** than R , the classification with respect to R is **finer** than the one with respect to S , or the classification with respect to S is **coarser** than the one with respect to R . The relations “ x is equal to y ” and “ x and y are in X ” are the strongest and the weakest equivalence relations, respectively. Any two equivalence relations on X are ordered by their strength, and the set of equivalence relations on X forms a \dagger complete lattice with respect to this ordering.

136 (XVII.15) Ergodic Theory

A. General Remarks

The origin of ergodic theory was the so-called **ergodic hypothesis**, which provided the foundation for classical statistical mechanics as created by L. Boltzmann and J. Gibbs toward the end of the 19th century (\rightarrow 402 Statistical Mechanics). Attempts by various mathematicians to give a rigorous proof of the hypothesis resulted in the **recurrence theorem** of H. Poincaré and C. Carathéodory and the **ergodic theorems** of G. D. Birkhoff and J. von Neumann, which marked the beginnings of ergodic theory as we know it today. As the theory developed it acquired close relationships with other branches of mathematics, for example, the theory of dynamical systems, probability theory, functional analysis, number theory, differential topology, and differential geometry.

The principal object of modern ergodic theory is to study properties of \dagger measurable transformations, particularly transformations with an invariant measure. In most cases, the transformations studied are defined on a **Lebesgue measure space with a finite** (or σ -finite) **measure**. A Lebesgue measure space with a finite measure (σ -finite measure) is a \dagger measure space that is measure-theoretically isomorphic to a bounded interval (to the real line) with the usual \dagger Lebesgue measure, possibly together with an at most countable number of atoms. It is known that any separable complete \dagger metric space with a complete regular Borel \dagger probability measure is a Lebesgue measure space with a finite measure. We assume, unless stated otherwise, that the measure space (X, \mathcal{B}, m) is a Lebesgue measure space. All the subsets of X mentioned are assumed measurable, and a pair of sets or functions that coincide almost everywhere are identified. We use the abbreviation “a.e.” to denote “almost everywhere.”

B. Ergodic Theorems

Let (X, \mathcal{B}, m) be a σ -finite measure space. A transformation φ defined on X is called **measurable** if for every $B \in \mathcal{B}$, $\varphi^{-1}(B) \in \mathcal{B}$. A \dagger bijective transformation φ on X is called **bimeasurable** if both φ and φ^{-1} are measurable. A measurable transformation φ is called **measure-preserving** (or equivalently, the measure m is **invariant** under φ) if $m(\varphi^{-1}(B)) = m(B)$ holds for every B . It is called **nonsingular** if $m(\varphi^{-1}(B)) = 0$ whenever $m(B) = 0$, and **ergodic**

if $m((\varphi^{-1}(B) \cup B) - (\varphi^{-1}(B) \cap B)) = 0$ implies either $m(B) = 0$ or $m(X - B) = 0$.

The **mean ergodic theorem** of von Neumann (*Proc. Nat. Acad. Sci. US*, 18 (1932)) states that if φ is a measure-preserving transformation on (X, \mathcal{B}, m) , then for every function f belonging to the \dagger Hilbert space $L_2(X) = L_2(X, \mathcal{B}, m)$ (\rightarrow 168 Function Spaces), the sequence

$$A_n f(x) = \frac{1}{n} \left(\sum_{k=0}^{n-1} f(\varphi^k x) \right)$$

converges in the \dagger norm of $L_2(X)$ as $n \rightarrow \infty$ to a function f^* that satisfies $f^*(\varphi x) = f^*(x)$ a.e. The **individual (or pointwise) ergodic theorem** of Birkhoff (*Proc. Nat. Acad. Sci. US*, 17 (1931)) states that for every f belonging to the \dagger function space $L_1(X)$, the sequence $A_n f(x)$ converges a.e. to f^* . From either of these theorems it follows that for any set E satisfying $\varphi^{-1}(E) = E$ and $m(E) < \infty$, the limit function f^* satisfies $\int_E f^* dm = \int_E f dm$. In particular, if $m(X) = 1$ and φ is ergodic, then the limit f^* equals the constant $\int f dm$ a.e. This fact therefore gives a mathematical justification to the ergodic hypothesis, which states that the "time mean" $(\sum_{k=0}^{n-1} f(\varphi^k x))/n$ of what is observable over a sufficiently long time can be replaced by the "phase mean" $\int f dm$. Both von Neumann's theorem and Birkhoff's theorem were subsequently generalized in various directions by many authors.

(1) Mean ergodic theorems are concerned with the \dagger strong convergence of the sequence of averages $A_n = (\sum_{k=0}^{n-1} T^k)/n$ of the iterates of a \dagger bounded linear operator T on some \dagger Banach space. A generalization of von Neumann's theorem due to F. Riesz, K. Yosida, and S. Kakutani dispenses with the assumptions that the linear operator T is induced by a measure-preserving transformation φ and that T acts on the Hilbert space $L_2(X)$. A version of this generalization states that if a linear operator T defined on a Banach space \mathcal{X} satisfies the conditions

$$(i) \sup_{n \geq 1} \left\| \frac{1}{n} \sum_{k=0}^{n-1} T^k \right\| < \infty,$$

$$(ii) \lim_{n \rightarrow \infty} \frac{1}{n} \|T^n\| = 0,$$

then for an element $f \in \mathcal{X}$ the sequence of averages $A_n f$ converges strongly to an element $f^* \in \mathcal{X}$ if and only if there exists a subsequence converging \dagger weakly to f^* . From this theorem of Riesz, Yosida, and Kakutani follows the L_p -mean ergodic theorem ($1 < p < \infty$) for so-called **Markov operators**: If T is a linear operator defined on each of the Banach spaces $L_p(X)$ ($1 \leq p \leq \infty$) by means of the formula $Tf(x) = \int f(y)P(x, dy)$, where $P(x, B)$ is the \dagger transition probability of a \dagger Markov process on

(X, \mathcal{B}) leaving the measure m invariant (i.e., $\int P(x, B) dm = m(B)$ for every $B \in \mathcal{B}$) (\rightarrow 261 Markov Processes), then for every f belonging to $L_p(X)$ ($1 < p < \infty$) the sequence $A_n f$ converges in the norm of $L_p(X)$ to a limit function f^* .

(2) Birkhoff's ergodic theorem has been extended to the following individual ergodic theorem by E. Hopf (1954): If T is a \dagger positive linear operator mapping $L_1(X)$ into $L_1(X)$ and $L_\infty(X)$ into $L_\infty(X)$ with $\|T\|_1 \leq 1$ and $\|T\|_\infty \leq 1$, then for every f in $L_1(X)$ the sequence $A_n f$ converges a.e. to a limit f^* . If T is a Markov operator, then T maps each $L_p(X)$ into itself and satisfies $\|T\|_p \leq 1$ for each p ($1 \leq p \leq \infty$), and therefore Hopf's ergodic theorem applies to such T . Special cases of this theorem were proved earlier by J. Doob and by Kakutani. Later, N. Dunford and J. Schwartz showed that the assumption of the positivity of T can be dispensed with in Hopf's theorem. For a positive linear operator T on $L_1(X)$ satisfying $\|T\|_1 \leq 1$, R. Chacon and D. Ornstein (1960) proved that the **ratio ergodic theorem** holds: For every pair of functions f and g in $L_1(X)$ with $g \geq 0$ a.e., $\lim_{n \rightarrow \infty} \sum_{k=0}^{n-1} T^k f(x) / \sum_{k=0}^{n-1} T^k g(x)$ exists and is finite a.e. on the set $\{x | \sum_{k=0}^{n-1} T^k g(x) > 0\}$. This theorem extends earlier results of Hopf and W. Hurewicz dealing with special classes of operators arising from measurable transformations. Hopf's ergodic theorem can be deduced from the Chacon-Ornstein theorem, while it is known that there are positive operators T on $L_1(X)$ satisfying $\|T\|_1 \leq 1$ for which $\lim_{n \rightarrow \infty} A_n f$ fails to exist on a set of positive measure for some $f \in L_1(X)$. This shows that the assumption $\|T\|_\infty \leq 1$ is crucial in Hopf's theorem.

(3) As was the case in the original proof by Birkhoff of his ergodic theorem, every known proof of an individual ergodic theorem depends crucially on the so-called **maximal ergodic lemma** (or **maximal inequality**). For the case of a positive linear operator T on $L_1(X)$ with $\|T\|_1 \leq 1$, Hopf proved the relevant maximal ergodic lemma: If $E(f)$ is the set $\{x | \sup_{n \geq 1} A_n f(x) > 0\}$ for each f in $L^1(X)$, then $\int_{E(f)} f dm \geq 0$. Hopf's original proof of this lemma was quite intricate, but A. Garcia (1965) succeeded in giving an extremely simple and elegant proof. From the maximal ergodic lemma the following so-called **dominated ergodic theorem** can also be obtained: Let T be a linear operator mapping each $L_p(X)$ into $L_p(X)$ satisfying $\|T\|_p \leq 1$ for each p ($1 \leq p \leq \infty$). If for f in $L_p(X)$ we let $\tilde{f}(x) = \sup_{n \geq 1} |A_n f(x)|$, then if $1 < p < \infty$ we have

$$\int \tilde{f}(x)^p dm \leq \frac{2^p}{p-1} \int |f(x)|^p dm,$$

while if $p = 1$ and $m(X) < \infty$ we have

$$\int \tilde{f}(x) dm \leq 2 \left[m(X) + \int |f(x)| \log^+ |f(x)| dm \right].$$

This theorem was obtained first by N. Wiener (1939) for the special case of T induced by a measure-preserving transformation. M. Akcoglu (1975) proved an isometric "dilation" theorem for positive contractions (i.e., positive linear operators T for which $\|T\| \leq 1$) in the space $L_p(X)$ for $1 < p < \infty$, by means of which he was able to deduce a dominated ergodic theorem for an arbitrary positive contraction in $L_p(X)$ from the corresponding theorem for a positive linear isometry in $L_p(X)$ proved earlier by A. Ionescu-Tulcea. From this theorem of Akcoglu one can obtain the following individual ergodic theorem: If T is a positive contraction in $L_p(X)$ for some p with $1 < p < \infty$, then for every f in $L_p(X)$, the sequence $A_n f$ converges a.e.

(4) Both mean and individual ergodic theorems can be extended without difficulty to a continuous time parameter semigroup $\{T_t | t \geq 0\}$ of bounded linear operators such that $T_t T_s = T_{t+s}$ ($T_0 = I$), under a suitable continuity assumption on T_t with respect to t , by replacing the discrete time average $(\sum_{k=0}^{n-1} T^k)/n$ with $(\int_0^t T_s ds)/t$. Further extensions to n -parameter semigroups were obtained by N. Wiener and by N. Dunford and A. Zygmund. For mean ergodic theorems, even further extensions were possible to \dagger amenable semigroups of bounded linear operators. For 1-parameter semigroups, the behavior of the mean at zero, $(\int_0^t T_s ds)/t$ as $t \downarrow 0$ (**local ergodic theorem**) or $\lambda \int_0^\infty e^{-\lambda s} T_s ds$ as $\lambda \downarrow 0$ or $\lambda \uparrow \infty$ (**Abelian ergodic theorem**), has also been investigated by Wiener, U. Krengel, E. Hille, Yosida, and others. Abelian ergodic theorems are related to properties of the \dagger resolvent of the semigroup $\{T_t\}$ (\rightarrow 378 Semigroups of Operators and Evolution Equations). Further extensions of all these theorems in various directions have been given by many authors; for these extensions and related topics \rightarrow [5–7].

(5) J. F. C. Kingman (1968) proved an interesting and useful extension of (both mean and individual) ergodic theorems, called the **subadditive ergodic theorem**. A real-valued \dagger stochastic process $\{X_{i,k} | 0 \leq i < k, k = 1, 2, 3, \dots\}$ is called a **subadditive process** if it satisfies the following conditions: (i) Whenever $i < j < k$, $X_{i,k} \leq X_{i,j} + X_{j,k}$. (ii) The \dagger joint distribution of $\{X_{i+1,j+1}\}$ is the same as that of $\{X_{i,j}\}$. (iii) The \dagger expectation $g_k = E(X_{0,k})$ exists, and satisfies $g_k \geq -Ak$ for some constant A and for all $k > 1$. Kingman proved that if $\{X_{i,k}\}$ is a subadditive stochastic process, then the limit $\xi = \lim_{n \rightarrow \infty} (1/n)X_{0,n}$ exists a.e. and in the mean,

and $E(\xi) = \lim_{n \rightarrow \infty} (1/n)g_n$. Note that if φ is a measure-preserving transformation on a finite measure space (X, \mathcal{B}, m) and if f is an element of $L_1(X)$, then $X_{i,k} = \sum_{j=i}^{k-1} f \circ \varphi^j$ for $0 \leq i < k$, where $k = 1, 2, 3, \dots$ defines a subadditive process (in fact, $X_{i,k} = X_{i,j} + X_{j,k}$ for $i < j < k$). The **multiplicative ergodic theorem**, proved by V. Oseledec, which plays a significant role in ergodic theory of \dagger nonhyperbolic smooth dynamical systems and which has found applications also in \dagger algebraic groups, can be derived from the subadditive ergodic theorem [8, 9].

C. Recurrence and Invariant Measures

In this section we assume that the measure space (X, \mathcal{B}, m) is nonatomic. A nonsingular measurable transformation φ defined on (X, \mathcal{B}, m) is called **recurrent (infinitely recurrent)** if for every set B and for almost all $x \in B$, there exists an $n \in \mathbb{Z}^+$ (infinitely many $n \in \mathbb{Z}^+$) such that $\varphi^n(x) \in B$. A set W is called **wandering under** φ if $\varphi^{-n}(W) \cap \varphi^{-k}(W) = \emptyset$ for $n \neq k$. The transformation φ is called **conservative** if no sets of positive measure are wandering under φ , and **incompressible** if $B \supset \varphi^{-1}B$ implies $m(B - \varphi^{-1}B) = 0$. The following statements about a nonsingular measurable transformation φ are equivalent: (i) φ is recurrent; (ii) φ is infinitely recurrent; (iii) φ is incompressible; (iv) φ is conservative. An immediate consequence of this is the following **recurrence theorem** of Poincaré (in the form formulated by Carathéodory): A measure-preserving transformation on a finite measure space is infinitely recurrent. In fact, in order for a nonsingular measurable transformation φ to be recurrent (and hence infinitely recurrent) it is sufficient that there exist a finite measure μ invariant under φ and equivalent to (i.e., mutually \dagger absolutely continuous with) the given measure m .

The **invariant measure problem** is one of the basic problems in ergodic theory and is formulated abstractly in the following way: Given a nonsingular measurable transformation φ on a σ -finite measure space (X, \mathcal{B}, m) , find necessary and sufficient conditions for the existence of a finite (or σ -finite) measure invariant under φ and equivalent to m . The given measure m specifies only the class of equivalent measures among which an invariant measure is to be found. Therefore we can assume without loss of generality that m is a finite measure. For the remainder of this section, unless we explicitly state otherwise, we always mean by an invariant measure the one that is equivalent to m .

The Poincaré recurrence theorem states that φ being recurrent is necessary for the existence

of a finite invariant measure. The recurrence of φ is, however, not sufficient, since an ergodic transformation with an infinite but σ -finite invariant measure is recurrent and has no finite invariant measure. A necessary and sufficient condition for the existence of a finite invariant measure was given by a theorem of A. Hajian and Kakutani (1964) which states: φ has a finite invariant measure if and only if φ has no **weakly wandering sets** (a set W is called **weakly wandering under** φ if there exists an infinite subset $\{n_k\}$ of \mathbb{Z}^+ such that $\varphi^{-n_k}W \cap \varphi^{-n_j}W = \emptyset, k \neq j$). Hajian also proved that a bimeasurable transformation φ has a finite invariant measure if and only if φ is **strongly recurrent** in the following sense: For every set E with $m(E) > 0$, there exists a positive integer $k = k(E)$ such that

$$\max_{0 \leq j \leq k} m(\varphi^{n-j}E \cap E) > 0$$

for every $n \in \mathbb{Z}$.

H. Fürstenberg [11] obtained the following striking extension of the Poincaré recurrence theorem: If a bimeasurable transformation φ possesses a finite invariant measure, then for every set E with $m(E) > 0$ and for every integer $k \geq 2$, there exists $n \geq 1$ such that $m(E \cap \varphi^n E \cap \varphi^{2n} E \cap \dots \cap \varphi^{(k-1)n} E) > 0$. From this theorem one can deduce a difficult theorem of E. Szemerédi on \dagger arithmetic progressions which states: Any subset of the integers having positive \dagger upper density contains arithmetic progressions of arbitrary length. In fact, it is not difficult to show that the theorems of Fürstenberg and of Szemerédi are mutually equivalent, and for this reason the theorem of Fürstenberg is sometimes referred to as the **ergodic Szemerédi theorem**.

For a nonsingular bimeasurable transformation φ , a pair of sets A and B are said to be **countably equivalent under** φ if there exist countable decompositions $\{A_k | k \in \mathbb{Z}^+\}$ and $\{B_k | k \in \mathbb{Z}^+\}$ for A and B , respectively, and an infinite subset $\{n_k\}$ of \mathbb{Z} such that $\varphi^{n_k}A_k = B_k$ for each k . A and B are said to be **finitely equivalent under** φ if finite decompositions $\{A_k\}$ and $\{B_k\}$ can be chosen. It was proved by Hopf that (i) φ is recurrent if and only if no set of positive measure is finitely equivalent under φ to one of its proper subsets, and (ii) φ has a finite invariant measure if and only if no set of positive measure is countably equivalent under φ to one of its proper subsets. It can be shown that if φ is ergodic, then φ has no σ -finite invariant measure if and only if every pair of sets of positive measure are countably equivalent under φ .

The first example of a transformation admitting no σ -finite invariant measure was constructed by Ornstein in 1960. Since then, a

number of simpler examples have been obtained by L. Arnold, Brunel, and others. It is now known that there are many different types of transformations having no σ -finite invariant measure (\rightarrow Section F). Furthermore, it was shown by Ionescu-Tulcea that in the group of all nonsingular bimeasurable transformations with a suitable metric, those having a σ -finite invariant measure form a subset of the \dagger first category.

Various extensions of results on the invariant measure problem for nonsingular transformations to the case of \dagger Markov processes having nonsingular transition probabilities were obtained by Y. Ito, J. Neveu, S. Foguel, and others [12].

For investigation of detailed properties of particular transformations arising from classical dynamical systems, problems in number theory, and so on, rather than the existence of invariant measures it is more important to determine a specific form of an invariant measure with desirable properties and to develop methods to decide when such a measure is unique. Various people have considered special classes of transformations; these workers have been able to obtain explicit descriptions of invariant measures with nice properties for the transformations in question and have derived interesting consequences. Most important among these is the so-called **Gibbs measure**, introduced and investigated by Ya. Sinai. He obtained this notion by generalizing the concept of the **equilibrium Gibbs distribution**, which plays a prominent role in \dagger statistical mechanics. It is defined in the following way: Let X be a compact metric space, φ a homeomorphism on X , and μ_0 a probability measure on X invariant under φ . For a function g belonging to $L_\infty(X)$ and for $m, n > 0$ let

$$\Xi_{m,n}(g | \mu_0) = \int_X \exp \left(\sum_{k=-n}^m g(\varphi^k x) \right) d\mu_0(x),$$

and form a sequence of probability measures $\mu_{m,n}(g)$ absolutely continuous with respect to μ_0 , for which the \dagger Radon-Nikodym derivative

$$\frac{d\mu_{m,n}(g | g)}{d\mu_0(x)} = \frac{\exp \sum_{k=-n}^m g(\varphi^k x)}{\Xi_{m,n}(g | \mu_0)}$$

holds. A measure that is a limit point, in the sense of \dagger weak convergence, of the sequence of measures $\mu_{m,n}(g)$ is called a Gibbs measure constructed from μ_0 and g . It is clear that a Gibbs measure is invariant under φ . For mixing topological Markov shifts (\rightarrow Section D), Sinai showed that if one starts with the invariant measure μ_0 of **maximal entropy** (\rightarrow Section H), the existence of which was earlier shown by W. Parry, one can determine a class of functions g for which the Gibbs measure

is unique, i.e., $\mu(g) = \lim_{m,n \rightarrow \infty} \mu_{m,n}(g)$ exists. Sinai further investigated the properties of the unique measure $\mu(g)$ in detail. R. Bowen and D. Ruelle, defining the Gibbs measure somewhat differently, investigated the existence and uniqueness of such measures, thereby recapturing the results of Sinai in the case of mixing topological Markov shifts. With the aid of **Markov partitions** (\rightarrow Section G), these results on Gibbs measures were carried over to the case of \dagger Anosov and “axiom A” diffeomorphisms, and they provided essential tools in the investigation of the ergodic behavior of these transformations. For details \rightarrow [13, 14].

The explicit form of the density of the invariant measure with respect to the Lebesgue measure for the transformation associated with \dagger continued fraction expansion was already known to Gauss, and one can draw from it numerous conclusions about metric properties of continued fractions. The way in which Gauss was able to determine this invariant measure, however, was never explained. Recently, Sh. Ito, H. Nakada, and S. Tanaka (*Keio Eng. Rep.*, 30 (1977)) developed an interesting method to describe the mechanism used to arrive at this density function for the invariant measure for the continued fraction transformation. They employed similar methods in subsequent work to determine explicit density functions for invariant measures for other related number-theoretic transformations and for certain classes of continuous mappings over an interval; by means of the explicit forms of invariant measures they were able to describe the metric properties of these transformations in detail.

D. Examples and Construction of Measure-Preserving Transformations

Examples of measure-preserving transformations appear in many different contexts. We describe some of the important ones.

(1) Let G be a \dagger locally compact Abelian group satisfying the second axiom of \dagger countability (\rightarrow 423 Topological Groups), \mathcal{B} a σ -algebra of Borel subsets of G , and m its \dagger Haar measure (normalized if G is compact). Then (G, \mathcal{B}, m) is a Lebesgue measure space. For a fixed element $g_0 \in G$, define the transformation $\varphi_{g_0}: G \rightarrow G$ by $\varphi_{g_0}(g) = g + g_0$. Then φ_{g_0} is a bijective measure-preserving transformation on (G, \mathcal{B}, m) and is called the **rotation** on G by the element g_0 . If G is compact, then the rotation φ_{g_0} is ergodic if and only if the cyclic subgroup generated by the element g_0 is dense in G . If this happens, the element g_0 is called the **topological generator** of G . A group

is called **monothetic** if it has a topological generator.

(2) If φ is a group \dagger endomorphism of a compact Abelian group G , then φ preserves the Haar measure m . If φ is a group \dagger automorphism, then it is a bijective measure-preserving transformation on (G, \mathcal{B}, m) . A continuous group automorphism φ induces a group automorphism φ^* of the character group G^* .

The measure-preserving transformation φ is ergodic if and only if every character except the identity has an infinite orbit under the induced automorphism φ^* . When the group is the n -dimensional torus \mathbf{T}^n , a continuous group automorphism φ is uniquely represented by an $n \times n$ matrix with integer entries and with determinant ± 1 . In this case, φ is ergodic if and only if no roots of unity appear among the eigenvalues of the representing matrix.

(3) Let (Y, \mathcal{A}) be a measurable space, let $(Y_n, \mathcal{A}_n) = (Y, \mathcal{A})$ for each $n \in \mathbb{Z}$, and define (Y^*, \mathcal{A}^*) to be the \dagger product measurable space $(\prod_{n \in \mathbb{Z}} Y_n, \prod_{n \in \mathbb{Z}} \mathcal{A}_n)$. The transformation φ defined on (Y^*, \mathcal{A}^*) by

$$y^* = (\dots, y_{-1}, y_0, y_1, \dots) \\ \rightarrow \varphi(y^*) = (\dots, y'_{-1}, y'_0, y'_1, \dots)$$

with $y'_n = y_{n+1}$ for each n is called the **shift transformation**. Let μ be a probability measure on (Y, \mathcal{A}) such that (Y, \mathcal{A}, μ) is a Lebesgue measure space, let $\mu_n = \mu$ for each n , and define μ^* to be the \dagger product measure $\prod_{n \in \mathbb{Z}} \mu_n$ on (Y^*, \mathcal{A}^*) . Then $(Y^*, \mathcal{A}^*, \mu^*)$ is a Lebesgue measure space, and the shift transformation φ is a bijective measure-preserving transformation. Considered with the product measure, φ is called a **generalized Bernoulli shift**. When the set Y is at most countable and the measure μ on Y is given by a sequence $\{p_j\}$ of positive numbers with $\sum p_j = 1$, φ is called a **Bernoulli shift**. Suppose that $P(y, A)$ is a Markov transition function on (Y, \mathcal{A}) and π is a probability measure invariant under $P(y, A)$. Then we can define the **Markov measure** π^* on the product space (Y^*, \mathcal{A}^*) by setting

$$\pi^*(E^*) = \int_{A_{i+s}} \dots \int_{A_{i+1}} \int_{A_i} \pi(dy_0) P(y_0, dy_1) \\ \times P(y_1, dy_2) \dots P(y_{s-1}, dy_s),$$

for a cylinder set

$$E^* = \left(\prod_{j < i} Y_j \right) \times \left(\prod_{i \leq k \leq i+s} A_k \right) \times \left(\prod_{n > i+s} Y_n \right),$$

and extending it to all of \mathcal{A}^* . The shift transformation φ preserves the Markov measure π^* . Considered as a measure-preserving transformation on $(Y^*, \mathcal{A}^*, \pi^*)$, φ is called a **Markov shift**.

A generalized Bernoulli shift is always ergodic. A Markov shift is ergodic if and only if the corresponding Markov process is irreducible, which is the case if and only if the following property is satisfied: For every pair of sets A and B with $\pi(A)\pi(B) > 0$, there exists an $n \in \mathbb{Z}^+$ such that $\int_A P^n(y, B) d\pi > 0$.

There are other measures besides the product measure and the Markov measure that can be defined on the product space (Y^*, \mathcal{A}^*) and are invariant under the shift transformation φ . For example, if Y is a Borel subset of \mathbb{R} and \mathcal{A} is the σ -algebra of Borel subsets of Y , then any \dagger stationary stochastic process taking values in Y induces such a measure on (Y^*, \mathcal{A}^*) . When considered with a measure of this type, the shift transformation φ is called the **shift associated with the stationary process**. Properties of the shift associated with a \dagger stationary Gaussian process have been investigated by G. Maruyama, I. Girsanov, H. Totoki, and others. In particular, it is known that the shift is ergodic if and only if the \dagger spectral measure for the \dagger covariance function of the associated Gaussian process is continuous [15].

(4) Other important examples of measure-preserving transformations arise from classical dynamical systems, which will be described in Section G.

(5) There are several ways of constructing new measure-preserving transformations from given ones. We describe important cases.

(i) Let φ be a nonsingular, measurable, recurrent transformation (not necessarily measure-preserving) on a σ -finite measure space (X, \mathcal{B}, m) , and let A be a set of positive measure. For $x \in A$, let $n(x) = \min\{n \in \mathbb{Z}^+ \mid \varphi^n(x) \in A\}$. The transformation $\varphi_A: A \rightarrow A$ defined by $\varphi_A(x) = \varphi^{n(x)}(x)$ is a nonsingular measurable transformation on the measure space $(A, \mathcal{B} \cap A, m_A)$, where $m_A(B) = m(A \cap B)/m(A)$, and it is measure-preserving if φ is. We call φ_A the **transformation induced by φ on A** . It is ergodic if φ is ergodic.

(ii) Let φ be a nonsingular measurable transformation on a σ -finite measure space (X, \mathcal{B}, m) , and suppose that $\{A_n\}$ is a countable (possibly finite) partition of X . Define a function $f: X \rightarrow \mathbb{Z}^+$ by setting $f(x) = n$ for $x \in A_n$, and let $\tilde{X} = \{(x, j) \mid x \in X, 1 \leq j \leq f(x)\}$ be a subspace of the product measure space $(X \times \mathbb{Z}^+, \mathcal{B} \times \mathcal{C}, m \times \mu)$, where \mathcal{C} is the σ -algebra of all subsets of \mathbb{Z}^+ , and μ is the measure on $(\mathbb{Z}^+, \mathcal{C})$ defined by $\mu(\{n\}) = 1$ for each $n \in \mathbb{Z}^+$. The transformation $\tilde{\varphi}$ defined on \tilde{X} by $\tilde{\varphi}(x, j) = (x, j+1)$ if $1 \leq j < f(x)$ and $= (\varphi(x), 1)$ if $j = f(x)$ is a nonsingular measurable transformation on the measure space $(\tilde{X}, (\mathcal{B} \times \mathcal{C}) \cap \tilde{X}, (m \times \mu)_{\tilde{X}})$, and it is measure-preserving if φ is. We

call $\tilde{\varphi}$ the **transformation built from φ with the ceiling function f** . If φ is ergodic and $m(A_n) \rightarrow 0$ as $n \rightarrow \infty$, then $\tilde{\varphi}$ is also ergodic.

(iii) Suppose that ψ is a measure-preserving transformation on (X, \mathcal{B}, m) and φ_x is a measure-preserving transformation on (Y, \mathcal{A}, μ) for each $x \in X$. Assume that the mapping $(x, y) \rightarrow \varphi_x(y)$ is measurable with respect to the σ -algebras $\mathcal{B} \times \mathcal{A}$ and \mathcal{A} . The transformation θ defined on the product space $(X \times Y, \mathcal{B} \times \mathcal{A}, m \times \mu)$ by $\theta(x, y) = (\psi(x), \varphi_x(y))$ is measure-preserving and is called the **skew product** of ψ and $\{\varphi_x\}$. If $\varphi_x = \varphi$ for all $x \in X$, then we get a **direct product** transformation $\theta(x, y) = (\psi(x), \varphi(y))$.

(iv) A measure-preserving transformation φ on (Y, \mathcal{A}, μ) is said to be a **factor transformation** (or a **homomorphic image**) of a measure-preserving transformation ψ on (X, \mathcal{B}, m) if there exists a measurable transformation η from X onto Y such that $m \circ \eta^{-1} = \mu$ and $\varphi \eta = \eta \psi$. If \mathcal{B}' is a σ -subalgebra of \mathcal{B} and ψ leaves \mathcal{B}' invariant (i.e., $\psi^{-1}\mathcal{B}' \subset \mathcal{B}'$), then ψ induces a factor transformation φ on the measure space (X, \mathcal{B}', m) . Conversely, if a measure-preserving transformation φ on (Y, \mathcal{A}, μ) is a factor transformation of ψ on (X, \mathcal{B}, m) via a mapping η , then $\mathcal{B}' = \eta^{-1}\mathcal{A}$ is a σ -subalgebra of \mathcal{B} invariant under ψ .

(6) A one-parameter family $\{\varphi_t \mid t \in \mathbb{R}\}$ of bijective measure-preserving transformations on a measure space (X, \mathcal{B}, m) is called a **flow**. A flow is called **continuous** if the mapping $t \rightarrow T_t$ is \dagger weakly continuous where $\{T_t\}$ is the one-parameter family of \dagger unitary operators on $L^2(X)$ induced by the flow $\{\varphi_t\}$. A flow is called **measurable** if the mapping $(t, x) \rightarrow \varphi_t(x)$ is a measurable transformation of $\mathbb{R} \times X$ into X . A measurable flow is continuous. A. Vershik and Maruyama proved that for any continuous flow there exists a measurable flow, unique in a specified sense, which is spatially isomorphic (in the sense specified in Section E) to the given flow.

Important examples of flows are given by classical dynamical systems (\rightarrow Section G), and by continuous-time stationary stochastic processes.

An important tool in the study of flows is provided by the theorem of W. Ambrose and Kakutani: Every measurable ergodic flow without a fixed point is spatially isomorphic to an **S-flow**. A measurable flow $\{\varphi_t\}$ is called an **S-flow** (**special flow** or **flow built under a function**) if there exist a measure-preserving transformation φ of a measure space (X, \mathcal{B}, m) and an \mathbb{R}^+ -valued function f on (X, \mathcal{B}, m) such that each φ_t is a measure-preserving transformation on the subspace $\tilde{X} = \{(x, u) \mid x \in X, 0 \leq u \leq f(x)\}$ of the product measure space

$(X \times \mathbf{R}^+, \mathcal{B} \times \mathcal{M}, m \times \lambda)$ given by

$$\begin{aligned} \varphi_t(x, u) &= (x, u + t) \quad \text{if} \quad -u \leq t < -u + f(x), \\ &= \left(\varphi^n(x), u + t - \sum_{k=0}^{n-1} f(\varphi^k(x)) \right) \quad \text{if} \\ &\quad -u + \sum_{k=0}^{n-1} f(\varphi^k(x)) \leq t < -u + \sum_{k=0}^n f(\varphi^k(x)), \\ &= \left(\varphi^{-n}(x), u + t + \sum_{k=-n}^{-1} f(\varphi^k(x)) \right) \quad \text{if} \\ &\quad -u - \sum_{k=-n}^{-1} f(\varphi^k(x)) \leq t < -u - \sum_{k=-n+1}^{-1} f(\varphi^k(x)), \end{aligned}$$

$n \geq 1$. Here \mathcal{M} is the σ -algebra of Borel subsets of \mathbf{R}^+ , and λ is the usual Lebesgue measure.

E. Isomorphism Problems

In this section we assume that the Lebesgue measure spaces considered are probability spaces. For simplicity, following the common usage among Russian mathematicians, we call a measure-preserving transformation on (X, \mathcal{B}, m) an **endomorphism** and a bijective measure-preserving transformation an **automorphism**.

An automorphism φ_1 (a flow $\{\varphi_1^{(t)}\}$) on $(X_1, \mathcal{B}_1, m_1)$ is said to be **spatially isomorphic** (or **metrically isomorphic**) to an automorphism φ_2 (a flow $\{\varphi_2^{(t)}\}$) on $(X_2, \mathcal{B}_2, m_2)$ if there exist sets N_1 and N_2 with $m_1(N_1) = m_2(N_2) = 0$ and a bijective measurable transformation θ from $X_1 - N_1$ to $X_2 - N_2$ such that $m_2 \circ \theta = m_1$ and $\theta \varphi_1 = \varphi_2 \theta$ ($\theta \varphi_1^{(t)} = \varphi_2^{(t)} \theta$ for each t).

Classification of automorphisms and flows into isomorphism classes constitutes the central problem of modern ergodic theory. Properties of automorphisms and flows that are preserved under spatial isomorphisms are called **isomorphism invariants** (or **metric invariants**). There are several isomorphism invariants that are essential to the study of the isomorphism problem. We describe these below for the case of automorphisms. There are corresponding invariants for flows as well.

(1) Spectral Invariants. Two automorphisms φ_1 and φ_2 are said to be **spectrally isomorphic** if the unitary operators T_1 and T_2 induced by φ_1 and φ_2 on the Hilbert spaces $L_2(X_1)$ and $L_2(X_2)$, respectively, are unitarily equivalent (i.e., there exists an isometric isomorphism V of $L_2(X_1)$ onto $L_2(X_2)$ such that $VT_1 = T_2V$). Properties preserved under spectral isomorphisms are called **spectral invariants** (or **spectral properties**). If φ_1 and φ_2 are spatially isomorphic, it is clear that they are spectrally iso-

morphic; but the converse is not true in general.

(i) The property of φ being ergodic is a spectral property since φ is ergodic if and only if the number 1 is a simple eigenvalue of the induced unitary operator T . If φ is ergodic, then the set of all eigenvalues of the induced operator T forms a subgroup of the circle group, each eigenvalue is simple, and each eigenfunction has constant absolute value. If the spectrum of the induced operator T consists entirely of eigenvalues, φ is said to have **discrete spectrum** (or **pure point spectrum**). A theorem due to von Neumann and P. Halmos—the first theorem on the question of isomorphism—states that two ergodic automorphisms φ_1 and φ_2 with discrete spectra are spatially isomorphic if and only if they are spectrally isomorphic, which is the case if and only if the induced operators T_1 and T_2 have the same set of eigenvalues. Furthermore, every ergodic automorphism with discrete spectrum is spatially isomorphic to an ergodic rotation on a compact Abelian group [2].

Analogous results were obtained by L. Abramov for a bigger class of automorphisms, namely, for ergodic automorphisms having so-called **quasidiscrete spectra**.

(ii) An automorphism φ is ergodic if and only if for every pair of sets A, B ,

$$\lim_{n \rightarrow \infty} \frac{1}{n} \left(\sum_{k=0}^{n-1} m(\varphi^k(A) \cap B) \right) = m(A)m(B).$$

Strengthening this condition, we can define φ to be **weakly mixing** if for every pair of sets A, B ,

$$\lim_{n \rightarrow \infty} \frac{1}{n} \left(\sum_{k=0}^{n-1} |m(\varphi^k(A) \cap B) - m(A)m(B)| \right) = 0;$$

strongly mixing if

$$\lim_{k \rightarrow \infty} m(\varphi^k(A) \cap B) = m(A)m(B);$$

and **k -fold mixing** if for arbitrary choice of sets $A_j, j = 0, 1, \dots, k$,

$$\begin{aligned} \lim m(A_0 \cap \varphi^{n_1} A_1 \cap \varphi^{n_2} A_2 \dots \cap \varphi^{n_k} A_k) \\ = m(A_0)m(A_1) \dots m(A_k), \end{aligned}$$

where the limit is taken as $n_1, n_2, \dots, n_k \rightarrow \infty$ in such a way that $n_1 < n_2 < \dots < n_k$ and $\min_{1 \leq j \leq k} (n_j - n_{j-1}) \rightarrow \infty$. The property of an automorphism φ being weakly mixing or strongly mixing is a spectral property. For instance, φ is weakly mixing if and only if the number 1 is a simple eigenvalue and is the only eigenvalue of the induced operator T . It is also known that φ is weakly mixing if and only if the direct product automorphism $\varphi \times \varphi$ is ergodic. The set of all weakly mixing automorphisms forms a dense G_δ -set in the group

of all automorphisms on (X, \mathcal{B}, m) considered with the so-called weak topology (Halmos's theorem). On the other hand, it was shown by V. Rokhlin that the set of all strongly mixing automorphisms is a set of first category with respect to the weak topology. However, there are only a few known examples of automorphisms that are weakly mixing but not strongly mixing.

(iii) An automorphism φ is said to have **countable Lebesgue spectrum** if the maximal spectral type of the induced unitary operator T restricted to the $^\perp$ orthocomplement of the subspace of constant functions in $L_2(X)$ is equivalent to the Lebesgue measure and its $^\perp$ multiplicity is countably infinite.

(iv) An automorphism φ is called a **K-automorphism** (or **Kolmogorov automorphism**) if there exists a σ -subalgebra \mathcal{B}_0 of \mathcal{B} such that (a) $\varphi\mathcal{B}_0 \supset \mathcal{B}_0$ and $\varphi\mathcal{B}_0 \neq \mathcal{B}_0$, (b) $\bigvee_{n \in \mathbb{Z}} \varphi^n \mathcal{B}_0 = \mathcal{B}$, and (c) $\bigwedge_{n \in \mathbb{Z}} \varphi^n \mathcal{B}_0 = \mathcal{N}$, where \mathcal{N} is the σ -subalgebra of \mathcal{B} consisting of null sets and their complements. The notion of a **K-flow** (or **Kolmogorov flow**) is defined similarly. K-automorphisms are k -fold mixing for all orders k and have countable Lebesgue spectra.

Generalized Bernoulli shifts are all K-automorphisms. An ergodic Markov shift is a K-automorphism if and only if it is strongly mixing, which is the case if and only if the corresponding Markov process is $^\perp$ irreducible and $^\perp$ aperiodic (\rightarrow 260 Markov Chains B). A continuous group automorphism of a compact Abelian group is a K-automorphism if and only if it is ergodic. In particular, a continuous group automorphism of the n -dimensional torus \mathbb{T}^n is a K-automorphism if and only if no roots of unity appear among the eigenvalues of the representing matrix. Automorphisms and flows arising from classical dynamical systems also provide examples of K-automorphisms and K-flows. In particular, a $^\perp$ geodesic flow on a surface of negative curvature is a K-flow, and each automorphism (except the identity) of this flow is a K-automorphism. For the shift transformation φ associated with a stationary Gaussian process, it was shown by Maruyama [15] that φ is (a) weakly mixing if and only if it is ergodic, (b) strongly mixing if and only if the covariance function of the associated Gaussian process tends to 0 as $n \rightarrow \infty$, and (c) a K-automorphism if and only if the $^\perp$ spectral measure of the covariance function is absolutely continuous with respect to the Lebesgue measure.

(v) Examples of automorphisms having various types of spectra have been constructed by a number of authors by using stationary Gaussian processes and the theory of approximation developed by A. Katok and A. Stepin [16].

(vi) An ergodic automorphism with quasi-discrete spectrum has a mixed spectrum, that is, the spectrum of the induced unitary operator T has a continuous component and eigenvalues in addition to 1. Anzai (1951) constructed a special class of skew product automorphisms having mixed spectra and showed that in this class there are automorphisms that are spectrally isomorphic but not spatially isomorphic. However, the question of whether two spatially nonisomorphic automorphisms exist among automorphisms having the same purely continuous spectrum remained unanswered for a long time, until in 1958 Kolmogorov (*Dokl. Akad. Nauk SSSR*, (5) 119 (1958)) settled it affirmatively by using a new isomorphism invariant called **entropy**.

2. Generators and Entropy. (i) By a **partition** $\xi = \{A_\lambda\}$ of the space X we mean a collection of sets A_λ such that $A_\lambda \cap A_{\lambda'} = \emptyset$ whenever $\lambda \neq \lambda'$ and $\bigcup A_\lambda = X$. We denote by ε the partition of X into individual points, and by ν the trivial partition $\{X\}$. A partition into a finite (countable) number of sets is called a finite (countable) partition. A partition ξ is said to be finer than another partition ζ (or ζ is coarser than ξ) if for every $A \in \xi$ there is a set $B \in \zeta$ such that $A \subset B$. For a collection $\{\xi_\alpha\}$ of partitions of X , we denote by $\bigvee_\alpha \xi_\alpha$ the coarsest partition that is finer than each ξ_α , and by $\bigwedge_\alpha \xi_\alpha$ the finest partition that is coarser than each ξ_α . If $\xi_k = \{A_{k,n}\}$ is a sequence of countable (or finite) partitions, then $\bigvee_k \xi_k$ is precisely the partition of X into nonempty intersections of the form $\bigcap_k A_{k,n_k}$ with $A_{k,n_k} \in \xi_k$ for each k . With a partition ξ of X we associate a σ -subalgebra $\mathcal{B}(\xi)$ of \mathcal{B} which is the σ -algebra of all \mathcal{B} -measurable sets that are a union of elements in ξ . Two partitions ξ and ζ are said to coincide a.e. if $\mathcal{B}(\xi) = \mathcal{B}(\zeta)$ a.e. (i.e., for every $A \in \mathcal{B}(\xi)$ there exists a set B in $\mathcal{B}(\zeta)$ such that $m(A \cup B - A \cap B) = 0$ and conversely).

(ii) Suppose that φ is an endomorphism of (X, \mathcal{B}, m) and ξ a partition of X . By $\varphi^{-1}\xi$ we mean the partition $\{\varphi^{-1}(A) \mid A \in \xi\}$. If φ is an automorphism, we also define $\varphi\xi = \{\varphi(A) \mid A \in \xi\}$. A partition ξ is called a **generator** for an endomorphism φ if $\bigvee_{n=0}^\infty \varphi^{-n}\xi = \varepsilon$ a.s. If $\bigvee_{n=-\infty}^\infty \varphi^n\xi = \varepsilon$ a.s., ξ is called a **two-sided generator** for an automorphism φ .

An endomorphism φ is said to be **periodic at a point** $x \in X$ if there exists a positive integer n such that $\varphi^n(x) = x$ and **aperiodic** if the set of points of periodicity has measure zero. If the measure space (X, \mathcal{B}, m) is nonatomic, then every ergodic endomorphism on it is aperiodic. A theorem of Rokhlin states that every aperiodic automorphism φ has a countable two-sided generator. This implies that every such φ is spatially isomorphic to the shift

transformation on the infinite product space (Y^*, \mathcal{A}^*) considered with some invariant measure μ^* , where each coordinate space $Y_j = Y$ has at most a countable number of points. Krieger improved this result by showing that if an ergodic automorphism φ has finite entropy, then φ has a finite two-sided generator [17].

(iii) For a finite or countable partition $\xi = \{A_n\}$, define the **entropy $H(\xi)$ of the partition** to be $-\sum_n m(A_n) \log(m(A_n))$ (the logarithms here and below are natural logarithms). We denote by \mathcal{L} the set of all partitions ξ with $H(\xi) < \infty$. If $\xi \in \mathcal{L}$, then for any endomorphism φ the limit

$$h(\varphi, \xi) = \lim_{n \rightarrow \infty} \frac{1}{n} \left(H \left(\bigvee_{k=0}^{n-1} \varphi^{-k} \xi \right) \right)$$

exists and is finite. The **entropy $h(\varphi)$ of the endomorphism φ** is defined to be $\sup \{h(\varphi, \xi) \mid \xi \in \mathcal{L}\}$ and is an isomorphism invariant. Properties of entropy have been investigated extensively since the notion was introduced by Kolmogorov. We cite a few results.

(a) If a partition $\xi \in \mathcal{L}$ is a generator for an endomorphism φ or a two-sided generator for an automorphism φ , then $h(\varphi) = h(\varphi, \xi)$ (Sinaï's lemma). (b) For every integer n , $h(\varphi^n) = |n| h(\varphi)$, and for a measurable flow $\{\varphi_t\}$, $h(\varphi_t) = |t| h(\varphi_1)$ for every real number t . (c) If an automorphism φ is periodic, then $h(\varphi) = 0$. (d) If φ_1 is a factor transformation of φ_2 , then $h(\varphi_1) \leq h(\varphi_2)$. (e) $h(\varphi_1 \times \varphi_2) = h(\varphi_1) + h(\varphi_2)$. (There is a more complicated formula (due to Rokhlin) for the entropy of a skew product automorphism.) (f) If φ is a recurrent automorphism and φ_A is the automorphism induced by φ on a subset A with $m(A) > 0$, then $h(\varphi_A) = h(\varphi)/m(A)$ (**Abramov's formula**). (g) If φ is a Bernoulli shift with probability distribution $\{p_n\}$, then $h(\varphi) = -\sum_n p_n \log p_n$. (h) If φ is a Markov shift based on the Markov transition probability P_{ij} (defined on a countable or finite state space) and an invariant measure π_i , then

$$h(\varphi) = -\sum_i \sum_j \pi_i P_{ij} \log P_{ij}.$$

(i) If φ is ergodic and has a pure point spectrum, or more generally, has a quasisdiscrete spectrum, then $h(\varphi) = 0$. (j) For an ergodic group automorphism φ on an n -dimensional torus, $h(\varphi) = \sum \log |\lambda|$, where the sum is taken over all eigenvalues λ of modulus > 1 of the representing matrix. (k) If an automorphism φ has positive entropy, then in $L_2(X)$ there exists a subspace invariant under the induced unitary operator T such that the spectrum of T restricted to this subspace is countable Lebesgue (Rokhlin's theorem). It follows from (k) that automorphisms with singular spectra or spectra of finite multiplicity must have zero entropy. In proving assertion (g), Kolmogorov

established for the first time the fact that there are uncountably many spatially nonisomorphic Bernoulli shifts.

(iv) An automorphism φ is said to have **completely positive entropy** if $h(\varphi, \xi) > 0$ for every partition $\xi \neq v$. It was shown by Rokhlin and Sinaï that an automorphism φ has completely positive entropy if and only if φ is a K -automorphism. M. Pinsker proved that for every automorphism φ there exists a partition, called the **Pinsker partition**, that is invariant under φ and such that the factor transformation of φ with respect to this partition has zero entropy and is the largest among the factor transformations of φ with zero entropy.

(v) Rokhlin showed that $h(\varphi) = 0$ for an endomorphism φ if and only if all of its factor transformations are automorphisms. An endomorphism φ is called **exact** if $\bigwedge_{n=0}^{\infty} \varphi^{-n} \varepsilon = v$ a.e. Rokhlin introduced a way to associate with each endomorphism a certain automorphism, called the **natural extension**, which reflects the properties of the endomorphism. For example, an endomorphism and its natural extension are simultaneously ergodic or nonergodic, are mixing of the same order, and have equal entropy. The natural extension of an exact endomorphism is a K -automorphism.

(vi) Automorphisms φ_1 and φ_2 are said to be **weakly isomorphic** if each of them is a factor transformation of the other. Sinaï proved (1964) that for each ergodic automorphism with positive entropy, there exists a factor automorphism having the same entropy and isomorphic to a Bernoulli shift, and hence it follows in particular that Bernoulli shifts with the same entropy are weakly isomorphic. Ornstein (*Adv. in Math.*, 4 (1970)) went further and succeeded in proving the following remarkable result: Two Bernoulli shifts with equal entropy are spatially isomorphic. Partial results in this direction were obtained earlier by L. Meshalkin, J. Blum, and D. Hanson. In the proof of Ornstein's theorem, essential use was made of the following theorem of C. Shannon and B. McMillan, which plays a fundamental role in information theory (\rightarrow 213 Information Theory): Suppose that φ is an ergodic endomorphism on (X, \mathcal{B}, m) and ξ is a partition of X . For a point $x \in X$, let $A_n(x)$ denote the element in the partition $\bigvee_{k=0}^{n-1} \varphi^{-k} \xi$ that contains x . Then for almost all x ,

$$\lim_{n \rightarrow \infty} \left(-\frac{1}{n} \log m(A_n(x)) \right)$$

exists and equals $h(\varphi, \xi)$.

(vii) Techniques and ideas developed by Ornstein in his proof of the isomorphism theorem have been refined and extended further by himself, B. Weiss, N. Friedman, M. Smorodinsky, and others, and numerous re-

sults were subsequently obtained on the isomorphism problem. We describe below some of the main results and basic concepts; for more detailed accounts \rightarrow [21–24].

A sequence $\{\xi_n\}$ of partitions is said to be **independent** if for every choice of sets A_1, \dots, A_s with $A_k \in \xi_{n_k}$, $m(\bigcap_{k=1}^s A_k) = \prod_{k=1}^s m(A_k)$ whenever n_1, n_2, \dots, n_s are all distinct. For a fixed $\varepsilon > 0$, two partitions ξ and ζ are said to be ε -**independent** if

$$\sum_{A \in \xi, B \in \zeta} |m(A \cap B) - m(A)m(B)| < \varepsilon.$$

A pair (φ, ξ) , where φ is an automorphism of (X, \mathcal{B}, m) and ξ is a finite (or countable) partition of X , is called a **process** (on X).

$\mathcal{B}(\bigvee_{n=-\infty}^{\infty} \varphi^n \xi)$ is a σ -subalgebra of \mathcal{B} invariant under φ , and φ restricted to this σ -subalgebra is a factor automorphism of φ and is isomorphic to a shift transformation on an infinite product space, where each coordinate space has the same number of points as the number of atoms in ξ . A process (φ, ξ) is called a **Bernoulli process** (or an **independent process**) if the sequence of partitions $\{\varphi^n \xi | n \in \mathbb{Z}\}$ is independent, and a **weak Bernoulli (W.B.) process** if for every $\varepsilon > 0$ there exists a $k > 0$ such that the partitions $\bigvee_{i=k}^{k+n} \varphi^i \xi$ and $\bigvee_{i=-n}^0 \varphi^i \xi$ are ε -independent for all $n \geq 0$. Let J be a finite set and α, β be two functions from the set $\{1, 2, \dots, N\}$ to J . By $d_N(\alpha, \beta)$ we denote $(1/N) \# \{n | \alpha(n) \neq \beta(n)\}$, where $\#$ denotes the cardinality. d_N defines a metric on the space $J^{\{1, 2, \dots, N\}}$ called the **Hamming distance**. Now,

for a process (φ, ξ) on X with $\xi = \{A_j | j \in J\}$, we define for $x, y \in X$, $d_N^{\xi}(x, y)$ to be equal to $d_N(\xi_{\varphi}^N(x), \xi_{\varphi}^N(y))$, where for $x \in X$, $\xi_{\varphi}^N(x)$ is the point $(j(x), j(\varphi(x)), \dots, j(\varphi^{N-1}(x))) \in J^{\{1, 2, \dots, N\}}$ and $j(x)$ is the index $j \in J$ for which $x \in A_j$. A process (φ, ξ) is called **very weak Bernoulli (V.W.B.)** if for any $\varepsilon > 0$ there exists an N_0 such that whenever $N > N_0$ there is a set G with $m(G) > 1 - \varepsilon$ belonging to $\mathcal{B}(\bigvee_{n=-\infty}^0 \varphi^n \xi)$ satisfying the following condition: for any $A \in \mathcal{B}(\bigvee_{n=-\infty}^0 \varphi^n \xi)$ with $A \subset G$ and $m(A) > 0$, there exists a probability measure ν on $X \times X$ satisfying (i) $\nu(E \times X) = m(E)$ and $\nu(X \times F) = m(F)$ for all $E, F \in \mathcal{B}$ and (ii) $\int_{X \times X} d_N^{\xi}(x, y) d\nu < \varepsilon$. It is not difficult to show that W.B. processes are V.W.B. For processes (φ, ξ) on (X, \mathcal{B}, m) and $(\bar{\varphi}, \bar{\xi})$ on $(\bar{X}, \bar{\mathcal{B}}, \bar{m})$, where both ξ and $\bar{\xi}$ are indexed by the same finite set J , we define $\bar{d}_N((\varphi, \xi), (\bar{\varphi}, \bar{\xi}))$ to be $\inf \{ \int_{X \times \bar{X}} d_N^{\xi}(x, \bar{x}) d\rho(x, \bar{x}) \}$, where \inf is taken over all probability measures ρ on $X \times \bar{X}$ satisfying $\rho(E \times \bar{X}) = m(E)$ for all $E \in \mathcal{B}$ and $\rho(X \times \bar{E}) = \bar{m}(\bar{E})$ for all $\bar{E} \in \bar{\mathcal{B}}$. \bar{d}_N decreases with N , and we define $\bar{d}((\varphi, \xi), (\bar{\varphi}, \bar{\xi}))$ to be $\lim_{N \rightarrow \infty} \bar{d}_N((\varphi, \xi), (\bar{\varphi}, \bar{\xi}))$. Finally, a process (φ, ξ) is said to be **finitely determined (F.D.)** if for any $\varepsilon > 0$ there exists a $\delta > 0$ and N such that if $(\bar{\varphi}, \bar{\xi})$ is any

process satisfying (i) ξ and $\bar{\xi}$ are indexed by the same set J , (ii) $h(\varphi, \xi) - h(\bar{\varphi}, \bar{\xi}) < \delta$, and (iii) $\bar{d}_N((\varphi, \xi), (\bar{\varphi}, \bar{\xi})) < \delta$, then $\bar{d}((\varphi, \xi), (\bar{\varphi}, \bar{\xi})) < \varepsilon$. Let us call a partition ξ an **F.D. generator** for an automorphism φ if ξ is a two-sided generator for φ and the process (φ, ξ) is finitely determined. A general isomorphism theorem proved by Ornstein states: If automorphisms φ and $\bar{\varphi}$ have the same entropy and both have F.D. generators, then φ and $\bar{\varphi}$ are isomorphic. Ornstein and Weiss proved further that the process (φ, ξ) is F.D. if and only if it is V.W.B. From these basic results a number of results can be deduced. (a) Nontrivial factors of Bernoulli shifts are Bernoulli. (b) Strongly mixing Markov shifts have two-sided weak Bernoulli generators and hence are isomorphic to Bernoulli shifts. (c) Every Bernoulli shift can be embedded in a flow, which implies among other things that Bernoulli shifts have roots of all orders. (d) It was shown by Y. Katznelson that every ergodic group automorphism of an n -dimensional torus has a two-sided generator which can be shown to be V.W.B., and hence is also isomorphic to a Bernoulli shift. R. Adler and B. Weiss earlier proved by entirely different methods that on a 2-dimensional torus, two ergodic group automorphisms having the same entropy are spatially isomorphic. They have done this by constructing a two-sided generator ξ for such automorphisms which is also a Markov partition (\rightarrow Section G).

(viii) Among further positive results there are the following: (a) Except for a trivial change in the time scale, any two Bernoulli flows are isomorphic (Ornstein). (b) Every ergodic group automorphism of a compact group is isomorphic to a Bernoulli shift (Thomas and Miles; Lind). (c) A number of automorphisms and flows arising from classical dynamical systems are shown to be Bernoulli (\rightarrow Section G). (d) Examples of exact endomorphisms arise in connection with problems in number theory; for example, \dagger continued fraction expansion and β -expansion. The natural extensions of the exact endomorphisms associated with continued fraction expansion and β -expansion are now known to be spatially isomorphic to Bernoulli shifts.

(ix) Since many of the automorphisms that have been shown to be K -automorphisms are now known to be isomorphic to Bernoulli shifts, it is natural to expect that every K -automorphism is in fact Bernoulli. However, Ornstein (1973) constructed an example of a K -automorphism that is not a Bernoulli shift. A lot of work has since been done to investigate how bad K -automorphisms can be. It turns out that K -automorphisms share almost none of the finer properties of Bernoulli shifts. For example: (a) There are uncountably many

nonisomorphic K -automorphisms of the same entropy (Ornstein and P. Shields). (b) There is a K -flow that is not Bernoulli, and there are uncountably many nonisomorphic K -flows having the same entropy at time one (Smorodinsky). (c) There exists a K -automorphism not isomorphic to its inverse (Ornstein and Shields). (d) There exists an automorphism that cannot be written as a direct product of a K -automorphism and an automorphism with zero entropy. This example shows that a conjecture made earlier by Pinsker was false (Ornstein). (e) There are weakly isomorphic K -automorphisms that are not isomorphic (Politi and Rudolph).

F. Weak Equivalence and Monotone Equivalence

(1) Weak Equivalence. In order to construct examples of \dagger factors in the theory of von Neumann algebras (\rightarrow 308 Operator Algebras), F. Murray and von Neumann considered various ergodic groups of bimeasurable nonsingular transformations on a finite measure space. In this context a group $\mathcal{G} = \{g\}$ of transformations is called ergodic if $m((g^{-1}(B) \cup B) - (g^{-1}(B) \cap B)) = 0$ for every $g \in \mathcal{G}$ implies either $m(B) = 0$ or $m(X - B) = 0$. A measure μ is said to be invariant under the group $\mathcal{G} = \{g\}$ if μ is invariant under every transformation g in \mathcal{G} . Murray and von Neumann's construction (the so-called **group measure space construction**) gives a type II_1 \dagger factor if the group admits a finite equivalent invariant measure, a type II_∞ factor if it admits an infinite (but σ -finite) equivalent invariant measure, and a type III factor if it has no σ -finite equivalent invariant measure. In this connection we note that Hajian and Y. Itô extended the theorem of Hajian and Kakutani and proved that an arbitrary group $\mathcal{G} = \{g\}$ of nonsingular bimeasurable transformations admits a finite invariant measure if and only if no set of positive measure is weakly wandering under the group \mathcal{G} (a set W is said to be **weakly wandering under a group** \mathcal{G} if there exists an infinite subset $\{g_n | n \in \mathbb{Z}^+\}$ of \mathcal{G} such that $g_n(W) \cap g_k(W) = \emptyset$ for $n \neq k$). Analogously to the terminologies used in the theory of von Neumann algebras, we define ergodic countable group \mathcal{G} (or an ergodic bimeasurable nonsingular transformation φ) to be of **type** II_1 , II_∞ , or III if \mathcal{G} (or φ) has a finite equivalent invariant measure, a σ -finite infinite equivalent invariant measure, or no σ -finite equivalent invariant measure, respectively.

For a bimeasurable nonsingular transformation φ , define the **full group** $[\varphi]$ to be the group of all bimeasurable nonsingular transformations ψ such that, for some $n = n(x)$, $\psi(x)$

$= \varphi^n(x)$ for almost all x . Two transformations φ_1 and φ_2 are said to be **weakly equivalent** if there exists a bimeasurable nonsingular transformation θ such that $\theta[\varphi_1]\theta^{-1} = [\varphi_2]$. H. Dye proved that any pair of type II_1 transformations are weakly equivalent. It easily follows from this that the same is true for type II_∞ transformations. Krieger showed, on the other hand, that among type III transformations there are uncountably many weakly nonequivalent ones. In fact, Krieger [28] introduced an invariant for weak equivalence, called the **ratio set**, by means of which he classified type III transformations into mutually weakly nonequivalent subclasses III_λ for $0 \leq \lambda \leq 1$. Krieger showed further that (a) for $0 < \lambda \leq 1$, every pair of transformations in the class III_λ is weakly equivalent; (b) in the class III_0 there are uncountably many mutually weakly nonequivalent transformations; and (c) two ergodic transformations are weakly equivalent if and only if the corresponding factors constructed via the group measure space construction are \dagger *-isomorphic. An ergodic flow of nonsingular transformations (not necessarily measure-preserving) called the **associated flow** was constructed independently by Krieger [29] and by T. Hamachi, Y. Oka, and M. Osikawa [30], and was shown to give another effective invariant for weak equivalence. Krieger showed that the mapping which assigns to each ergodic transformation its associated flow gives a \dagger bijective mapping between the set of all weak equivalence classes of ergodic type III_0 transformations and the set of all isomorphism classes of aperiodic conservative ergodic flows. In this connection the theorem of U. Krengel and I. Kubo on the representation of ergodic flows, extending the theorem of Ambrose and Kakutani mentioned in Section D, plays a significant role.

A bimeasurable nonsingular transformation θ is called a **normalizer** of another transformation φ if it satisfies $\theta[\varphi] = [\varphi]\theta$. The set of all normalizers $\mathcal{N}(\varphi)$ of a transformation φ forms a group called the **normalizer group** which contains the full group $[\varphi]$ as a subgroup. One can introduce a suitable topology to $\mathcal{N}(\varphi)$ to make it a complete separable metrizable group. Hamachi [31] has shown that, for type III transformations φ , the quotient group $\mathcal{N}(\varphi)/[\varphi]^-$, where $[\varphi]^-$ denotes the closure of $[\varphi]$, is algebraically and topologically isomorphic to the \dagger commutant of the associated flow.

Results obtained by Krieger and others mentioned above were motivated in part by corresponding developments in von Neumann algebra theory due mainly to A. Connes (\rightarrow 308 Operator Algebras). From the recent deep result of Connes on the uniqueness of \dagger approximately finite-dimensional factors of type II_∞

it follows that every approximately finite-dimensional factor with the exception of type III₁ is \ast -isomorphic to a factor constructed from an ergodic transformation via the group measure space construction.

(2) Monotone Equivalence. The theory of weak equivalence discussed above deals with the structure of orbits of a transformation or of groups of transformations. In fact, transformations φ and ψ are weakly equivalent if and only if there exists a bimeasurable nonsingular transformation θ mapping the φ -orbit of almost all x onto the ψ -orbit of $\theta(x)$. A somewhat more stringent notion of equivalence dealing with orbit structure is called **monotone equivalence** or **Kakutani equivalence**. We say that measurable flows $\{\varphi_t\}$ and $\{\bar{\varphi}_t\}$ of measure-preserving transformations on finite measure spaces (X, \mathcal{B}, m) and $(\bar{X}, \bar{\mathcal{B}}, \bar{m})$, respectively, are monotonely equivalent if there exists a bimeasurable measure-preserving transformation θ on X to \bar{X} such that for almost all $x \in X$ and all $t \in \mathbb{R}$, $\theta\varphi_t(x) = \bar{\varphi}_{\tau(t,x)}\theta(x)$, where $\tau(t, x)$ is a monotone increasing function of t . Two S -flows (\rightarrow Section D) built over the same base transformation with different ceiling functions are monotonely equivalent, and it can be shown that monotonely equivalent ergodic flows are isomorphic to S -flows built over the same base transformation. This induces an equivalence relation on transformations, also called monotone equivalence or Kakutani equivalence: Two transformations φ and $\bar{\varphi}$ are monotonely equivalent if they can serve as base transformations of the same (or equivalent) flow. This notion of equivalence was introduced by Kakutani in [32], where he showed that φ and $\bar{\varphi}$ are monotonely equivalent if and only if there are sets $E \subset X$ and $\bar{E} \subset \bar{X}$ such that the induced transformations (\rightarrow Section D) φ_E and $\bar{\varphi}_{\bar{E}}$ are isomorphic. Abramov's formula mentioned in Section E implies that there are at least three classes of transformations (and flows) that are mutually nonequivalent: transformations (flows) of zero, finite, and infinite entropy. Nothing much was done in this equivalence theory for a number of years until in 1975 J. Feldman and E. Satayev independently showed that there are monotonely nonequivalent transformations within each class of zero, positive, and infinite entropy. Since then extensive work has been done by Feldman, Satayev, A. Katok, Ornstein, Weiss, D. Rudolph, M. Ratner, and others, and numerous results have been obtained. For detailed accounts of this development \rightarrow [22, 24, 33, 34]. The main idea employed by Feldman and Satayev was to introduce a new metric called an \bar{f} -metric and then to define a notion corresponding to

V.W.B. of the isomorphism theory described in Section E by using an \bar{f} - instead of a \bar{d} -metric. They then showed that this property, called **loosely Bernoulli (L.B.)** by Feldman and **monotonely very weak Bernoulli (M.V.W.B.)** by Satayev, stays invariant under monotone equivalence, and that there exist transformations with and without this property. An \bar{f} -metric is defined by starting off with an f_N -metric on the space $J^{\{1,2,\dots,N\}}$ instead of the Hamming distance d_N and proceeding in exactly same way as for the definition of \bar{d} , namely, by extending f_N to f_N^ξ and \bar{f}_N and finally to \bar{f} . For α and β in $J^{\{1,2,\dots,N\}}$, $f_N(\alpha, \beta)$ is defined by setting $1 - f_N(\alpha, \beta)$ equal to $1/N$ times the maximal integer n for which there are positive integers $j_1 < j_2 < \dots < j_n$, $k_1 < k_2 < \dots < k_n$ with $\alpha(j_i) = \beta(k_i)$, $i = 1, \dots, n$. Ornstein and Weiss discovered that by substituting \bar{f} for \bar{d} one can develop a theory of monotone equivalence that parallels the isomorphism theory described in Section E. One can define a process (φ, ξ) to be **finitely fixed (F.F.)** by substituting \bar{f} for \bar{d} in the definition of F.D. process, and, as was mentioned earlier, to be L.B. by doing the same in the definition of the V.W.B. process. Ornstein and Weiss proved: (a) If φ and $\bar{\varphi}$ have zero entropy, finite positive, or infinite entropy and if both have F.F. generators, then they are monotonely equivalent. (b) Let φ have an F.F. generator. If $h(\varphi) = 0$, then φ is monotonely equivalent to an irrational rotation of the circle. If $0 < h(\varphi) < \infty$, then φ is monotonely equivalent to a Bernoulli shift of finite entropy. If $h(\varphi) = \infty$, then φ is monotonely equivalent to a Bernoulli shift of infinite entropy. (c) If φ has an F.F. generator, then (φ, ξ) is F.F. for all nontrivial partitions ξ . (d) (φ, ξ) is F.F. if and only if it is L.B. It is known further that within each entropy class there exist uncountably many monotonely nonequivalent transformations. A measurable flow $\{\varphi_t\}$ is called L.B. if it can be represented as an S -flow built over an L.B. transformation. The L.B. flows of zero entropy are those monotonely equivalent to a Kronecker flow on a 2-dimensional torus, and L.B. flows of finite positive (infinite) entropy are those monotonely equivalent to the Bernoulli flow of finite (infinite) entropy. The direct product of an L.B. flow and a Bernoulli flow is L.B., while it was shown by M. Ratner that the horocycle flow (\rightarrow Section G) is L.B. but its direct product with itself is not.

G. Classical Dynamical Systems

By a **classical dynamical system** we mean a \ast diffeomorphism or a flow generated by a smooth \ast vector field on some \ast differentiable

manifold M^n . Such a system is nonsingular with respect to a measure defined by any \dagger Riemannian metric on M^n . For a fixed Riemannian metric, we call measures **smooth** if they have a smooth density with respect to the measure given by the metric.

(1) Among classical dynamical systems, **geodesic flows** have been investigated most extensively. Let $\mathcal{J}_1(M)$ be the unitary \dagger tangent bundle over the manifold M^n . A point $(x, e) \in \mathcal{J}_1(M)$ defines a unique \dagger geodesic through x in the direction of e . The geodesic flow on $\mathcal{J}_1(M)$ is the flow defined by $\varphi_t(x, e) = (x_t, e_t)$, where x_t is the point in M^n reached from x after time t under a motion with unit speed along the geodesic determined by (x, e) , and e_t is the unit vector at x_t tangent to the geodesic. The classical \dagger Liouville theorem in this context implies that the measure on $\mathcal{J}_1(M)$ that is the product of the measure on M^n induced by the metric and the Lebesgue measure on the $(n-1)$ -dimensional sphere gives a smooth invariant measure for the geodesic flow. A wide class of systems arising from mechanics can be described as geodesic flows.

Hopf and G. Hedlund proved that if the manifold M^n is compact and has constant negative curvature, then the geodesic flow is strongly mixing. Later, by using the theory of group \dagger representations, I. Gel'fand and S. Fomin proved that the spectrum of a geodesic flow on a compact manifold of constant negative curvature is Lebesgue, and is even countable Lebesgue in the case where the manifold is of dimension 2. F. Mautner and later L. Auslander, L. Green, and F. Hahn extended this algebraic method to flows obtained under the action of some one-parameter subgroup of a \dagger Lie group acting on its \dagger homogeneous space and obtained extensive results for the case of \dagger nilpotent and some \dagger solvable Lie groups [35].

(2) The flow on an n -dimensional torus defined by

$$\begin{aligned} \varphi_t(x_1, x_2, \dots, x_n) \\ = (x_1 + \omega_1 t, x_2 + \omega_2 t, \dots, x_n + \omega_n t) \end{aligned}$$

is called a **translational flow** or a **Kronecker flow**. The numbers $\omega_1, \omega_2, \dots, \omega_n$ are called **frequencies**. Every orbit of $\{\varphi_t\}$ is dense in the torus if and only if the frequencies are linearly independent over \mathbf{Z} . The motion under a translational flow with independent frequencies is called a **quasiperiodic** motion. A translation flow for a quasiperiodic motion has discrete spectrum.

(3) Sinai obtained a useful criterion for a classical dynamical system to be a K -system. Let M^n be compact, and suppose that $\{\varphi_t\}$ is a flow on M^n defined by a smooth vector field and preserving some smooth measure μ . A

one-parameter group $\{\psi_t\}$ of transformations of the space M^n , given by a vector field, is called the flow **transversal** to the flow $\{\varphi_t\}$ if (i) the decomposition of the space M^n into the trajectories of the flow $\{\psi_t\}$ is invariant under $\{\varphi_t\}$; (ii) the limit $\lim_{s \rightarrow 0} \lim_{t \rightarrow 0} (W_s(t, x) - t)/ts = \alpha(x)$ exists for the function $W_s(t, x)$, which is defined to be the time length of the segment $\{\varphi_s \psi_u(x) | 0 \leq u \leq t\}$ of the trajectory of the flow $\{\psi_t\}$. Sinai's fundamental theorem states that if a flow $\{\varphi_t\}$ is ergodic and has a transversal ergodic flow $\{\psi_t\}$ for which $\int \alpha(x) d\mu < 0$, then $\{\varphi_t\}$ is a K -flow. If $\alpha(x) < 0$, then we can even drop the assumption that $\{\varphi_t\}$ is ergodic. If $\int \alpha(x) d\mu > 0$, the theorem holds for the flow $\{\varphi_{-t}\}$.

A geodesic flow on a 2-dimensional manifold of constant negative curvature always has a transversal flow, called a **horocycle flow**. The ergodicity of a horocycle flow was proved by Hedlund. It follows from Sinai's fundamental theorem, therefore, that a geodesic flow on a surface of constant negative curvature is a K -flow. Sinai proved even more: A geodesic flow on any surface of negative curvature is a K -flow. There is an extension of the notion of transversal flow to higher dimensions, called **transversal field**. Using this notion Sinai proved that a geodesic flow on a manifold (of any dimension) of constant negative curvature is a K -flow. Finally, Ornstein and Weiss established that geodesic flows on compact manifolds of negative curvature are Bernoulli.

(4) D. Anosov considered a class of flows and diffeomorphisms satisfying a condition that characterizes unstable motions such as geodesic flows on a manifold of negative curvature. They are now called **Anosov flows** (or **Y-flows**) and **Anosov diffeomorphisms** (or **Y-diffeomorphisms**) (\rightarrow 126 Dynamical Systems). Anosov proved that if an Anosov flow has a smooth invariant measure, then it is ergodic and either it has a continuous nonconstant eigenfunction or it is a K -flow. Anosov diffeomorphisms with smooth invariant measures are K -automorphisms. Sinai constructed for \dagger transitive Anosov diffeomorphisms (and for Anosov flows) a special partition of the underlying manifold M called a **Markov partition** having desirable properties. The importance of such partitions lies in the fact that they enable one to represent such diffeomorphisms as Markov shifts. Starting with a measure invariant for such a Markov shift having the maximal entropy (\rightarrow Section H), Sinai constructed a Gibbs measure (\rightarrow Section C), which turned out to be unique in this case and gave rise to a natural invariant measure μ for the corresponding diffeomorphism. He proved further that the diffeomorphism φ considered as an

automorphism of the measure space (M, \mathcal{B}, μ) is a K -automorphism. It was shown subsequently by R. Azencott that φ is in fact Bernoulli with respect to μ . Sinai investigated further the uniqueness of the invariant measure attaining the maximal entropy for transitive Anosov diffeomorphisms, and he was able to show among other things that the set of transitive C^∞ -Anosov diffeomorphisms that do not have an invariant measure absolutely continuous with respect to the measure induced by the Riemannian metric on M contains an open dense subset. The methods employed by Sinai in these investigations were extended further by D. Ruelle, Bowen, and others. Bowen, in particular, was able to construct Markov partitions for a wider class of diffeomorphisms, namely, those satisfying the so-called **axiom A** introduced earlier by S. Smale, and characterized the Gibbs measures for diffeomorphisms in this class by means of the **variational principle** (\rightarrow Section H). For a more detailed account of the results of Sinai and Bowen \rightarrow [13, 14].

(5) An important example of a system that is neither an Anosov nor an "axiom A" system because of nonsmoothness has been studied by Sinai: the simplest mechanical model due to Boltzmann and Gibbs of an ideal gas, which is described as a system generated by tiny rigid spherical pellets moving inside a rectangular box and colliding elastically. Sinai succeeded in proving that this is a K -system, thereby giving an affirmative answer to the classical question of the ergodicity of the basic model of statistical mechanics [38]. It was shown subsequently by M. Aizenman, S. Goldstein, and J. Lebowitz that this system is Bernoulli. Sinai also investigated another nonsmooth system of classical importance: the system describing the motion of a billiard ball on a square table with a finite number of convex obstacles. He showed that such a system, is a K -system. Ornstein and G. Gallavotti then showed that Sinai's methods in fact show that the system is Bernoulli. Sinai's methods were extended further by L. Bunimovich and I. Kubo to study properties of billiard systems in more complicated domains. For more detailed account of these matters \rightarrow [24]. The results obtained by Sinai and Bowen for Anosov and "axiom A" systems were extended to even wider class of systems by A. Stepin, R. Sacksteder, M. Brin, and Ya. Pesin (\rightarrow [24]).

H. Miscellany

(1) An arbitrary aperiodic automorphism can be approximated by periodic automorphisms. More precisely, if φ is an aperiodic automor-

phism, then for any positive integer n and $\delta > 0$, there exists a periodic automorphism ψ of period n such that $m(\{x \mid \varphi(x) \neq \psi(x)\}) < (1/n) + \delta$ (theorem of Halmos and Rokhlin). The question as to how quickly this approximation can be carried out has been investigated in detail by Katok, Stepin, and others. The rate of this approximation was shown to have a close relationship with the entropy and spectral properties of the automorphism φ . By utilizing this relationship, various examples of automorphisms with specified spectral properties have been constructed [16].

(2) When an arbitrary automorphism φ is given on a Lebesgue measure space (X, \mathcal{B}, m) , there exists a unique decomposition $\xi = \{A_\lambda\}$ of X such that (i) each A_λ is invariant under φ and (ii) except for a negligible set (in a specified sense) of A_λ , each A_λ is turned (in a natural manner) into a Lebesgue measure space, and the restriction of φ to A_λ is an ergodic automorphism. This decomposition is called the **ergodic decomposition** of X with respect to φ . There is a corresponding decomposition with respect to a flow. A formula also exists that enables us to compute the entropy $h(\varphi)$ in terms of the entropies of ergodic components of φ .

(3) Let X be a compact metric space and $\varphi: X \rightarrow X$ a homeomorphism. N. Krylov and N. Bogolyubov showed that there always exists on X a Borel probability measure μ that is invariant under φ . Let \mathcal{P} be the collection of all Borel probability measures on X , and let \mathcal{P}_φ be the subset of \mathcal{P} consisting of those invariant under φ . Then \mathcal{P} and \mathcal{P}_φ are both convex sets compact with respect to the weak* topology. If \mathcal{E}_φ is the set of all extreme points in \mathcal{P}_φ , then by the Kreĭn-Milman theorem \mathcal{E}_φ is not empty. A measure μ in \mathcal{P}_φ belongs to \mathcal{E}_φ if and only if φ is ergodic with respect to μ . When the set \mathcal{E}_φ consists of a single element, φ is called **uniquely ergodic**; φ is called **minimal** if for every point $x \in X$, the orbit of x under $\varphi = \text{orb}_\varphi(x) = \{\varphi^n(x) \mid n \in \mathbb{Z}\}$ is dense in X . φ is called **strictly ergodic** if it is both minimal and uniquely ergodic. A theorem of J. Oxtoby states that φ is strictly ergodic if and only if for every continuous real-valued function f on X , the sequence of averages $(\sum_{k=0}^{n-1} f(\varphi^k(x)))/n$ converges uniformly to a constant $M(f)$. There are homeomorphisms that are minimal or uniquely ergodic but not strictly ergodic.

(4) R. Jewett proved that any weakly mixing measure-preserving transformation on a Lebesgue space is spatially isomorphic to a strictly ergodic transformation. Krieger extended the result by showing that if the entropy of an ergodic transformation φ is finite, then φ is spatially isomorphic to a strictly ergodic transformation. Similar results were

obtained for flows by K. Jacobs, M. Denker, and E. Eberlein (\rightarrow [39]).

(5) A topological analog of the notion of entropy, called **topological entropy**, was introduced by Adler, A. Konheim, and J. McAndrew. This is defined as follows: For every open covering \mathcal{A} of a compact topological space X , let $N(\mathcal{A})$ be the number of sets in the minimal subcovering of \mathcal{A} . For open coverings \mathcal{A} and \mathcal{B} , let $\mathcal{A} \vee \mathcal{B}$ be the open covering $\{A \cap B \mid A \in \mathcal{A}, B \in \mathcal{B}\}$. For any open covering \mathcal{A} and a continuous mapping φ on X , the limit $\lim_{n \rightarrow \infty} (\log N(\mathcal{A} \vee \varphi^{-1} \mathcal{A} \vee \dots \vee \varphi^{-(n-1)} \mathcal{A})) / n = h_{\text{top}}(\varphi, \mathcal{A})$ exists. Topological entropy $h_{\text{top}}(\varphi)$ of the continuous transformation φ is now defined by $h_{\text{top}}(\varphi) = \sup \{h_{\text{top}}(\varphi, \mathcal{A}) \mid \mathcal{A} \text{ an open covering of } X\}$.

L. Goodwyn showed that $h_{\text{top}}(\varphi) \geq h_{\mu}(\varphi)$ for any φ -invariant probability measure μ , where $h_{\mu}(\varphi)$ is the measure-theoretic entropy of φ regarded as a μ -preserving transformation. T. Goodman went further and succeeded in proving that $h_{\text{top}}(\varphi) = \sup \{h_{\mu}(\varphi) \mid \mu \text{ a } \varphi\text{-invariant probability measure}\}$. In connection with these results there is interest in the question of the existence and uniqueness of an invariant measure for φ with **maximal entropy**, i.e., a φ -invariant measure μ for which $h_{\mu}(\varphi) = h_{\text{top}}(\varphi)$. Such a measure does not always exist, and even if it does it may not be unique. The notions of topological entropy and of measures with maximal entropy are generalized by Ruelle in the following way. For an open covering \mathcal{A} , a continuous mapping φ , and a real-valued continuous function g on X , let $Z_n(\mathcal{A}, \varphi, g)$ be equal to $\inf \{ \sum_{O \in \Gamma} \sup_{x \in O} \exp \sum_{k=0}^{n-1} g(\varphi^k(x)) \}$, where the inf is taken over all subcoverings Γ of the covering $\mathcal{A} \vee \varphi^{-1} \mathcal{A} \vee \dots \vee \varphi^{-(n-1)} \mathcal{A}$. Then a finite limit $P(\mathcal{A}, \varphi, g) = \lim_{n \rightarrow \infty} 1/n \log Z_n(\mathcal{A}, \varphi, g)$ exists, and the quantity $P(\varphi, g) = \sup \{P(\mathcal{A}, \varphi, g) \mid \mathcal{A} \text{ an open covering of } X\}$ is called **topological pressure**. When $g=0$, $P(\varphi, g)$ reduces to $h_{\text{top}}(\varphi)$. Ruelle proved for expansive mappings φ that $P(\varphi, g) = \sup \{h_{\mu}(\varphi) + \int g d\mu \mid \mu \text{ is a } \varphi\text{-invariant probability measure}\}$. This assertion is called the **variational principle for the topological pressure**. The variation principle was proved for general continuous mappings φ by P. Walters. If a φ -invariant measure μ satisfies $P(\varphi, g) = h_{\mu}(\varphi) + \int g d\mu$, then μ is called an **equilibrium state** for g with respect to φ . It is known that for expansive mappings φ every continuous function g on X has an equilibrium state.

(6) Application of ergodic theory to problems in analytic number theory has been made by several authors. Ergodic or mixing properties of particular measure-preserving transformations that arise in connection with various problems in number theory have been ex-

ploited to give answers to these problems.

New and more striking applications of ideas of ergodic theory to different types of questions in number theory have been started by Yu. Linnik, Fürstenberg, W. Veech, T. Kamae, and others (\rightarrow [40, 41]).

7. Most of the results discussed in this article dealt with the action of a cyclic group of transformations or of one-parameter flow. There are significant extensions of many of these results to different types of group actions. For recent developments \rightarrow [22].

137 (VI.18) Erlangen Program

When F. Klein succeeded K. G. C. von Staudt as professor at the Philosophical Faculty of Erlangen University in 1872, he gave an inauguration lecture entitled “Comparative Consideration of Recent Geometric Researches,” which later appeared as an article [1]. In it he developed a penetrating idea, now called the Erlangen program, in which he utilized group-theoretic concepts to unify various kinds of geometries that until that time had been considered separately.

The concept of transformation is not new; it was, however, not until the 18th century that the concept of transformation groups was recognized as useful. The theory of invariants of linear groups and the †Galois theory of algebraic equations attracted attention in the 19th century. In the same century, †projective geometry made remarkable progress, for example, when A. Cayley and E. Laguerre discovered that metrical properties of Euclidean and †non-Euclidean geometries can be interpreted in the language of projective geometry. Cayley proclaimed, “All geometry is projective geometry.” After learning geometry under J. Plücker, Klein made the acquaintance of S. Lie. Both men understood the importance of the group concept in mathematics. Lie studied the theory of †continuous transformation groups, and Klein studied discontinuous transformation groups from a geometric standpoint. Klein was thus led to the idea of the Erlangen program, which provided a bird’s-eye view of geometry.

Klein’s idea can be summarized as follows: A space S is a given set with some geometric structure. Let a transformation group G of S be given. A subset of S , called a **figure**, may

have various kinds of properties. The study of the properties that are left invariant under all transformations belonging to G is called the **geometry of the space S subordinate to the group G** . Let this geometry be denoted by (S, G) . Two figures of S are said to be **congruent** in (S, G) if one of them is mapped to the other by a transformation of G . The geometry (S, G) is actually the theory of invariants of S under G , with the term **invariants** to be understood in a wider sense; it means both invariant quantities and invariant properties or relations.

Replacing G in (S, G) by a subgroup G' of G , we obtain another geometry (S, G') . A series of subgroups of G gives rise to a series of geometries. For instance, let A be a figure of S . The elements of G leaving A invariant form a subgroup $\hat{G}(A)$ of G that operates on $S' = S - A$. We thus obtain a geometry $(S', \hat{G}(A))$ in which A is called an **absolute figure**. In this way, many geometries are obtained from projective geometry. Klein gave numerous examples. It is noteworthy that he mentioned even the groups of \dagger rational and \dagger homeomorphic transformations.

Klein's idea not only synthesized the geometries known at that time, but also became a guiding principle for the development of new geometries.

In 1854 G. F. B. Riemann published his epochmaking idea of **Riemannian geometry**. This geometry has a metric, but in general lacks congruence transformations (isometries). Thus Riemannian geometry is a geometry that is not included in the framework of the Erlangen program. The importance of Riemannian geometry was acknowledged when it was used by A. Einstein in 1916 as a foundation of his general theory of relativity. H. Weyl, O. Veblen, and J. A. Schouten discovered geometries that are generalizations of affine, projective, and \dagger conformal geometries in the same way as Riemannian geometry is a generalization of Euclidean geometry. It became necessary to establish a theory that reconciled the ideas of Klein and Riemann; E. Cartan succeeded in this by introducing the notion of \dagger connection (\rightarrow 80 Connections). However, the Erlangen program, which gave an insight into the essential character of classical geometries, still maintains its role as one of the guiding principles of geometry.

138 (XV.3) Error Analysis

A. General Remarks

The data obtained by observations or measurements in astronomy, geodesy, and other sciences do not usually give exact values of the quantities in question. The **error** is the difference between the approximation and the exact value. The **theory of errors** originated from systematic work with data accompanied by errors, and the statistical treatment of experimental data was the main concern in the beginning stages (\rightarrow 397 Statistical Data Analysis). However, due to the recent development of high-speed computers it has become possible to carry out computations on a tremendously large scale, and the detailed analysis of errors has become an absolute necessity in modern numerical computation. Hence the analysis of errors in relation to numerical computation has become the center of research in error theory.

B. Errors

One rarely makes a mistake in counting a small number of things; therefore the exact value of the count can be determined. On the other hand, the exact value in decimals is never obtainable for a continuous quantity, say length, no matter how fine measurements are made, and a large or small stochastic error is thus inevitable in measuring a continuous quantity. A discrete finite quantity is a **digital quantity**, and a continuous quantity is an **analog quantity**. The natures of these two quantities are quite different. The values of a digital quantity are distributed on some discrete set, while the values of an analog quantity are distributed with a continuous

probability. Thus there is the possibility of error even for treatment of digital quantities, although checking the results for these quantities is easy. It is preferable to regard digital quantities as being analog quantities if the possible values are densely distributed.

On the other hand, when an appropriate analog computer is not available, analog quantities receive treatment similar to digital quantities. They are expressed as x times some unit, and x is expanded in the decimal or binary systems. An approximation to such an expansion is obtained by rounding off a numeral at some place, the position depending on the capacity for computation by available methods. There are two ways of rounding off numbers, the **fixed point method** and the **floating point method**. The former specifies the place of digits where the rounding off is made, and the latter essentially specifies the number of significant digits.

Classification of errors. (1) **Errors of input data** are the errors included in input data themselves. Such input-data errors include the errors that occur when we represent constants such as $1/3$, $\sqrt{2}$, π by finite decimals. (2) **Truncation errors** occur in approximate expressions for the computation formulas under consideration. (3) **Roundoff errors** occur in taking some finite number of digits from the earlier digits in the numerical value at each step. If the computation of an infinite number of digits were actually possible, no errors of this type would appear. Recently, it has been considered more preferable to call this "computational error."

The difference between fixed point and floating point rounding off is that the former is better suited for operations of addition and subtraction and the latter is better for multiplication and division. In fixed point rounding off, if a number is multiplied many times by numbers less than 1, a so-called **underflow** may occur, and many digits may disappear; a great deal of information can thus be lost. In computation for scientific research that involves frequent multiplication and division, floating point rounding off is preferable. It should be noted that rounding off for addition and subtraction may also cause a critical loss of information. This phenomenon is called **canceling** digits. For instance, in the subtraction $7.6325071 - 7.6318425 = 0.0006646$, where the subtrahend and minuend share several early significant digits, the difference loses those digits. Thus, relative errors may be magnified tremendously. By taking a large number of significant digits, such a situation may be avoided to some extent. So-called **high-precision computation** shows its effectiveness in such cases. Similarly, when a small number b is

added to a large number a , the result may be just a and the information of b could be lost completely. This kind of **loss of information** can often cause serious trouble.

C. Methods of Error Analysis

In order to analyze the **propagation of errors**, let us assume that all numbers are carried to infinitely many digits so that no roundoff error occurs. Suppose that we are to evaluate the function $y = f(x_1, \dots, x_n)$ when x_1, x_2, \dots, x_n are assigned. Let η be the truncation error of an approximate expression. If an input error δ_i for x_i exists, then the corresponding error for y is

$$\eta + \sum_{i=1}^n \frac{\partial f}{\partial x_i} \delta_i.$$

Moreover, suppose that at the final step we round off to get a result with a finite number of digits, by which an error ε is introduced. Then the final error δ for y is

$$\delta = \varepsilon + \eta + \sum_{i=1}^n \frac{\partial f}{\partial x_i} \delta_i.$$

This procedure is performed for each step needed in the computation. If $y = f(x_1, \dots, x_n)$ is a specified step, then the input error δ_i for that step involves all the errors arising before that step, i.e., δ_i is an **accumulated error**. **Forward analysis** is a method to estimate the total accumulated error from the initial input data. It is usually quite difficult to obtain precise estimates by means of this method. In contrast, J. H. Wilkinson proposed the following **backward analysis**. Here, the computational value y is considered as the exact result for the modified initial data $\tilde{x}_1, \dots, \tilde{x}_n$, say $y = f(\tilde{x}_1, \dots, \tilde{x}_n)$, and the estimates for $|x_i - \tilde{x}_i|$ are given. For example, in the binary floating point arithmetic of u bits, we always have the relation:

$$\begin{aligned} &\text{computational value of } a \pm b \\ &= a(1 + \delta) \pm b(1 + \varepsilon), \end{aligned}$$

with $|\delta|, |\varepsilon| \leq 2^{-u}$, even when cancellation or loss of information occurs. Wilkinson has made a deep investigation of error analysis for linear computation, algebraic equations, and eigenvalue problems by means of backward analysis [4, 5].

D. Proliferation of Errors

The phenomena usually called "accumulation of errors" should more appropriately be called the **proliferation** of errors, where the algorithm itself includes a particular mechanism to increase a small error indefinitely. An example is the recursion formula for [†]Bessel functions

stated as

$$J_{n+1}(x) = (2n/x)J_n(x) - J_{n-1}(x).$$

It is customary to compute $J_n(x)$ by this formula, starting with the values of $J_0(x)$ and $J_1(x)$, with x given. By putting $J_{n-1}(x) = y_n$, $J_n(x) = z_n$, the recursion formula can be regarded as a linear transformation of the point $P_n(y_n, z_n)$ in a plane into another point $P_{n+1}(y_{n+1}, z_{n+1})$, where

$$y_{n+1} = z_n, \quad z_{n+1} = -y_n + (2n/x)z_n.$$

The †eigenvalues λ_1, λ_2 of this †difference equation satisfy the following: As long as $n < |x|$, we have $|\lambda_1| = |\lambda_2| = 1$, while if $n > |x|$, λ_1 is greater than 1 and increases rapidly as n tends to infinity. Consequently, even the slightest discrepancy in the position of P_n gives rise to a greatly magnified error in the result [3].

Many studies have been made of the propagation of errors and of instability phenomena in the numerical solution of ordinary differential equations (\rightarrow 303 Numerical Solution of Ordinary Differential Equations; [2]).

139 (VI.3) Euclidean Geometry

A. History

Attempts to construct axiomatically the geometry of ordinary 3-dimensional space were undertaken by the ancient Greeks, culminating in Euclid's *Elements* (\rightarrow 187 Greek Mathematics). The **fifth postulate** of Euclid's *Elements* requires that two straight lines in a plane that meet a third line, as shown in Fig. 1, in angles α, β whose sum is less than 180° , have a common point. In the *Elements*, two straight lines in a plane without a common point are said to be **parallel**. It can be proved from other

axioms in the *Elements* that if $\alpha + \beta = 180^\circ$, the two lines l and l' in Fig. 2 are parallel. Hence given a line l and a point P not lying on l ,

Fig. 1

Fig. 2

there exists a line l' passing through P that is parallel to l . The fifth postulate ensures the uniqueness of the parallel l' passing through the given point P . For this reason, the fifth postulate is also called the **axiom of parallels**. Utilizing this axiom, we can prove the well-known theorems on parallel lines, the sum of interior angles of triangles, etc. The axiom plays an important role in the proof of the Pythagorean theorem in the *Elements*. The axiom is also called **Euclid's axiom**.

However, Euclid states this axiom in a quite complicated form, and unlike his other axioms, it cannot be verified within a bounded region of the space.

Many mathematicians tried in vain to deduce it from other axioms. Finally the axiom was shown to be independent of other axioms in the *Elements* by the invention of non-Euclidean geometry in the 19th century (\rightarrow 285 Non-Euclidean Geometry).

The term *Euclidean geometry* is used in contrast to *non-Euclidean geometry* to refer to the geometry based on Euclid's axiom of parallels as well as on other axioms explicit or implicit in Euclid's *Elements*. It was in the 19th century that a complete system of Euclidean geometry was explicitly formulated (\rightarrow 155 Foundations of Geometry). From the standpoint of present-day mathematics, it would be natural to define first the group of motions by the axiom of free mobility due to H. Helmholtz (\rightarrow Section B) and then, following F. Klein, to define Euclidean geometry as the study of properties of spaces that are invariant under the groups of these motions (\rightarrow 137 Erlangen Program).

B. Group of Motions

Let P be an †ordered field and A^n the n -dimensional †affine space over P . Let B^r be an r -dimensional affine subspace of A^n , B^{r-1} an $(r-1)$ -dimensional subspace of B^r , B^{r-2} an $(r-2)$ -dimensional subspace of B^{r-1} , etc. In the sequence of subspaces B^r, B^{r-1}, \dots, B^0 , each $B^k - B^{k-1}$ consists of two †half-spaces ($k = r, r-1, \dots, 1$). Let H^k be one of these half-

spaces. Then the sequence of half-spaces H^r, H^{r-1}, \dots, H^1 is called an r -dimensional **flag**, denoted by \mathfrak{H}^r ($n \geq r \geq 1$), and B^r and H^r are called the **principal space** and the **principal half-space** of \mathfrak{H}^r , respectively. If f is a †proper affine transformation of A^n , $f(H^r), f(H^{r-1}), \dots, f(H^1)$ form an r -dimensional flag \mathfrak{H}^r . We write $f(\mathfrak{H}^r) = \mathfrak{H}^r$.

Let \mathfrak{U}^n be the group of all proper affine transformations of A^n . The subgroup \mathfrak{B}^n of \mathfrak{U}^n with the following two properties is called the **group of motions**, and any element of \mathfrak{B}^n is called a **motion** (or **congruent transformation**).
(1) Let r be an integer between 1 and n , and let $\mathfrak{H}^r, \mathfrak{K}^r$ be any two r -dimensional flags. Then there exists an element f of \mathfrak{B}^n that carries \mathfrak{H}^r to \mathfrak{K}^r : $f(\mathfrak{H}^r) = \mathfrak{K}^r$. (2) Let f, g be two elements of \mathfrak{B}^n with $f(\mathfrak{H}^r) = \mathfrak{K}^r, g(\mathfrak{H}^r) = \mathfrak{K}^r$, and let p be any point on the principal space of \mathfrak{H}^r . Then $f(p) = g(p)$, that is, f, g have the same “effect” on the principal space. In particular, when $r = n$, then $f = g$. That \mathfrak{U}^n possesses a subgroup \mathfrak{B}^n with properties (1) and (2) is called the **axiom of free mobility**.

When $n = 1$, it is easy to see that the elements of \mathfrak{B}^1 are only those elements f of \mathfrak{U}^1 that can be expressed in the form $f(x) = \pm x + a$ ($a \in P$). When $n \geq 2$, P must satisfy the following condition in order that a subgroup \mathfrak{B}^n with properties (1) and (2) exists in \mathfrak{U}^n : If $a, b \in P$, then P contains an element x such that $x^2 = a^2 + b^2$. When this condition is satisfied, the ordered field P is called a **Pythagorean field**. Every †real closed field (e.g., the field \mathbf{R} of real numbers) is Pythagorean. If \mathfrak{B}^n exists, its uniqueness is assured by (1) and (2). Furthermore, if P contains a square root of every positive element (this condition is satisfied, for example, by \mathbf{R}), then conditions (1) and (2) are reducible to the case $r = n$ only, i.e., conditions (1) and (2) for other values of r follow from (1) and (2) with $r = n$. Hereafter, we assume the existence of \mathfrak{B}^n .

Suppose that we have $A^n \supset B^r \supset B^k$ ($n \geq r \geq k \geq 0$), and let \mathfrak{H}^r be a flag with the principal space B^r : $\mathfrak{H}^r = (H^r, \dots, H^k, \dots, H^1)$. Let \mathfrak{K}^r be another flag with the same principal space B^r : $\mathfrak{K}^r = (K^r, \dots, K^k, \dots, K^1)$, where we suppose that $H^j = K^j$ for $k \geq j \geq 1$, whereas for $r \geq i \geq k + 1$, we suppose that H^i and K^i are different half-spaces on B^i divided by B^{i-1} . The flag \mathfrak{K}^r is denoted by \mathfrak{H}_k^r . An element f of \mathfrak{B}^n with $f(\mathfrak{H}^r) = \mathfrak{H}_k^r$ is called a **symmetry** (or **reflection**) of B^r with respect to B^k . It leaves every point on B^k invariant, and its effect on B^r is determined only by B^k independently of the choice of half-spaces in \mathfrak{H}^r and \mathfrak{K}^r (subject to the conditions mentioned above). In particular, the symmetry of A^n with respect to a point $A^0 = p$ is called a **central symmetry** with respect to the **center** p ; and the symmetry of A^n

with respect to a hyperplane $A^{n-1} = h$ is called a **hyperplanar symmetry**. They are uniquely determined by p and h , respectively, and are denoted by S_p and $S(h)$, respectively. If $H(A^n)$ is the set of all hyperplanes of A^n , then \mathfrak{B}^n is generated by $\{S(h) | h \in H(A^n)\}$. Furthermore, if p, q are two points of A^n , the composite $S_p S_q$ is a parallel translation by $2 \cdot \overline{pq}$ (Fig. 3). The parallel translations generate a normal subgroup \mathfrak{T}^n of \mathfrak{B}^n . For $p, q \in A^n$, the element of \mathfrak{T}^n that carries p to q is denoted by τ_{pq} . The

Fig. 3

subgroup of \mathfrak{B}^n that leaves a point p of A^n invariant is denoted by O_p^n . Obviously, we have $O_q^n = \tau_{pq} O_p^n \tau_{pq}^{-1}$. Thus all the O_p^n (for $p \in A^n$) are isomorphic. We call O_p^n the **orthogonal group** around p and any element of O_p^n an **orthogonal transformation** around p . More generally, any element of \mathfrak{B}^n that leaves a subspace A^k of A^n invariant is called an **orthogonal transformation around the subspace A^k** .

An element of \mathfrak{B}^n that preserves the **orientation** of A^n , i.e., is represented by a †proper affinity with a positive determinant, is called a **proper motion**. Proper motions form a subgroup \mathfrak{B}_0^n of \mathfrak{B}^n . Rotations are, by definition, orthogonal transformations belonging to \mathfrak{B}_0^n . Sometimes \mathfrak{B}_0^n is called the group of motions; then \mathfrak{B}^n is called the group of motions in the wider sense. In this article, however, we shall continue to use the terminology introduced above.

The study of the properties of A^n invariant under \mathfrak{B}^n is **n -dimensional Euclidean geometry**. Since $\mathfrak{U}^n \supset \mathfrak{B}^n$, every proposition in affine geometry (\rightarrow 7 Affine Geometry) can be considered a proposition in Euclidean geometry, but there are many propositions that are proper to Euclidean geometry. Sometimes the subgroup of \mathfrak{U}^n generated by \mathfrak{B}^n and the **homotheties** of A^n , i.e., elements of \mathfrak{U}^n represented by †scalar matrices, is called the **group of motions in the wider sense**, and the study of properties of A^n invariant under this group is called **n -dimensional Euclidean geometry in the wider sense**.

C. Length of Segments

Two figures F, F' in A^n are said to be **congruent** if there exists an $f \in \mathfrak{B}^n$ such that $f(F) = F'$.

Then we write $F \equiv F'$. The congruence relation is an \dagger equivalence relation. Let $s = \overline{pq}$, $s' = \overline{p'q'}$ be two \dagger segments in A^n . We say that s, s' have equal **length** when $s \equiv s'$. Length is an attribute of the equivalence class of segments. The length of s is denoted by $|s|$. All segments of the form \overline{pp} are congruent, and we define $|\overline{pp}| = 0$. If we are given a length and a \dagger half-line starting from a point p , we can find a unique point q on it such that $|\overline{pq}| =$ the given length (Fig. 4). Let r be a point on the extension of \overline{pq} . The length $|\overline{pr}|$ is then uniquely determined by $|pq|$ and $|qr|$. It is defined as the

Fig. 4

sum of the lengths: $|\overline{pr}| = |\overline{pq}| + |\overline{qr}|$. With respect to the addition thus defined, lengths of segments in A^n form a \dagger commutative semigroup with the cancellation law, which can be extended to an \dagger Abelian group M with 0 as the identity element (\rightarrow 190 Groups P).

Let $|s| \neq 0$ and $|s'|$ be any length. On a half-line starting from p , we can find points q, r with $|\overline{pq}| = |s|$, $|\overline{pr}| = |s'|$. Then the element $pr/pq = \lambda \in P$ (\rightarrow 7 Affine Geometry) is a positive element of P uniquely determined by $|s|$ and $|s'|$. We call λ the **measure** of $|s'|$ with the **unit** $|s|$ and denote it by $|s'| : |s|$. If P is \dagger Archimedean, λ can be represented by a real number (\rightarrow 149 Fields N). We have $(|s'| + |s''|) : |s| = (|s'| : |s|) + (|s''| : |s|)$, $(|s''| : |s'|)(|s'| : |s''|) = |s''| : |s'|$ (if $|s'| \neq 0$). Thus the mapping $|s'| \rightarrow |s'| : |s|$ sends the additive semigroup of lengths to that of the positive elements of P . This is actually an isomorphism, which can be extended to an isomorphism of M onto the additive group of the field P .

Let $\varphi(X, X', \dots, X^a)$ be a \dagger homogeneous rational function of a finite number of variables X, X', \dots, X^a . If a relation $\varphi(\lambda, \lambda', \dots, \lambda^a) = 0$ holds for $\lambda = |s| : |s_0|$, $\lambda' = |s'| : |s_0|$, \dots , $\lambda^a = |s^a| : |s_0|$, where $|s_0|$ is a length $\neq 0$, then $\varphi(\lambda_1, \lambda'_1, \dots, \lambda_1^a) = 0$ holds also for $\lambda_1 = |s| : |s_1|$, $\lambda'_1 = |s'| : |s_1|$, \dots , $\lambda_1^a = |s^a| : |s_1|$, where $|s_1|$ is any other length $\neq 0$. Hence, in this case, the expression $\varphi(|s|, |s'|, \dots, |s^a|) = 0$ is meaningful.

D. Angles and Their Measure

An **angle** $\angle AOB$ is a figure constituted by two half-lines OA, OB starting from the same point O but belonging to different straight lines. The point O is called the **vertex**, and the two half-

lines OA, OB are called the **sides** of $\angle AOB$ (Fig. 5). Two congruent angles are said to have the same **measure**, denoted by $|\angle AOB|$ or sometimes simply by α . Let $\mathfrak{H}^2 = (H^2, H^1)$ (H^1 = half-line QR) be a given 2-dimensional flag and the given measure of an angle. Then we can find a unique half-line QP in the given half-plane H^2 such that $|\angle PQR| = \alpha$ (Fig. 6). The angle $\angle PQR$ is said to “belong” to \mathfrak{H}^2 . Let K^2 be the half-plane separated by the line $P \cup Q$ containing the half-line QR . Then $H^2 \cap K^2$ is called the **interior** of the angle

Fig. 5

Fig. 6

$\alpha' + \alpha'' = \alpha$.

$\angle PQR$. Let $\angle P'QR$ be another angle belonging to \mathfrak{H}^2 . If the interior of the latter angle is a subset of the interior of $\angle PQR$ and $QR \neq QP'$, then $|\angle PQR|$ is said to be greater than $|\angle P'QR|$, and we write $|\angle PQR| > |\angle P'QR|$. Actually, it can be shown that $>$ is a relation between the measures of $\angle PQR$ and $\angle P'QR$, and that the set of measures of angles forms a \dagger linearly ordered set with respect to the relation \geq defined in the obvious way. When $|\angle PQR| > |\angle P'QR|$, we write $|\angle PQR| = |\angle PQP'| + |\angle P'QR|$. Actually, these are relations between measures of angles. Furthermore, if the measure α of an angle is given, the set of measures of angles $\leq \alpha$ forms a linearly ordered set order-isomorphic to a segment and satisfying: (i) If $\beta < \gamma$ then there exists a δ such that $\beta + \delta = \gamma$; (ii) $\beta + \delta = \delta + \beta$; $(\beta_1 + \beta_2) + \beta_3 = \beta_1 + (\beta_2 + \beta_3)$ if all these sums exist; and (iii) $\beta_1 + \delta = \beta_2 + \delta$ implies $\beta_1 = \beta_2$. When P is Archimedean, these properties imply that the measure of angles $\leq |\angle PQR|$ can be represented by positive real numbers $\leq k$ (k is any given positive number) such that the relations of ordering an addition are preserved.

This one-to-one correspondence between the measures of angles and a subset S of the interval $(0, k]$ of real numbers can be extended to a correspondence between the measures of **general angles** and the subset of \mathbf{R} obtained from S . When $P = \mathbf{R}$, then we have $S = (0, k]$, and any real number appears as a measure of a general angle. We can choose $\angle PQR$ and the positive number k arbitrarily, but it is customary to choose them as follows. Suppose we are given an angle $\angle AOB$. Let the extensions of the half-lines OA and OB in the opposite directions be OA' and OB' , respectively. The angles $\angle AOB$ and $\angle A'OB$ are called **supplementary angles** of each other, and so are

$\angle AOB$ and $\angle A'OB'$. The angles $\angle AOB$ and $\angle A'OB'$ are called **vertical angles** to each other (Fig. 7). Any angle is congruent to its vertical angle, and an angle that is congruent to its supplementary angle has a fixed measure.

Fig. 7

Such an angle (or its measure) is called a **right angle**. In the description of the measurement of angles, we usually consider the case where the special angle $\angle PQR$ is a right angle, and we set $k = \pi/2$. (The existence and uniqueness of the right angle can be proved.) An angle that is greater (smaller) than a right angle is called an **obtuse (acute) angle**. A general angle whose measure is twice (four times) a right angle is called a **straight angle (perigon)**. Sometimes we choose as the "unit angle" $1/90$ of a right angle, which is called a **degree** (hence a right angle = 90 degrees, denoted by 90°); $1/60$ of a degree is called a **minute** ($1^\circ = 60$ minutes, denoted by $60'$), and $1/60$ of a minute is called a **second** ($1' = 60$ seconds, denoted by $60''$). If, as usual, we put the right angle equal to $\pi/2$, then the unit angle is $(2/\pi)(\text{right angle})$. This is called a **radian**, and $1 \text{ radian} = 180^\circ/\pi = 57^\circ 17' 44.806 \dots'' \approx 57.3^\circ$.

If a straight line m intersects two straight lines l, l' , eight angles $\alpha, \beta, \gamma, \delta, \alpha', \beta', \gamma', \delta'$ appear, as in (Fig. 8). In this figure, α and α', β and β', γ and $\gamma',$ and δ and δ' are called **corresponding angles**, while α and γ', β and δ', γ and $\alpha',$ and δ and β' are called **alternate angles** to each other. When l and l' are parallel, each of these angles is congruent to its corresponding or alternate angle.

The **Pythagorean theorem** asserts that if a triangle $\triangle ABC$ is given for which $\angle ABC$ is a right angle (Fig. 9), then $|AB|^2 + |BC|^2 = |CA|^2$ (which makes sense since $X^2 + Y^2 - Z^2$ is a homogeneous polynomial).

Fig. 8

Fig. 9

E. Rectangular Coordinates

When two straight lines l, m intersect, two pairs of vertical angles appear. If one of these angles is a right angle, then all are. Then we

say that l and m are **orthogonal** (or **perpendicular**) to each other, and write $l \perp m$. Let l be a line and A^r an r -dimensional subspace of A^n ($1 \leq r \leq n-1$) intersecting l at a point $O = A^r \cap l$. If l is orthogonal to all lines on A^r passing through O , then l is said to be orthogonal to A^r , and we write $l \perp A^r$ (Fig. 10). If A^{n-1} is any hyperplane in A^n , then there exists a unique line l through a given point P of A^n that is orthogonal to A^{n-1} ; this l is called the **perpendicular** to A^{n-1} through P , and the

Fig. 10

intersection $l \cap A^{n-1}$ is called the **foot of the perpendicular** through P . When A^{n-1} is given, the mapping from A^n to A^{n-1} assigning to every point P of A^n the foot of the perpendicular through P is called the **orthogonal projection** from A^n to A^{n-1} .

Let $\mathfrak{H}^n = (H^n, H^{n-1}, \dots, H^1)$ be an n -dimensional flag of A^n and O the initial point of the half-line H^1 . Then we can find a point E_i in H^i ($i = 1, 2, \dots, n$) such that $O \cup E_i \perp O \cup E_j$ ($i \neq j, i, j = 1, 2, \dots, n$). Moreover, if $|e|$ is any unit of length, then E_i can be chosen uniquely so that $|OE_i| = |e|$ ($i = 1, 2, \dots, n$). Then O, E_1, \dots, E_n are independent points in A^n , and we have $A^n = O \cup E_1 \cup \dots \cup E_n$. Thus we have a frame $\Sigma = (O; E_1, \dots, E_n)$ of A^n with O as origin and the E_i as unit points. Such a frame is called an **orthogonal frame**. A coordinate system with this frame, called an **orthogonal coordinate system adapted to \mathfrak{H}^n** , is uniquely determined by \mathfrak{H}^n . A motion is characterized as an affinity sending one orthogonal frame onto another or onto itself.

Utilizing an orthogonal coordinate system, the lengths of segments and the measures of angles can be expressed simply. Let (x_1, \dots, x_n) be the coordinates of X with respect to such a coordinate system. Then the length of the segment $|OX|$ (with $|e|$ as unit) is equal to $(\sum_{i=1}^n x_i^2)^{1/2}$, and when Y is another point, with coordinates (y_1, \dots, y_n) , $O \neq X, O \neq Y$, then we have

$$\cos |\angle XOY| = \frac{\sum_{i=1}^n x_i y_i}{(\sum_{i=1}^n x_i^2)^{1/2} (\sum_{i=1}^n y_i^2)^{1/2}}.$$

In particular, we have $O \cup X \perp O \cup Y$ if and only if $\sum_{i=1}^n x_i y_i = 0$.

We may write $\mathbf{x} = \overrightarrow{OX}$ for the location vector of X . Then the affinity $A\mathbf{x} + \mathbf{b}$ is a motion if and only if A is an orthogonal matrix. Thus the inner product (\mathbf{x}, \mathbf{y}) is invariant

under motions; it therefore has meaning in Euclidean geometry. If we put $|\mathbf{x}| = (\mathbf{x}, \mathbf{x})^{1/2}$, then the right-hand sides of the formulas for $|OX|$ and $\cos \angle XOY$ can be written as $|\mathbf{x}|$ and $(\mathbf{x}, \mathbf{y})/(|\mathbf{x}| \cdot |\mathbf{y}|)$. More generally, we have $|XY| = |\mathbf{y} - \mathbf{x}|$. This is the **Euclidean distance** (or simply **distance**) between X and Y . Then A^n becomes a \dagger metric space with this distance, i.e., a Euclidean space. Historically, the notion of metric spaces was introduced in generalizing Euclidean spaces (\rightarrow 273 Metric Spaces).

F. Area and Volume

The subset I^n of A^n consisting of points (x_1, \dots, x_n) with respect to an orthogonal coordinate system, with $0 \leq x_i \leq 1$, $i = 1, \dots, n$, is called an n -dimensional **unit cube**. A function m that assigns to \dagger polyhedra in the wider sense P, Q, \dots in A^n nonnegative real numbers $m(P), m(Q), \dots$ is called an n -dimensional **volume** if it satisfies the following four conditions: (1) $m(\emptyset) = 0$. (2) $m(P \cup Q) + m(P \cap Q) = m(P) + m(Q)$. (3) If P is sent to Q by a translation, then $m(P) = m(Q)$. (4) $m(I^n) = 1$. It has been proved that such a function is unique and has the property that $P \equiv Q$ implies $m(P) = m(Q)$. Thus the concept of volume can be defined in the framework of Euclidean geometry. More generally, if the affinity $f(\mathbf{x}) = A\mathbf{x} + \mathbf{b}$ sends P onto Q , then $m(Q) = cm(P)$, where c is the absolute value of the determinant $|A|$. If P is covered by a finite number of hyperplanes, then $m(P) = 0$, and if P is a \dagger parallelootope with n independent edges $\mathbf{a}_1, \dots, \mathbf{a}_n$, then $m(P) = \text{abs}|\mathbf{a}_1, \dots, \mathbf{a}_n|$, where $|\mathbf{a}_1, \dots, \mathbf{a}_n|$ is the determinant of the $n \times n$ matrix with \mathbf{a}_i as the i th column vector, and $\text{abs } x$ is the absolute value of the real number x . If P is an n -simplex whose vertices have location vectors $\mathbf{x}_0, \mathbf{x}_1, \dots, \mathbf{x}_n$, then we have

$$m(P) = \frac{1}{n!} \text{abs} \begin{vmatrix} 1 & 1 & \dots & 1 \\ \mathbf{x}_0 & \mathbf{x}_1 & \dots & \mathbf{x}_n \end{vmatrix}.$$

The volume of any polyhedron can be obtained by dividing it into n -simplexes and summing their volumes. If P is an r -dimensional polyhedron in A^n , then the r -dimensional volume of P is obtained by dividing P into r -simplexes and summing their r -dimensional volumes (in the respective r -dimensional Euclidean spaces containing them). In particular, when $r = 1$, we speak of **length** (e.g., the length of a broken line), and when $r = 2$, of **area**. If V is the r -dimensional volume of an r -dimensional parallelootope with r edges $\mathbf{a}_1, \dots, \mathbf{a}_r$, we have the formula

$$V^2 = \begin{vmatrix} (\mathbf{a}_1, \mathbf{a}_1) & \dots & (\mathbf{a}_1, \mathbf{a}_r) \\ \vdots & \ddots & \vdots \\ (\mathbf{a}_r, \mathbf{a}_1) & \dots & (\mathbf{a}_r, \mathbf{a}_r) \end{vmatrix}.$$

The notion of measure of point sets other than polyhedra is a generalization of the notion of volume of polyhedra (\rightarrow 270 Measure Theory).

G. Orthonormalization

Let O, A_1, \dots, A_n be $n+1$ \dagger independent points in A^n . Then the n vectors $\overrightarrow{OA_i} = \mathbf{a}_i$, $i = 1, \dots, n$, are independent. The points O, A_1, \dots, A_n determine an n -dimensional flag \mathfrak{H}^n of A^n as follows. Let H_1 be the half-line OA_1 , H_2 be the half-plane on the plane $O \cup A_1 \cup A_2$ separated by the line $O \cup A_1$ in which A_2 lies, \dots , H_n be the half-space on A^n separated by the hyperplane $O \cup A_1 \cup \dots \cup A_{n-1}$ in which A_n lies. Let $\mathbf{b}_1, \dots, \mathbf{b}_n$ be the unit vectors of the rectangular coordinate system adapted to \mathfrak{H}^n . Suppose further that we are given a rectangular coordinate system. Then $\mathbf{b}_1, \dots, \mathbf{b}_n$ can be obtained from $\mathbf{a}_1, \dots, \mathbf{a}_n$ by the following procedure, called **orthonormalization** (E. Schmidt): First put $\mathbf{b}_1 = \mathbf{a}_1/|\mathbf{a}_1|$, so that $|\mathbf{b}_1| = 1$. Then $\mathbf{c}_2 = \mathbf{a}_2 - (\mathbf{a}_2, \mathbf{b}_1)\mathbf{b}_1$ satisfies $(\mathbf{b}_1, \mathbf{c}_2) = 0$, $\mathbf{c}_2 \neq 0$. Put $\mathbf{b}_2 = \mathbf{c}_2/|\mathbf{c}_2|$. Then we have $(\mathbf{b}_1, \mathbf{b}_2) = 0$, $|\mathbf{b}_2| = 1$. When $\mathbf{b}_1, \dots, \mathbf{b}_{i-1}$ are obtained in this way, so that $(\mathbf{b}_j, \mathbf{b}_k) = \delta_{jk}$ for $1 \leq j, k \leq i-1$, then $\mathbf{c}_i = \mathbf{a}_i - (\mathbf{a}_i, \mathbf{b}_1)\mathbf{b}_1 - \dots - (\mathbf{a}_i, \mathbf{b}_{i-1})\mathbf{b}_{i-1}$ satisfies $(\mathbf{b}_j, \mathbf{c}_i) = 0$, $\mathbf{c}_i \neq 0$. Hence $\mathbf{b}_i = \mathbf{c}_i/|\mathbf{c}_i|$ added to $\mathbf{b}_1, \dots, \mathbf{b}_{i-1}$ retains the property $(\mathbf{b}_j, \mathbf{b}_k) = \delta_{jk}$ for $1 \leq j, k \leq i$, and this procedure can be continued to $i = n$.

Two vectors \mathbf{u}, \mathbf{v} are called **orthogonal** (denoted $\mathbf{u} \perp \mathbf{v}$) if $(\mathbf{u}, \mathbf{v}) = 0$, and \mathbf{u} is called **normalized** when $|\mathbf{u}| = 1$. Thus any two of the vectors $\mathbf{b}_1, \dots, \mathbf{b}_n$ are orthogonal, and each of them is normalized. Between given vectors $\mathbf{a}_1, \dots, \mathbf{a}_n$ and $\mathbf{b}_1, \dots, \mathbf{b}_n$ we have the relation $\{\mathbf{a}_1, \dots, \mathbf{a}_i\}$ ($=$ the linear space generated by $\mathbf{a}_1, \dots, \mathbf{a}_i$) $= \{\mathbf{b}_1, \dots, \mathbf{b}_i\}$, $i = 1, \dots, n$.

Let $\mathfrak{M}_1, \mathfrak{M}_2$ be two subspaces of the linear space \mathfrak{M} of the vectors of the Euclidean space A^n . If any element of \mathfrak{M}_1 is orthogonal to any element of \mathfrak{M}_2 , then \mathfrak{M}_1 and \mathfrak{M}_2 are called **orthogonal** and written $\mathfrak{M}_1 \perp \mathfrak{M}_2$. For any proper subspace \mathfrak{M}_1 of \mathfrak{M} , it can be shown by the method of orthonormalization that there exists a unique proper subspace \mathfrak{M}_2 of \mathfrak{M} such that $\mathfrak{M} = \mathfrak{M}_1 \cup \mathfrak{M}_2$, $\mathfrak{M}_1 \perp \mathfrak{M}_2$. Such a subspace \mathfrak{M}_2 is called the **orthocomplement** of \mathfrak{M}_1 (with respect to \mathfrak{M}). Then $\mathfrak{M}_1 \cap \mathfrak{M}_2 = \{0\}$ follows, and hence $\mathfrak{M} = \mathfrak{M}_1 + \mathfrak{M}_2$. Every element \mathbf{a} of \mathfrak{M} is therefore written uniquely in the form $\mathbf{a}_1 + \mathbf{a}_2$, $\mathbf{a}_1 \in \mathfrak{M}_1$, $\mathbf{a}_2 \in \mathfrak{M}_2$; we call \mathbf{a}_1 the \mathfrak{M}_1 -component of \mathbf{a} and \mathbf{a}_2 the **orthogonal component** of \mathbf{a} with respect to \mathfrak{M}_1 . The mapping from \mathfrak{M} to \mathfrak{M}_1 assigning \mathbf{a}_1 to \mathbf{a} is called the **orthogonal projection** from \mathfrak{M} to \mathfrak{M}_1 ; it is a linear and \dagger idempotent mapping.

H. Distance between Subspaces

Since the Euclidean space A^n is a metric space, the distance is defined between any two non-empty subsets of A^n (\rightarrow 273 Metric Spaces).

Let A^r, B^s be two subspaces of dimensions r, s of A^n , and let d be the distance between them. Then it can be shown that there exist points $p \in A^r, q \in B^s$ such that $d = \overline{pq}$, and if $p' \in A^r, q' \in B^s$ are any other points with $d = \overline{p'q'}$, then $\overline{pq} = \overline{p'q'}$. In particular, when $r = 0$ and $s = n - 1$ (i.e., when $A^r = p$ is a point and $B^s = B^{n-1}$ is a hyperplane), the distance d can be obtained as follows: If $(\mathbf{a}, \mathbf{x}) = b$ is an equation of B^{n-1} and \mathbf{p} is the location vector of p , then $d = |(\mathbf{a}, \mathbf{p}) - b|/|\mathbf{a}|$. If $|\mathbf{a}| = 1$ in this equation of B^{n-1} , then d is given simply by $|(\mathbf{a}, \mathbf{p}) - b|$. An equation $(\mathbf{a}, \mathbf{x}) = b$ of a hyperplane is said to be in **Hesse's normal form** if $|\mathbf{a}| = 1$.

I. Spheres and Subspaces

The set of points in a Euclidean space lying at a fixed distance r from a given point is called the **sphere of radius r** with **center** at the given point. If \mathbf{p} is the location vector of the center of this sphere with respect to a given rectangular coordinate system, then the equation of the sphere is $|\mathbf{x} - \mathbf{p}| = r$ or $(\mathbf{x}, \mathbf{x}) - 2(\mathbf{p}, \mathbf{x}) + (\mathbf{p}, \mathbf{p}) - r^2 = 0$. The set of points lying at equal distances from $k + 1$ points with location vectors $\mathbf{p}_0, \mathbf{p}_1, \dots, \mathbf{p}_k$ ($k \geq 1$) is a linear subspace of the space (which may be \emptyset or the entire space). If these points are independent, then the subspace has dimension $n - k$, where n is the dimension of the entire space. In particular, if these points are vertices of an n -dimensional \dagger simplex, then there is a unique sphere passing through them, called the **circumscribing sphere** of the simplex. In this case, the simplex is said to be **inscribed** in the sphere. If $\mathbf{p}_0, \mathbf{p}_1, \dots, \mathbf{p}_n$ are location vectors of the vertices of the simplex, then the equation of the circumscribing sphere of the simplex is given by

$$\begin{vmatrix} 1 & 1 & \dots & 1 & 1 \\ \mathbf{p}_0 & \mathbf{p}_1 & \dots & \mathbf{p}_n & \mathbf{x} \\ \mathbf{p}_0^2 & \mathbf{p}_1^2 & \dots & \mathbf{p}_n^2 & \mathbf{x}^2 \end{vmatrix} = 0.$$

When $n = 2$ or 3 , there are many classical results concerning the circumscribing circle of a triangle, the circumscribing sphere of a simplex, and other figures related to a triangle or a simplex.

140 (VI.4)
Euclidean Spaces

A space satisfying the axioms of Euclidean geometry is called a **Euclidean space**. An \dagger affine space having as \dagger standard vector space an n -dimensional Euclidean \dagger inner product space over a real number field \mathbf{R} is an n -dimensional Euclidean space E^n . In an n -dimensional Euclidean space E^n , we fix an \dagger orthogonal frame $\Sigma = (O, E_1, \dots, E_n)$, $e_i = \overline{OE_i}$, $(e_i, e_j) = \delta_{ij}$. The frame Σ determines \dagger rectangular coordinates (x_1, x_2, \dots, x_n) of each point in E^n . We can thus establish a one-to-one correspondence between E^n and $\mathbf{R}^n = \{(x_1, \dots, x_n) | x_i \in \mathbf{R}\}$. In this sense we identify E^n and \mathbf{R}^n and usually call \mathbf{R}^n itself a Euclidean space. The 1-dimensional space \mathbf{R}^1 is a straight line, and the \dagger Cartesian product of n copies of \mathbf{R}^1 is an n -dimensional Euclidean space (or **Cartesian space**). Given points $x = (x_1, x_2, \dots, x_n)$ and $y = (y_1, y_2, \dots, y_n)$ in the Euclidean space \mathbf{R}^n , the \dagger distance $d(x, y)$ between them is given by

$$\sqrt{(y_1 - x_1)^2 + \dots + (y_n - x_n)^2}.$$

Thus the distance $d(x, y)$ supplies \mathbf{R}^n with the structure of a \dagger metric space. We call x_i the i th coordinate of the point x , the point $(0, \dots, 0)$ the **origin** of \mathbf{R}^n , and the set of points $\{x | -\infty < x_i < \infty; x_j = 0, j \neq i\}$ the x_i -**axis** (or i th **co-ordinate axis**). For an integer m such that $-1 \leq m \leq n$, we define m -dimensional \dagger subspaces in \mathbf{R}^n ; a -1 -dimensional subspace is the empty set, a 0 -dimensional subspace is a point, and a 1 -dimensional subspace is a straight line. If we take an orthogonal frame, an m -dimensional subspace is represented as an \mathbf{R}^m (\rightarrow 139 Euclidean Geometry; 7 Affine Geometry).

As a \dagger topological space, \mathbf{R}^n is \dagger locally compact and \dagger connected. A bounded closed set in \mathbf{R}^n is \dagger compact (**Bolzano-Weierstrass theorem**).

Given a point $a = (a_1, \dots, a_n)$ in \mathbf{R}^n and a real positive number r , the subset $\{x | d(x, a) \leq r\}$ of

\mathbf{R}^n is called an n -dimensional **solid sphere**, **solid n -sphere**, **ball**, **n -ball**, **disk**, or **n -disk** with center a and radius r , its \dagger interior $\{x \mid d(x, a) < r\}$ an n -dimensional **open sphere**, **open n -sphere**, **open ball**, **open n -ball**, **open disk**, or **open n -disk**, and its \dagger boundary $\{x \mid d(x, a) = r\}$ an $(n-1)$ -dimensional **sphere** or **$(n-1)$ -sphere**. In particular, a 2-dimensional solid sphere is called a **circular disk**, its interior an **open circle**, and its boundary a **circumference**. A disk or a circumference is sometimes called simply a **circle**.

The family of n -dimensional open spheres with center a gives a base for a neighborhood system of the point a . Suppose that we are given a sphere S and two points x, y on S . The points x, y are called **antipodal points** on the sphere S if there exists a straight line L passing through the center of S such that $S \cap L = \{x, y\}$. The segment (or the length of the segment) whose endpoints are antipodal points is called the **diameter** of the solid sphere (or of the sphere). The notion of \dagger diameter (\rightarrow 273 Metric Spaces) of a solid sphere or of a sphere considered as a subset of the metric space \mathbf{R}^n coincides with the notion of diameter of the corresponding set defined above. When $n \geq 3$, the intersection of a sphere and a 2-dimensional plane passing through the center of the sphere is called a **great circle** of the sphere. For m such that $1 \leq m \leq n$, we consider an m -dimensional solid sphere or an $(m-1)$ -dimensional sphere in an m -dimensional plane \mathbf{R}^m . These spheres are also called m -dimensional solid spheres or $(m-1)$ -dimensional spheres in \mathbf{R}^n .

In particular, the solid sphere of radius 1 having the origin as its center is called the **unit disk**, **unit ball**, or **unit cell**, and its boundary is called the **unit sphere**. (In particular, when we deal with the 2-dimensional space \mathbf{R}^2 , we use the term *circle* instead of *sphere*, as in **unit circle**.) The points $(0, \dots, 0, 1)$ and $(0, \dots, 0, -1)$ are called the **north pole** and **south pole** of the unit sphere, respectively. The $(n-2)$ -dimensional sphere, which is the intersection of the unit sphere and the hyperplane $x_n = 0$, is called the **equator**; the part of the unit sphere that is "above" this hyperplane (i.e., in the half-space $x_n \geq 0$) is called the **northern hemisphere**, and the part that is "below" the hyperplane (i.e., in the half-space $x_n \leq 0$) the **southern hemisphere**.

Let a_i, b_i be real numbers satisfying $a_i < b_i$ ($i = 1, 2, \dots, n$). The subset $\{x \mid a_i < x_i < b_i, i = 1, 2, \dots, n\}$ of \mathbf{R}^n is called an **open interval** of \mathbf{R}^n , and the subset $\{x \mid a_i \leq x_i \leq b_i\}$ a **closed interval**. They are sometimes called **rectangles** (when $n = 2$), **rectangular parallelepipeds**, or **boxes**. An open interval is actually an open set of \mathbf{R}^n , and a closed interval is a closed set. In particular, the closed interval $\{x \mid 0 \leq x_i \leq 1, i = 1, 2, \dots, n\}$ is called the **unit cube** (or **unit n -**

cube) of \mathbf{R}^n . We can take the set of open intervals as base for a neighborhood system of \mathbf{R}^n .

All the \dagger convex closed sets (for example, closed intervals) having interior points in \mathbf{R}^n are homeomorphic to an n -dimensional solid sphere. A topological space I^n that is homeomorphic to an n -dimensional solid sphere is called an n -dimensional (**topological**) **solid sphere**, (**topological**) **n -cell**, or **n -element**. A topological space S^{n-1} homeomorphic to an $(n-1)$ -dimensional sphere is called an $(n-1)$ -dimensional **topological sphere** (or simply $(n-1)$ -dimensional sphere). The spaces I^n and S^{n-1} are \dagger orientable \dagger topological manifolds whose orientations are determined by assigning the generators of the (relative) \dagger homology groups $H_n(I^n, \dot{I}^n)$ and $H_{n-1}(S^{n-1})$, respectively (both are infinite cyclic groups). By means of the \dagger boundary operator $\partial: H_n(I^n, \dot{I}^n) \rightarrow H_{n-1}(S^{n-1})$, the orientation of I^n or S^{n-1} determines that of the other.

141 (XXI.22) Euler, Leonhard

Leonhard Euler (April 15, 1707–September 18, 1783) was born in Basel, Switzerland. In his mathematical development he was greatly influenced by the Bernoullis (\rightarrow 38 Bernoulli Family). He was invited to the St. Petersburg Academy in 1726 and remained there until 1741, when he was invited to Berlin by Frederick the Great (1712–1786). Euler was active at the Berlin Academy until 1766, when he returned to St. Petersburg. Already having lost the sight of his right eye in 1735, he now became blind in his left eye also. This, however, did not impede his research in any way, and he continued to work actively until his death in St. Petersburg.

Euler was the central figure in the mathematical activities of the 18th century. He was interested in all fields of mathematics, but especially in analysis in the style of \dagger Leibniz, which had been passed down through the Bernoullis and was developed by him into a form that led to the mathematics of the 19th century. Through his work analysis became more easily applicable to the fields of physics and dynamics. He developed calculus further and dealt formally with complex numbers. He also contributed to such fields as \dagger partial differential equations, the theory of \dagger elliptic func-

tions, and the calculus of variations. He contributed much to the progress of algebra and theory of numbers in this period, and also did pioneering work in topology. He had, however, little of the concern for rigorous foundations that characterized the 19th century. He was the most prolific mathematician of all time, and his collected works are still incomplete, though some seventy volumes have already been published.

142 (XV.11) Evaluation of Functions

A. History

By the evaluation of a function $f(x)$ we mean the application of algorithms for obtaining the approximate value of the function. The evaluation methods are classified roughly into two groups: (1) evaluation of functions using approximation formulas, and (2) evaluation using microprogramming techniques. The advent of high-speed computers has brought about drastic changes in the evaluation of functions. Before the introduction of high-speed computers in the 1940s, mathematical tables had played a prominent role. The first issue (published in 1943) of the journal *Mathematical tables and other aids to computation* (MTAC), the predecessor of the journal *Mathematics of computation*, was primarily concerned with tables of mathematical functions. One of the aims of this journal was to facilitate the exchange of information on errors in the tables. The tables, obtained in the past by tedious hand calculation, can now be easily prepared by high-speed computers, and there was a period when more accurate and extensive tables were published one after another. It is ironic, however, that high-speed computers revolutionized numerical analysis and prompted a shift of emphasis in the field, beginning in the 1950s, away from the use of numerical tables and toward exploration of the most efficient methods of approximation of the functions, thus causing a rapid decrease in the need for tables.

Recently, a significant trend in computer design has replaced the conventional logic control section with “stored logic,” or microprogrammed control, stored in high-speed,

nondestructive Read-Only Storage (ROS). For example, the microprogrammed control used for the unified COordinate Rotation DIGital Computer (CORDIC) algorithm is effective in calculating elementary functions because of its simplicity, accuracy, and capability of high-speed execution via parallel processing. It is not clear whether the applications of approximation formulas heretofore in use will be superseded by microprogramming techniques in all kinds of computers. However, the value of the approximation formulas recognized in the 1950s has been declining insofar as elementary functions are concerned. Recently, as a method for the evaluation of functions based on a new viewpoint, some “unrestricted” algorithms have been proposed by Brent [1], which are useful for the computation of elementary and special functions when the required precision is not known in advance or when high accuracy is necessary. It is expected that methods for the evaluation of functions using approximation formulas will be further developed as microprogramming techniques and unrestricted algorithms see wider use.

B. Evaluation of Functions Using Approximation Formulas

Suppose we approximate a function $f(x)$ by a function $g(x)$ using the following class of functions $p_i(x)$ and $q_j(x)$. Let continuous functions $p_1(x), \dots, p_n(x)$ and $q_1(x), \dots, q_m(x)$ defined on a closed interval $[a, b]$ satisfy the following conditions: (i) p_1, \dots, p_n and q_1, \dots, q_m are both linearly independent; (ii) there exist at most a finite number of zeros for $\sum_{j=1}^m b_j q_j(x)$ in $[a, b]$ for any choice of b_1, b_2, \dots, b_m , except for the case $b_1 = b_2 = \dots = b_m = 0$; (iii) there is a continuous function $g(x)$ with a nonzero denominator in $[a, b]$ representable as

$$g(x) = \sum_{i=1}^n a_i p_i(x) \Big/ \sum_{j=1}^m b_j q_j(x), \quad (1)$$

where $a_i, i = 1, \dots, n$, and $b_j, j = 0, 1, \dots, m$, are constants. Then $g(x)$ is called a **generalized rational function** based on a class of functions $\{p_i(x)\}, i = 1, \dots, n$, and $\{q_j(x)\}, j = 1, \dots, m$. If $p_i(x) = x^{i-1}$ and $q_j(x) = x^{j-1}$, (1) is reduced to a rational function. If $m = 1$ and $q_1(x) = 1$, (1) is a linear combination of $p_i(x)$ and is called an approximation of linear type to $f(x)$; and further, if $p_i(x) = x^{i-1}$, (1) is reduced to a polynomial. The crux of the approximation problem lies in the criterion to be used in choosing the approximate constants in (1). There are three methods for choosing them, which lead to three types of approximation of major importance: (i) interpolatory approximations, (ii) least-squares approximations, and (iii)

min-max error approximations (sometimes called **best approximations**). As a major aim of computer approximation of a function is to make the maximum error as small as possible, the third type of approximation has been used for digital computers.

For every continuous function $f(x)$, there always exist min-max error approximations of the form (1). In generating a min-max error approximation in practice, we essentially depend upon the following conditions and theorems. Let a function space F be a d -dimensional linear space. If for $f \in F$ which is not identically zero, there exist at most $(d-1)$ zeros of $f(x)$ in $[a, b]$, then F is called the **unsolvent** space or the **Haar space**.

Let one of the best approximations to a continuous function $f(x)$ be $g(x)$. If the linear space D of all the functions of the form $\{\sum a_i p_i(x) + \sum b_k g(x) q_k(x)\}$ is unsolvent, then the best approximation is unique. For the case where $g(x)$ is an approximation of linear type to $f(x)$, Haar [2] proved the following theorem.

Let $g(x)$ be the best approximation to $f(x)$ and $g(x) = \sum_{i=1}^m a_i p_i(x)$. A necessary and sufficient condition for the best approximation to be always unique is that the m -dimensional linear space generated by the functions p_1, p_2, \dots, p_m be unsolvent. In particular, we have the best unique polynomial approximation (one variable) of $f(x)$ defined on $[a, b]$.

Let the necessary and sufficient condition of the previous theorem be satisfied in a d -dimensional linear space D . A necessary and sufficient condition for $g(x)$ given by (1) to be the best approximation of $f(x)$ is that there exist points $a \leq x_0 < x_1 < \dots < x_{d-1} < x_d \leq b$, called deviation points, such that $(-1)^i(f(x_i) - g(x_i)) = \mu$ ($i=0, 1, \dots, d$).

A great number of algorithms are known by means of which one can calculate the best approximation $g(x)$ of a function $f(x)$ for the given values of n and m and for $p_i(x) = x^{i-1}$ and $g_j(x) = x^{j-1}$ in (1). However, the following three kinds of algorithms are used most frequently for generating min-max approximations on computers: Remes's second algorithm [3], the differential correction algorithm, and Yamauti's folding-up method.

C. Evaluation of Elementary Functions Based on Microprogramming

Chen [6] has given a general algorithm for calculating an elementary function $z = f(x)$ as follows. Let $F(x, y) = yg(x) + h(x)$, where y is some parameter for evaluating $z_0 = f(x_0) = F(x_0, y_0)$. We assume that (x_0, y_0) has been given and that z_0 is unknown. Suppose that a

new point (x_{k+1}, y_{k+1}) is obtained from (x_k, y_k) according to a pair of transformations, $x_{k+1} = \varphi(x_k, y_k)$ and $y_{k+1} = \psi(x_k, y_k)$, keeping the value of $F(x_0, y_0)$ invariant. If x_k is forced to converge to x_ω and if $g(x_\omega) = 1$ and $h(x_\omega) = 0$, then $z_0 = f(x_0) = F(x_0, y_0) = F(x_1, y_1) = \dots = F(x_\omega, y_\omega) = y_\omega$. In this procedure it is necessary to determine $g(x)$, $h(x)$, $\varphi(x)$, and $\psi(x)$ for the given $f(x)$. Most of the elementary functions can be evaluated by Chen's algorithm, which is essentially identical with Specker's Sequential Table Look-up (STL) method based on addition formulas [7], e.g., $\log x = \log(x\alpha) - \log \alpha$ or $e^x = e^{x-\beta} e^\beta$. The iteration equations (2) of CORDIC given later can also be derived by the STL method with complex numbers.

The use of coordinate rotation to evaluate elementary functions is not new. In 1956 and 1959 Volder [8] described the CORDIC for the calculation of trigonometric functions, multiplication, division, and conversion between the binary and the decimal and r -adic number systems. Daggett, in 1959, discussed the use of CORDIC for decimal-binary conversion. It was recognized by Walther [9] in 1971 that these algorithms could be merged into one unified algorithm. Consider coordinate systems parameterized by m in which the radius R and angle A of the vector $P = (x, y)$ are defined as $R = (x^2 + my^2)^{1/2}$ and $A = m^{-1/2} \arctan(m^{1/2} y/x)$. The basis of Walther's algorithm is the coordinate rotation in a linear ($m=0$), circular ($m=1$), or hyperbolic ($m=-1$) coordinate system, depending on which function is calculated. Iteration equations of CORDIC are as follows. The point $(x_{i+1}, y_{i+1}, z_{i+1})$ is obtained from the point (x_i, y_i, z_i) by means of the transformation

$$\begin{aligned} x_{i+1} &= x_i + m y_i \delta_i, \\ y_{i+1} &= y_i - x_i \delta_i, \\ z_{i+1} &= z_i + \alpha_i, \end{aligned} \quad (2)$$

where m is a parameter for the coordinate system, $\alpha_i = m^{-1/2} \arctan(m^{1/2} \delta_i)$, and δ_i is a suitable value, e.g., $\pm 2^{-i}$. The angle A_{i+1} and radius R_{i+1} are $A_{i+1} = A_i - \alpha_i$ and $R_{i+1} = R_i \times K_i \equiv R_i \times (1 + m \delta_i^2)^{1/2}$. After n iterations we find $A_n = A_0 - \alpha$ and $R_n = R_0 \times K$, and then

$$\begin{aligned} x_n &= K \{x_0 \cos(\alpha m^{1/2}) + y_0 m^{1/2} \sin(\alpha m^{1/2})\}, \\ y_n &= K \{y_0 \cos(\alpha m^{1/2}) - x_0 m^{-1/2} \sin(\alpha m^{1/2})\}, \\ z_n &= z_0 + \alpha, \end{aligned}$$

where $\alpha = \sum_{i=0}^{n-1} \alpha_i$ and $K = \prod_{i=0}^{n-1} K_i$. These relations are summarized in Table 1 for $m=1$, $m=0$, and $m=-1$ in the following special cases. (i) The value of A is forced to converge to zero; $y_n \rightarrow 0$. (ii) The value of z is forced to converge to zero; $z_n \rightarrow 0$.

Table 1. Input and Output Functions for CORDIC

Function	m	Input			Quantity to be 0	Output
		x_0	y_0	z_0		
$\sin t$	1	$1/K$	0	t	$z_n \rightarrow 0$	$y_n \rightarrow \sin t$
$\cos t$	1	$1/K$	0	t	$z_n \rightarrow 0$	$x_n \rightarrow \cos t$
$\tan^{-1} t$	1	1	t	0	$y_n \rightarrow 0$	$z_n \rightarrow \tan^{-1} t$
xz	0	x	0	z	$z_n \rightarrow 0$	$y_n \rightarrow xz$
y/x	0	x	y	0	$y_n \rightarrow 0$	$z_n \rightarrow y/x$
$\sinh t$	-1	$1/K_{-1}$	0	t	$z_n \rightarrow 0$	$y_n \rightarrow \sinh t$
$\cosh t$	-1	$1/K_{-1}$	0	t	$z_n \rightarrow 0$	$x_n \rightarrow \cosh t$
$\tanh^{-1} t$	-1	1	t	0	$y_n \rightarrow 0$	$z_n \rightarrow \tanh^{-1} t$

$$K_1 = \prod_{j=0}^{n-1} (1 + \delta_j^2)^{1/2}, \quad K_{-1} = \prod_{j=0}^{n-1} (1 - \delta_j^2)^{1/2}$$

D. Fast Fourier Transform (FFT)

When a function $f(x)$ can be taken to be periodic, it is advantageous to use trigonometric polynomials as least-squares approximating functions. The summations arising in least-squares approximations based on the trigonometric polynomials play an important role in various applications, and a quite efficient algorithm for the evaluation of such sums was developed by Cooley and Tukey [10] in 1965, known as the **fast Fourier transform (FFT)**. Let x_m , ($0 \leq m \leq N-1$) be a set of complex numbers, and consider

$$X_n = (1/N) \sum_{m=0}^{N-1} x_m \exp(-2\pi i m n / N) \quad (0 \leq n \leq N-1). \quad (3)$$

Equation (3) is often called the **discrete Fourier transform (DFT)** of the sequence x_m , it being analogous to the continuous Fourier transform,

$$X_n = (1/T) \int_0^T x(t) \exp(-2\pi i n t / T) dt \quad (0 \leq n \leq N), \quad (4)$$

where $x(t)$ is a periodic function of t with period T . X_n is called the n th Fourier coefficient of a set of N equally spaced samples of size N for the function $x(t)$ ($t = jT/N, 0 \leq j \leq N$). In the same way as for the continuous Fourier transform, the discrete transform can be inverted to yield

$$x_n = \sum_{m=0}^{N-1} X_m \exp(2\pi i m n / N) \quad (0 \leq n \leq N-1).$$

Here x_n is called the coefficient of the inverse Fourier transform, and X_m and x_n thus form a transform pair.

The FFT algorithm for a finite sequence of length N in (3) is based on the fact that the calculation of (3) can be performed in stages by using the direct product decomposition if $N = N_1 N_2$, with N_1 and N_2 relatively prime. For

example, the 2-dimensional Fourier transform coefficient is given by

$$X_{n_1, n_2} = [1/(N_1 N_2)] \times \sum_{m_1=0}^{N_1-1} \sum_{m_2=0}^{N_2-1} \exp(-2\pi i (n_1 m_1 / N_1 + n_2 m_2 / N_2)) x_{m_1, m_2} \quad (0 \leq n_1 \leq N_1-1, 0 \leq n_2 \leq N_2-1).$$

If by an elementary operation we mean one complex multiplication and one complex addition, we can evaluate X_{n_1, n_2} through $(N_1 N_2)^2$ such operations using Horner's scheme. By the direct product decomposition method, however, the $(N_1 N_2)^2$ operations can be reduced to only $N_1 N_2 (N_1 + N_2)$ operations. Because the matrix corresponding to the transformation mentioned above is a direct product of $N_1 \times N_1$ and $N_2 \times N_2$ matrices, we can perform the calculations in two stages: first to obtain ξ_{m_1, n_2} for $0 \leq m_1 \leq N_1-1$ and $0 \leq n_2 \leq N_2-1$ and then to obtain X_{n_1, n_2} for $0 \leq n_1 \leq N_1-1$ and $0 \leq n_2 \leq N_2-1$. We have

$$\xi_{m_1, n_2} = (1/N_2) \sum_{m_2=0}^{N_2-1} \exp(-2\pi i n_2 m_2 / N_2) x_{m_1, m_2}, \\ X_{n_1, n_2} = (1/N_1) \sum_{m_1=0}^{N_1-1} \exp(-2\pi i n_1 m_1 / N_1) \xi_{m_1, n_2}.$$

This direct product decomposition method is well known for 2- or 3-dimensional Fourier transforms. Even for a 1-dimensional Fourier transform of length $N = N_1 N_2$, if N_1 and N_2 are relatively prime, one can use the method of direct product decomposition. Even when N_1 and N_2 are not prime, we can use a method of "pseudo"-direct product decomposition to reduce the number of operations. Namely, we can put $m = m_1 + N_1 m_2$ ($0 \leq m_1 < N_1, 0 \leq m_2 < N_2$); $n = N_2 n_1 + n_2$ ($0 \leq n_1 < N_1, 0 \leq n_2 < N_2$). Then, similarly as before, X_n in (3) can be rewritten as

$$X_n = (1/N_1) \sum_{m_1=0}^{N_1-1} \exp(-2\pi i n_1 m_1 / N_2) \times \exp(-2\pi i m_1 n_2 / (N_1 N_2)) \xi_{m_1, n_2},$$

where

$$\xi_{m_1, n_2} = (1/N_2) \sum_{m_2=0}^{N_2-1} \exp(-2\pi i n_2 m_2 / N_2) x_{m_1 + N_1 m_2}, \quad (5)$$

which is a DFT of length N_2 . If we put

$$\tilde{\xi}_{m_1, n_2} = \exp(-2\pi i n_1 n_2 / (N_1 N_2)) \xi_{m_1, n_2}, \quad (6)$$

then

$$X_n = (1/N_1) \sum_{m_1=0}^{N_1-1} \exp(-2\pi i n_1 m_1 / N_1) \tilde{\xi}_{m_1, n_2}. \quad (7)$$

Formula (7) is nothing but a DFT of length N_1 . Thus an FFT of length $N = N_1 N_2$ can be calculated by decomposing it into three stages as follows: (i) obtain N_1 transforms of length N_2 in (5); (ii) multiply ξ_{m_1, n_2} by $\exp(-2\pi i n_1 n_2 / N)$ in (6) (phase rotation); (iii) calculate N_2 transforms of length N_1 in (7). If either or both of N_1 and N_2 can be factored further so that, e.g., $N = N_1 N_2 = N_1 N_{21} N_{22} = \dots$, an FFT of length N_2 can be calculated similarly by decomposing it, and so on, and in this way one can reduce the total number of operations. This is the principle of FFT pointed out by H. Takahasi. When N is a power of two, it can be shown that the FFT algorithm requires approximately $N \log_2 N/2$ operations.

E. Padé Approximation

Let $f(x) \sim c_0 + c_1 x + c_2 x^2 + \dots$ be a formal power series. For any pair of nonnegative integers (p, q) , we define the (p, q) th **Padé approximation** of $f(x)$ as follows: The Padé approximation is a rational function

$$(a_0 + a_1 x + a_2 x^2 + \dots + a_p x^p) / (b_0 + b_1 x + b_2 x^2 + \dots + b_q x^q)$$

satisfying the condition that all terms in the formal power series

$$(b_0 + b_1 x + \dots + b_q x^q)(c_0 + c_1 x + \dots) - (a_0 + a_1 x + \dots + a_p x^p)$$

should vanish up to the term x^{p+q} . An infinite matrix whose (p, q) th entry is the (p, q) th Padé approximation is called the **Padé table** for $f(x)$. The Padé approximation is uniquely determined, provided that every **Hankel determinant**

$$\begin{vmatrix} c_p & c_{p+1} & \dots & c_{p+q} \\ c_{p+1} & c_{p+2} & \dots & c_{p+q+1} \\ \dots & \dots & \dots & \dots \\ c_{p+q} & c_{p+q+1} & \dots & c_{p+2q} \end{vmatrix}$$

never vanishes.

When we expand $f(x)$ into a continued

fraction of Stieltjes type, say,

$$f(x) \sim \frac{c_0}{1} + \frac{\alpha_1 x}{1} + \frac{\alpha_2 x}{1} + \dots,$$

then its $2p$ th and $(2p+1)$ th approximate fractions are the (p, p) th and $(p+1, p)$ th Padé approximation of $f(x)$, respectively.

143 (XI.18) Extremal Length

A. General Remarks

The notable relation between the lengths of certain families of curves in a plane domain and the area of the domain has long been recognized and utilized in function theory. L. V. Ahlfors and A. Beurling formulated this relation by introducing the notion of extremal length for families of curves [1]. Although there are various definitions of extremal length, they are essentially the same except for one due to J. Hersch [3] and A. Pfluger [2].

The image of an interval under a continuous mapping is called a curve. We say that it is **locally rectifiable** if every †continuous arc of the curve is †rectifiable. Let C be a finite or countable collection of locally rectifiable curves in a plane and ρ , $0 \leq \rho \leq \infty$, be a †Baire function defined in the plane. Represent C in terms of arc length s (\rightarrow 246 Length and Area), and set $\langle C, \rho \rangle = \int_C \rho ds$. For a family Γ of finite or countable collections C , ρ is called **admissible** if $\langle C, \rho \rangle \geq 1$ for every $C \in \Gamma$. If no $C \in \Gamma$ consists of a finite or countable number of points, then $\rho \equiv \infty$ is always admissible for Γ . Call $\inf \{ \int \rho^2 dx dy \}$, where ρ runs over admissible Baire functions, the **module** of Γ , and denote it by $M(\Gamma)$. The reciprocal $\lambda(\Gamma) = 1/M(\Gamma)$ is called the **extremal length** of Γ . If no Baire functions are admissible for Γ , we set $\lambda(\Gamma) = 0$. The extremal length is defined equivalently in two other ways as follows: Let ρ be a nonnegative Baire function, and put $L(\Gamma, \rho) = \inf \{ \langle C, \rho \rangle \mid C \in \Gamma \}$, then $\lambda(\Gamma) = \sup L(\Gamma, \rho)^2 / \int \rho^2 dx dy$, where ρ runs over nonnegative Baire functions. Next, let Φ be the collection of nonnegative Baire functions ρ such that $\int \rho^2 dx dy \leq 1$; then $\lambda(\Gamma) = \sup \{ L(\Gamma, \rho)^2 \mid \rho \in \Phi \}$. We obtain the same value for $\lambda(\Gamma)$ if we require an admissible ρ to be †lower semicontinuous. If ρ is required to be continuous, then the **extremal length defined by Hersch and Pfluger** is obtained. As is shown in example (1) of Section B, there is a case where the two definitions actually differ.

If an admissible ρ yields $M(\Gamma) = \int \rho^2 dx dy$, then $\rho |ds|$ is called an extremal metric. Beurling gave a necessary and sufficient condition for a metric to be extremal [4].

We list four properties of extremal length:

(1) $\lambda(\Gamma_1) \geq \lambda(\Gamma_2)$ if $\Gamma_1 \subset \Gamma_2$. (2) $M(\bigcup_n \Gamma_n) \leq \sum_n M(\Gamma_n)$. (3) Let $\{\Gamma_n\}$ and Γ be given. Suppose that there are mutually disjoint measurable sets $\{E_n\}$ such that each $C_n \in \Gamma_n$ is contained in E_n . If each element of $\bigcup_n \Gamma_n$ contains at least one $C \in \Gamma$, then $M(\Gamma) \geq \sum_n M(\Gamma_n)$, and

hence

$$M\left(\bigcup_n \Gamma_n\right) = \sum_n M(\Gamma_n).$$

If each $C \in \Gamma$ contains at least one $C_n \in \Gamma_n$ for every n , then $\lambda(\Gamma) \geq \sum_n \lambda(\Gamma_n)$. (4) Let f be an analytic function in a domain Ω and $\{C\}$ be given in Ω . Denote by $f(C)$ the image of C by f . Then $\lambda(\{C\}) \leq \lambda(\{f(C)\})$. The equality holds if f is one-to-one. This shows that $\lambda(\{C\})$ is conformally invariant.

B. Extremal Distance

Let Ω be a domain in a plane, $\partial\Omega$ its boundary, and X_1, X_2 sets on $\Omega \cup \partial\Omega$. The extremal length of the family of curves in Ω connecting points of X_1 and points of X_2 is called the **extremal distance** between X_1 and X_2 (relative to Ω) and is denoted by $\lambda_\Omega(X_1, X_2)$.

Example (1). Let $\Omega = \{z \mid |z| < 2\}$, $X_1 = \partial\Omega$, and X_2 be a countable set in $|z| < 1$ such that the set of accumulation points of X_2 coincides with $|z| = 1$. Then $\lambda_\Omega(X_1, X_2) = \infty$, but the extremal distance in the sense of Hersch and Pfluger is equal to $(2\pi)^{-1} \log 2$.

Example (2). In a rectangle with sides a and b , the extremal distance between the sides of length a is b/a .

Example (3). Let Ω be an annulus $r_1 < |z| < r_2$. The extremal distance λ between the two boundary circles of Ω is equal to $(2\pi)^{-1} \log(r_2/r_1)$. The extremal length of the family of curves in Ω homotopic to the boundary circles is equal to $1/\lambda$.

Example (4). Let Ω be a domain in the extended z -plane such that $\infty \in \Omega$. Let $z_0 \in \Omega$ and $\{|z - z_0| = r\} \subset \Omega$, and denote by λ_r the extremal distance between $\{|z - z_0| = r\}$ and a set $X \subset \partial\Omega$ relative to Ω . Then $\lambda_r - (2\pi)^{-1} \log r$ increases with r . We call the limit the **reduced extremal distance** and denote it by $\tilde{\lambda}_\Omega(X, \infty)$. †Robin's constant for †Green's function in Ω with pole at $z = \infty$ is equal to $2\pi \tilde{\lambda}_\Omega(\partial\Omega, \infty)$.

Extremal length is also defined on Riemann surfaces. Some classical conformal invariants can be given in a generalized form in terms of extremal length. The notion of extremal length has applications in various branches of function theory, such as †conformal and †quasi-conformal mappings, the †Phragmén-Lindelöf theorem, the †coefficient problem, the †type problem of Riemann surfaces, and studies of the boundary properties of functions of finite Dirichlet integrals. It is also applied to problems in differential geometry. Extending the notion of extremal length, M. Ohtsuka considered **extremal length with weight**, and B. Fuglede introduced the notion of **generalized**

module in higher-dimensional spaces [8]. These notions have useful properties and applications.

F

144 (XXI.23) Fermat, Pierre de

Pierre de Fermat (August 20, 1601–January 12, 1665) was born into a family of leather merchants near Toulouse, France. He became an attorney and in 1631 a member of the Toulouse district assembly. When not engaged in such work, he did research in mathematics, so that he consigned his results only to his correspondence or to unpublished manuscripts. The manuscripts were published posthumously by his son in 1679 and are known as *Varia opera mathematica*. His research into number theory, stimulated by Bachet's (1581–1638) translation of the *Arithmetika* of Diophantus (published in 1621), made Fermat's name immortal and initiated modern number theory. He posed the famous Fermat's Problem, which has yet to be solved (\rightarrow 145 Fermat's Problem). He began analytic geometry by studying the theory of †conic sections of Apollonius, and utilizing this theory he dealt with the notions of tangent lines, maximal (minimal) values of functions, and quadrature, which made him a pioneer in calculus. He also wrote a precursory work in the theory of probability in the course of his correspondence with †Pascal. †Fermat's principle is important in the field of optics, where it is known as the law of least action. Unlike †Descartes, he emphasized the revival rather than the criticism of Greek mathematics.

145 (V.16) Fermat's Problem

The **last theorem of Fermat** (c. 1637) asserts that if n is a natural number greater than 2, then

$$x^n + y^n = z^n \quad (1)$$

has no rational integral solution x, y, z with $xyz \neq 0$. In the case $n=2$, equation (1) has integral solutions called **Pythagorean numbers** (\rightarrow 118 Diophantine Equations). Fermat read a Latin translation of Diophantus' *Arithmetika*, in which the problem of finding all Pythagorean numbers is treated. In his personal copy of that book, Fermat wrote his as-

sertion as a marginal note at the point at which $n=2$ in equation (1) is treated and added the famous words, "I have discovered a truly remarkable proof of this theorem which this margin is too small to contain." It is not known whether Fermat actually had a proof. Fermat's problem asks for a proof or disproof of this conjecture, which itself has not been solved despite centuries of efforts by many mathematicians; but its study has promoted remarkable advances in number theory. In particular, E. E. Kummer's theory of ideal numbers and the development of the theory of †cyclotomic fields were originally conceived in treating Fermat's problem.

In this article, we consider only those integral solutions x, y, z of equation (1) with $xyz \neq 0$ that are relatively prime. We also restrict ourselves to the cases $n=l$ (odd prime) and $n=4$, without loss of generality.

For smaller values of n , the nonsolvability of equation (1) was proved long ago, for $n=3$ by L. Euler (1770), and later again by A. M. Legendre; for $n=4$ by Fermat and Euler; for $n=5$ by P. G. L. Dirichlet and Legendre (1825); and for $n=7$ by G. Lamé (1839). S. Germain and Legendre found some results on more general cases, but the most remarkable result was obtained by Kummer (*J. Reine Angew. Math.*, 40 (1850), *Abh. Akad. Wiss. Berlin* (1857)).

Let l be an odd prime, ζ a primitive l th root of unity, and h the †class number of the cyclotomic field $\mathbf{Q}(\zeta)$. Then the class number h_2 of the real subfield $\mathbf{Q}(\zeta + \zeta^{-1})$ of $\mathbf{Q}(\zeta)$ divides h . We call $h_1 = h/h_2$ and h_2 the †first and †second factors of h , respectively.

(1) If l is †regular, that is, if $(h, l) = 1$, then $x^l + y^l = z^l$ has no solution (Kummer, 1850).

There are infinitely many irregular primes [3]; those under 100 are 37, 59, and 67. There are 7,128 regular primes and 4,605 irregular primes between 3 and 125,000. It is not yet known whether there are infinitely many regular prime numbers, although the beginning part of the sequence of natural numbers contains a larger number of these than the number of irregular prime numbers. The condition $(l, h) = 1$ is equivalent to saying that the numerators of †Bernoulli numbers B_{2m} ($m = 1, 2, \dots, (l-3)/2$) are not divisible by l (Kummer, 1850).

Kummer obtained a result on irregular primes (1857) which was improved later as follows. Note that if l is not regular then h_1 is divisible by l (Kummer, 1850) (\rightarrow 14 Algebraic Number Fields).

(2) If $(h_2, l) = 1$ and the numerators of Bernoulli numbers B_{2m} ($m = 1, 2, \dots, (l-3)/2$) are not divisible by l^3 , then $x^l + y^l = z^l$ has no solution (H. S. Vandiver, *Trans. Amer. Math. Soc.*, 31 (1929)). By computation Vandiver confirmed that $x^l + y^l = z^l$ has no solution for

$l < 619$. At present, this procedure has been continued for $l \leq 125,080$ using computers by the method of D. H. Lehmer, E. Lehmer, and H. S. Vandiver, *Proc. Nat. Acad. Sci. US*, 40 (1954) (S. S. Wagstaff, *Math. Comp.*, 32 (1978)).

When the condition $(xyz, l) = 1$ or $(xyz, l) = l$ is added, we speak of Case I or Case II, respectively. The following theorems hold for Case I.

(3) If $x^l + y^l = z^l$ has a solution in Case I, then

$$B_{2m} f_{l-2m}(t) \equiv 0 \pmod{l}, \quad m = 1, 2, \dots, (l-3)/2, \tag{2}$$

holds for $-t = x/y, y/x, y/z, z/y, x/z$, and z/x , where $f_m(t) = \sum_{r=0}^{l-1} r^{m-1} t^r$, and B_m is the m th Bernoulli number. This is called **Kummer's criterion** (D. Mirimanov, 1905).

A simplification of the above result is

(4a) If $x^l + y^l = z^l$ has a solution in Case I, then

$$(2^{l-1} - 1)/l \equiv 0 \pmod{l}$$

(A. Wieferich, *J. Reine Angew. Math.*, 136 (1909)). This result created a sensation at the time of its publication. It was first shown that 1093 and 3511 are the only primes with $l < 3700$ for which the above congruence holds; it is presently known that no other l with $l \leq 6 \times 10^9$ satisfies this congruence. The criterion (4a) was gradually improved by Mirimanov (1910, 1911), P. Furtwängler (1912), Vandiver (1914), G. Frobenius (1914), F. Pollaczek (1917), T. Morishima (1931), and J. B. Rosser (1940, 1941). For example:

(4b) If $x^l + y^l = z^l$ has a solution in Case I, then

$$(m^{l-1} - 1)/l \equiv 0 \pmod{l} \tag{3}$$

holds for all m with $2 \leq m \leq 43$. By means of this result, Rosser (1941) showed for $l < 41,000,000$, and D. H. Lehmer and E. Lehmer (*Bull. Amer. Math. Soc.*, 47 (1941)) showed for $l < 253,747,889$ that $x^l + y^l = z^l$ has no solution in Case I.

We have hitherto been concerned with rational integral solutions of $x^l + y^l = z^l$. We may also consider the problem of proving or disproving that $\alpha^l + \beta^l = \gamma^l$ has no solution α, β, γ with $\alpha\beta\gamma \neq 0$ in the ring of l algebraic integers of $\mathbf{Q}(\zeta)$. Case I means the impossibility of

$$\alpha^l + \beta^l + \gamma^l = 0, \quad (\alpha\beta\gamma, l) = 1, \tag{4}$$

and Case II means the impossibility of

$$\alpha^l + \beta^l = \varepsilon \lambda^{nl} \gamma^l, \quad (\alpha\beta\gamma, l) = 1, \tag{5}$$

where n is a natural number, ε is a l unit in $\mathbf{Q}(\zeta)$, and $\lambda = 1 - \zeta$. We have the following results:

(1*) If $(h, l) = 1$, then neither equation (4) nor equation (5) has a solution (Kummer, 1850).

(2*) Under the same conditions as in statement (2), equation (4) has no solution. If we additionally restrict α, β, γ to relatively prime integers of $\mathbf{Q}(\zeta + \zeta^{-1})$ and replace λ by $(1 - \zeta)(1 - \zeta^{-1})$, then equation (5) also has no solution (Vandiver, 1929).

(4b*) If equation (4) has solutions α, β, γ in $\mathbf{Q}(\zeta)$, then congruence relation (3) holds for all m with $2 \leq m \leq 43$ (Morishima, 1934).

When l is sufficiently large, we have the results of M. Krasner (*C. R. Acad. Sci. Paris* (1934)) and Morishima (*Proc. Japan Acad.*, 11 (1935)).

Bibliographies are given in Vandiver and Wahlin [1] and Vandiver [2].

146 (XX.30) Feynman Integrals

A. Introduction

As the S -matrix or 'Green's function in quantum field theory is usually prohibitively difficult to calculate, perturbative expansions in terms of coupling constants have been employed since the beginning of the theory (\rightarrow 386 S -Matrices). R. P. Feynman (*Phys. Rev.*, 76 (1949)) invented a way of calculating the series in terms of **Feynman integrals**. His method drastically simplified the preceding method due to S. Tomonaga and J. S. Schwinger, even though, as was later shown, the two methods are theoretically equivalent (F. J. Dyson, *Phys. Rev.*, 75 (1949)). A Feynman integral is an integral associated with a **Feynman graph** according to the **Feynman rule** explained in Section B. Feynman integrals inherit the troublesome problem of divergence, and some recipe which systematically provides them with a definite meaning is needed. Such a recipe is given by the renormalization theory of Tomonaga, Schwinger, Feynman, and Dyson. A mathematically rigorous renormalization theory was given by N. N. Bogolyubov and O. S. Parasiuk (*Acta Math.*, 97 (1957)), later supplemented by K. Hepp (*Comm. Math.*

Phys., 2 (1966)). See also W. Zimmermann (*Comm. Math. Phys.*, 15 (1969)) and S. A. Anikin et al. (*Theor. Math. Phys.*, 17 (1973)). Furthermore, E. R. Speer [1] gave a mathematically convenient recipe of renormalization (under the condition that massless particles are irrelevant). Although the series expansion in coupling constants is a divergent series even after renormalization (\rightarrow 386 S-Matrices), the study of Feynman integrals has given much insight into the qualitative aspects of the S-matrix, and in particular, into its analytic structure (e.g., R. J. Eden et al. [2]). In this respect the discovery of the Landau-Nakanishi equations, which describe the location of singularities of Feynman integrals, was crucially important (L. D. Landau, N. Nakanishi, and J. Bjorken, 1959; \rightarrow Section C). Later, R. E. Cutkosky found a formula which gives important information concerning the ramification of Feynman integrals near their singularities (\rightarrow Section C). It gave impetus to J. Leray's mathematical study of Feynman integrals from the viewpoint of integration of multi-valued analytic functions (Leray, *Bull. Soc. Math. France*, 87 (1959)). Such studies were subsequently carried out by D. Fotiadi, M. Froissart, J. Lascoux, F. Pham, etc.; \rightarrow [3–5] and references cited there for this topic. An extensive study by G. Ponzano, T. Regge, Speer, and J. M. Westwater on the monodromy structure of Feynman integrals is closely related to the studies by Pham and others (\rightarrow Regge in [6] and references cited there). On the other hand, the progress of microlocal analysis has thrown new light on the Feynman integrals and has given a unified foundation to these various other studies (\rightarrow Section C; also Pham, M. Kashiwara, and T. Kawai in [6], M. Sato et al. in [6] and references cited there).

B. Definitions

First, the notion of **Feynman graphs** is introduced. A Feynman graph is sometimes called a **Feynman diagram**. A Feynman graph G consists of finitely many points (called vertices) $\{V_j\}_{j=1,\dots,n}$, finitely many 1-dimensional segments (called internal lines) $\{L_l\}_{l=1,\dots,N}$ and finitely many half-lines (called external lines) $\{L_r^e\}_{r=1,\dots,n}$, all of which are located in a 4-dimensional affine space. Each of the end-points W_l^+ and W_l^- of L_l and the endpoint of L_r^e coincide with some vertex V_j . A four-vector $p_r = (p_{r,0}, p_{r,1}, p_{r,2}, p_{r,3})$ is associated with each external line L_r^e and a constant $m_l \geq 0$ is associated with each internal line L_l . For simplicity, we usually suppose, in addition, that each internal line and each external line are

oriented, that $W_l^+ \neq W_l^-$ and that G is connected. The orientation of a line is indicated by the symbol \rightarrow . Given an orientation, we define the incidence number $[j:l]$ to be +1 or -1 according to whether L_l ends or starts from V_j . In other cases, $[j:l]$ is defined to be zero. The incidence number $[j:r]$ is defined in the same way but with L_r^e replacing L_l (Fig. 1).

Fig. 1

In this example of a Feynman graph, the internal lines L_2 and L_4 do not intersect and this diagram should be drawn in \mathbf{R}^4 , not in \mathbf{R}^2 ; this is indicated by \nearrow . For convenience, multiple lines such as L_7 and L_8 are usually drawn in a curvilinear manner, as shown.

The **Feynman rule** associates the following integral $F_G(p)$ with each Feynman graph G :

$$F_G(p) = \int \frac{\prod_{j=1}^n \delta^4(\sum_{r=1}^n [j:r] p_r + \sum_{l=1}^N [j:l] k_l)}{\prod_{l=1}^N (k_l^2 - m_l^2 + \sqrt{-1} \ 0)} \times \sum_{i=1}^N d^4 k_i, \quad (1)$$

where $k_l^2 = k_{l,0}^2 - \sum_{v=1}^3 k_{l,v}^2$. Here $1/(k_l^2 - m_l^2 + \sqrt{-1} \ 0)$ means $\lim_{\epsilon \downarrow 0} (1/(k_l^2 - m_l^2 + \sqrt{-1} \ \epsilon))$ (\rightarrow 125 Distributions and Hyperfunctions).

Here we consider the case where the interaction Lagrangian density does not contain differential operators (i.e., direct coupling) and all relevant particles are spinless. In general, we should multiply the integrand of $F_G(p)$ by a matrix of polynomials of the p_r and k_l .

$F_G(p)$ has the form $\delta(\sum_{j,r} [j:r] p_r) f_G(p)$; we often investigate $f_G(p)$ instead of $F_G(p)$. The function $f_G(p)$ is studied on $M = \text{def} \{p \in \mathbf{R}^{4n} \mid \sum_{j,r} [j:r] p_r = 0\}$, and is called a **Feynman amplitude**. The integral (1) is not well defined as it stands because of the following problems: (a) Is the product appearing in the integrand well defined? (b) Is the integral convergent? The first problem is not serious if $m_l \neq 0$ (\rightarrow 274 Microlocal Analysis E). However, the second problem, called the **ultraviolet divergence**, is serious. The renormalization procedure is intended to overcome this difficulty. When some m_l is equal to zero, even the first problem, called the **infrared divergence**, is serious. See D. R. Yennie et al. (*Ann. Phys.*, 13 (1961)) and T. Kinoshita (*J. Math. Phys.*, 3 (1962)) for analyses of the infrared divergence. In this article we always assume for simplicity that every m_l is strictly positive, even though

such an assumption is too restrictive from the physical viewpoint.

Calculations of Feynman integrals are often done by means of the **parametric representation** of the integral (1), of the form

$$\delta\left(\sum_{j,r}[j:r]p_r\right)\int_0^1\dots\times\int_0^1\frac{\delta(1-\sum_{i=1}^N\alpha_i)\prod_{i=1}^N d\alpha_i}{U(\alpha)^2(V(p,\alpha)+\sqrt{-1}\,0)^{-N+2n'-2}},$$

where $U(\alpha)$ and $V(p,\alpha)$ are determined by the topological structure of the graph G . See [7] for the derivation of this formula and the treatment of the integral written in this form. It is useful not only for the study of the singularity structure of $f_G(p)$ but also for the study of spectral representations, etc. (\rightarrow , e.g., [7, 8]). Note that several different notations are used in the literature for the parametric representation of the integral. Hence one should be careful in referring to papers which use parametric representations.

C. Analytic Properties of Feynman Integrals

The celebrated result of Landau (*Nuclear Phys.*, 13 (1959)), Nakanishi (*Prog. Theor. Phys.*, 22 (1959)) and Bjorken (thesis, Stanford Univ., 1959) asserts that the singularities of a Feynman amplitude $f_G(p)$ are confined to the subset $L^+(G)$ (called a **positive- α Landau-Nakanishi variety**) of $M = \{p \in \mathbb{R}^{4n} \mid \sum_{j,r}[j:r]p_r = 0\}$, defined by the following set of equations (called **Landau-Nakanishi equations**), where u_r , w_j , and k_l are real four-vectors and α_i is a real number, all of which are to be eliminated to define relations among the p_r (note, however, that a positive- α Landau-Nakanishi variety is not strictly a subvariety of M , because of the constraint (2e):

$$u_r = \sum_{j=1}^{n'} [j:r]w_j \quad (r=1, \dots, n), \quad (2a)$$

$$\sum_{r=1}^n [j:r]p_r + \sum_{l=1}^N [j:l]k_l = 0 \quad (j=1, \dots, n'), \quad (2b)$$

$$\sum_{j=1}^{n'} [j:l]w_j = \alpha_l k_l \quad (l=1, \dots, N), \quad (2c)$$

$$\alpha_l(k_l^2 - m_l^2) = 0 \quad (l=1, \dots, N), \quad (2d)$$

$$\alpha_l \geq 0, \quad (2e)$$

with some

$$\alpha_l \neq 0. \quad (2f)$$

Usually a Landau-Nakanishi variety (resp., equation) is called a **Landau variety** (resp., equation) for short. The equation (2a) is conventional; (2b) represents the energy-

momentum conservation law at the vertex V_j ; (2d) corresponds to the mass-shell constraint (if $\alpha_l \geq 0$) on the internal line L_l . Since (2c) entails $\sum_l \varepsilon_l(C)\alpha_l k_l = 0$ for a closed circuit (= loop) C of G for some set of values $\varepsilon_l(C) = \pm 1$ or 0 with $\varepsilon_l(C)$ being 0 if L_l does not belong to C , the equation (2c) is usually called the closed-circuit condition. By attaching w_j to the vertex V_j and associating $\alpha_l k_l$ to the internal line L_l , we get a diagram representing a multiple collision of classical point particles, since the relations (2a)–(2f) are just the classical conditions for such a collision (S. Coleman and R. E. Norton, *Nuovo Cimento*, 38 (1965)). The fact that the Landau-Nakanishi equations admit such an interpretation is neither accidental nor superficial in view of the †macroscopic causality of the S -matrix. Note also that there is another interpretation of the Landau-Nakanishi equations, which emphasizes their resemblance to †Kirchhoff's law (Nakanishi, *Prog. Theor. Phys.*, 23 (1960)). Such a resemblance can be used to study the structure of Feynman integrals from the viewpoint of †graph theory. See [7] and the references cited there for this topic.

An important observation by Pham and Sato (1973), which opened a way to the microlocal analysis of Feynman integrals and the S -matrix, is the following: If we consider the Landau-Nakanishi equations to define a subvariety of S^*M , the †spherical cotangent bundle of M , by eliminating only w , k , and α , then the resulting variety describes the †singularity spectrum of $f_G(p)$. More precisely, $S.S.f_G(p)$ is confined to the set $(p; \sqrt{-1}u)$, where $(p; u)$ satisfies the Landau-Nakanishi equations. The rigorous proof of this statement was given by Sato et al. in [6]. The subset of S^*M or $\sqrt{-1}S^*M$ thus obtained is denoted by $\mathcal{L}^+(G)$ and is also called a positive- α Landau-Nakanishi variety. It is noteworthy that the microlocalization of the classical result of Landau, Nakanishi, and Bjorken had essentially been achieved in a less sophisticated manner by D. Iagolnitzer and H. P. Stapp (*Comm. Math. Phys.*, 14 (1969)) in the framework of S -matrix theory. The variety defined by (2a)–(2d) and (2f) is denoted by $L(G)$ or $\mathcal{L}(G)$ and is a Landau-Nakanishi variety. In a neighborhood of p^0 in $L^+(G)$, $f_G(p)$ is the boundary value of a holomorphic function $\tilde{f}_G(p)$ whose domain of definition is determined by u -vectors (\rightarrow 274 Microlocal Analysis E). Furthermore, in simple cases one can verify that $\tilde{f}_G(p)$ can be analytically continued to define a holomorphic function on the universal covering space $\widetilde{U-L(G)^C}$ of $U-L(G)^C$ for a complex neighborhood U of p^0 , where $L(G)^C$ denotes a complexification of $L(G)$. Hence we can discuss the difference of

$\tilde{f}_G(\gamma p)$ and $\tilde{f}_G(p)$, where γ denotes a loop encircling $L(G)^c$. Cutkosky (*J. Math. Phys.*, 1 (1960)) observed that it can be expressed (in simple cases) by the integral obtained by replacing $1/(k_i^2 - m_i^2 + \sqrt{-10})$ in the right-hand side of (1) by $-2\pi\sqrt{-1}\delta^+(k_i^2 - m_i^2) =_{\text{def}} -2\pi\sqrt{-1}Y(k_{i,0})\delta(k_i^2 - m_i^2)$, where $Y(k_{i,0})$ denotes the \dagger Heaviside function. A result of this type is called a **discontinuity formula** and is now obtained for the S -matrix itself in a suitably modified manner, i.e., the discontinuity formula holds beyond the framework of perturbation theory (\rightarrow 386 S -Matrices). As is mentioned in 386 S -Matrices, the discontinuity formula is closely related to Sato's conjecture on the \dagger holonomic character of the S -matrix (T. Kawai and Stapp in [6]). Actually, M. Kashiwara and Kawai (in [6]) proved that $f_G(p)$ satisfies a \dagger holonomic system of linear differential equations whose characteristic variety is confined to the extended Landau-Nakanishi variety $L(G)$. They further proved that the system has regular singularities (\rightarrow 274 Microlocal Analysis G). Their result gives, on one hand, a precise version of Regge's statement to the effect that $f_G(p)$ is a generalization of a \dagger hypergeometric function (in *Battelle Rencontres*, C. DeWitt and J. A. Wheeler (eds.), Benjamin, 1968), and, on the other hand, a rigorous proof of the fact that $\tilde{f}_G(p)$ is a Nils-son class function. This fact is closely related to the works of D. Fotiadis, J. Lascoux, Pham, and others. Kashiwara and Kawai (*Comm. Math. Phys.*, 54 (1977)) also showed that the holonomic character of the Feynman amplitude is an important clue for understanding the so-called hierarchical principle, which had been proposed and studied in connection with the \dagger Mandelstam representation by the Cambridge group (Eden et al. [2]). Furthermore, Kashiwara et al. (*Comm. Math. Phys.*, 60 (1978)) gave a useful expression of $f_G(p)$ at several physically important points by analyzing the microlocal structure of the holonomic system that $f_G(p)$ satisfies. Thus the use of \dagger (micro-) differential equations in analyzing Feynman amplitudes has turned out to be effective in understanding their singularity structures in a unified manner.

147 (IX.13) Fiber Bundles

A. General Remarks

E. Stiefel [2] introduced certain \dagger diffeomorphism invariants of \dagger differentiable manifolds by considering a field of a finite number of linearly independent vectors attached to each point of a manifold; and H. Whitney [3] obtained the notion of fiber bundles as a compound idea of a manifold and such a field of tangent vectors. S. S. Chern [4] emphasized the global point of view in differential geometry by recognizing the relation between the notion of \dagger connections (due to E. Cartan) and the theory of fiber bundles. The theory of fiber bundles is also applied to various fields of mathematics, for example, the theory of \dagger Lie groups, \dagger homogeneous spaces, \dagger covering spaces, and general vector bundles, vector bundles of class C^r , or analytic vector bundles.

Homological properties of fiber bundles are studied by means of \dagger spectral sequences, and cohomology structures of several homogeneous spaces and several characteristic classes are determined explicitly by means of \dagger cohomology operations. Also, the group $K(X)$, formed by equivalence classes of vector bundles over a finite \dagger CW complex X , is a \dagger generalized cohomology group, treated in $\dagger K$ -theory, in which further development is expected (\rightarrow 237 K -Theory).

B. Definitions

Let E, B, F be topological spaces, $p: E \rightarrow B$ a continuous mapping, and G an \dagger effective left topological \dagger transformation group of F . If there exist an \dagger open covering $\{U_\alpha\}$ ($\alpha \in \Lambda$) of B and a homeomorphism $\varphi_\alpha: U_\alpha \times F \approx p^{-1}(U_\alpha)$ for each $\alpha \in \Lambda$ having the following three properties, then the system $(E, p, B, F, G, U_\alpha, \varphi_\alpha)$ is

called a **coordinate bundle**: (1) $p\varphi_\alpha(b, y) = b$ ($b \in U_\alpha, y \in F$). (2) Define $\varphi_{\alpha, b}: F \approx p^{-1}(b)$ ($b \in U_\alpha$) by $\varphi_{\alpha, b}(y) = \varphi_\alpha(b, y)$; then $g_{\beta\alpha}(b) = \varphi_{\beta, b}^{-1} \circ \varphi_{\alpha, b} \in G$ for $b \in U_\alpha \cap U_\beta$. (3) $g_{\beta\alpha}: U_\alpha \cap U_\beta \rightarrow G$ is continuous. We say that this bundle is **equivalent** to a coordinate bundle $(E, p, B, F, G, U'_\mu, \varphi'_\mu)$ if $\bar{g}_{\mu\alpha}(b) = \varphi'^{-1}_{\mu, b} \circ \varphi_{\alpha, b} \in G$ ($b \in U_\alpha \cap U'_\mu$) and $\bar{g}_{\mu\alpha}: U_\alpha \cap U'_\mu \rightarrow G$ is continuous. An equivalence class $\xi = (E, p, B, F, G)$ of coordinate bundles is called a **fiber bundle** (or **G-bundle**), and E is called the **total space** (or **bundle space**), p the **projection**, B the **base space**, F the **fiber**, and G the **bundle group** (or **structure group**). Also, U_α of a coordinate bundle $(E, p, B, F, G, U_\alpha, \varphi_\alpha)$ belonging to the class ξ is called the **coordinate neighborhood**, φ_α the **coordinate function**, and $g_{\beta\alpha}$ the **coordinate transformation** (or **transition function**).

Let $\xi = (E, p, B, F, G)$ and $\xi' = (E', p', B', F, G)$ be two fiber bundles with the same fiber and group. A continuous mapping $\Psi: E \rightarrow E'$ is called a **bundle mapping** (**bundle map**) from ξ to ξ' if the following two conditions are satisfied: (1) There is a continuous mapping $\psi: B \rightarrow B'$ with $p' \circ \Psi = \Psi \circ p$. (2) $\psi_{\mu\alpha}(b) = \varphi'^{-1}_{\mu, b'} \circ \Psi \circ \varphi_{\alpha, b} \in G$ ($b \in U_\alpha \cap \psi^{-1}(V'_\mu)$, $b' = \psi(b)$), and $\psi_{\mu\alpha}: U_\alpha \cap \psi^{-1}(V'_\mu) \rightarrow G$ is continuous, where $\{U_\alpha, \varphi_\alpha\}$ and $\{V'_\mu, \varphi'_\mu\}$ are pairs of coordinate neighborhoods and functions of ξ and ξ' , respectively. Moreover, if ψ is a homeomorphism, then Ψ is also a homeomorphism and Ψ^{-1} is a bundle mapping.

Let $\xi = (E, p, B, F, G)$ and $\xi' = (E', p', B', F, G)$ be two fiber bundles with the same base space, fiber, and group. If there is a bundle mapping $\Psi: E \rightarrow E'$ such that $\psi: B \rightarrow B$ as described before is the identity mapping, then we say that ξ is **equivalent** (or **isomorphic**) to ξ' and write $\xi \equiv \xi'$. Take the same coordinate neighborhoods $\{U_\alpha\}$, and let $g_{\beta\alpha}$ and $g'_{\beta\alpha}$ be the coordinate transformations of ξ and ξ' , respectively. Then $\xi \equiv \xi'$ if and only if there are continuous mappings $\lambda_\alpha: U_\alpha \rightarrow G$ with $g'_{\beta\alpha}(b) = \lambda_\beta(b)g_{\beta\alpha}(b)\lambda_\alpha(b)^{-1}$ ($b \in U_\alpha \cap U_\beta$).

For a system $\{g_{\beta\alpha}\}$ of coordinate transformations of a fiber bundle, we have $g_{\gamma\beta}(b)g_{\beta\alpha}(b) = g_{\gamma\alpha}(b)$ ($b \in U_\alpha \cap U_\beta \cap U_\gamma$). Conversely, given an open covering $\{U_\alpha\}$ and a system of $g_{\beta\alpha}: U_\alpha \cap U_\beta \rightarrow G$ satisfying this condition, there is a unique G -bundle (E, p, B, F, G) with $\{g_{\beta\alpha}\}$ as a system of coordinate transformations. Actually, E is the \dagger identification space of $\tilde{E} = \{(b, y, \alpha) | b \in U_\alpha\} \subset B \times F \times \Lambda$ obtained by identifying two points $(b, y, \alpha), (b', y', \beta)$ with $b = b', y' = g_{\beta\alpha}(b) \cdot y$, and p is defined by $p\{(b, y, \alpha)\} = b$, where the index set $\Lambda = \{\alpha\}$ is considered a discrete space.

C. Principal Fiber Bundles

A fiber bundle $\eta = (P, q, B, G, G)$ is called a **principal fiber bundle** (or simply **principal**

bundle) if G operates on G by left translations. This is also defined by the following conditions: G is a right \dagger topological transformation group of P , and there exist an open covering $\{U\}$ of B and homeomorphisms $\varphi: U \times G \approx q^{-1}(U)$ with $q\varphi(b, g) = b$, $\varphi(b, g) \cdot g' = \varphi(b, gg')$ ($b \in U; g, g' \in G$). A bundle mapping $\Psi: P \rightarrow P'$ between two principal bundles $\eta = (P, q, B, G)$ and $\eta' = (P', q', B', G)$ is also defined as a continuous mapping Ψ with $\Psi(x \cdot g) = \Psi(x) \cdot g$.

D. Associated Fiber Bundles

Let $\eta = (P, q, B, G)$ be a principal bundle, and let F be a topological space having G as an effective left topological transformation group. Then G is a right topological transformation group of the product space $P \times F$ by $(x, y) \cdot g = (x \cdot g, g^{-1} \cdot y)$ ($x \in P, y \in F, g \in G$). Consider the \dagger orbit space $P \times_G F = (P \times F)/G$, and define the continuous mapping $p: P \times_G F \rightarrow B$ by $p\{(x, y)\} = q(x)$. Then $\eta \times_G F = (P \times_G F, p, B, F, G)$ is a fiber bundle, called the **associated fiber bundle** of η with fiber F . On the other hand, η is called an **associated principal bundle** of $\xi = (E, p, B, F, G)$ if $\xi \equiv \eta \times_G F$. A principal bundle η having the same coordinate transformations as ξ is an associated principal bundle of ξ , and two fiber bundles are equivalent if and only if their associated principal bundles are equivalent. Therefore, given a fiber bundle ξ , there exists a principal bundle η such that $\xi = \eta \times_G F$.

E. Examples of Fiber Bundles

(1) **Product bundle**. $(B \times F, p_1, B, F, G)$, where p_1 , the projection of the product space, is called a **product bundle** if there is just one coordinate neighborhood B and the coordinate function is the identity mapping of $B \times F$. A bundle that is equivalent to a product bundle is called a **trivial bundle**.

(2) A \dagger covering (\tilde{Y}, p, Y) is a fiber bundle whose fiber is the discrete space $p^{-1}(y_0)$ ($y_0 \in Y$), and the structure group is a factor group of the \dagger fundamental group $\pi_1(Y, y_0)$. In particular, a \dagger regular covering is a principal bundle.

(3) **Hopf bundle**. Let Λ be the real number field \mathbf{R} , the complex number field \mathbf{C} , or the quaternion field \mathbf{H} , $\lambda = \dim_{\mathbf{R}} \Lambda$, and Λ^{n+1} the $(n+1)$ -dimensional linear space over Λ . Identify two points $(z_0, \dots, z_n), (z'_0, \dots, z'_n)$ of the subspace $\Lambda^{n+1} - \{0\}$ (0 is the origin) if there is a $z \in \Lambda$ such that $z_i = z'_i z$ ($i = 0, \dots, n$). Then we obtain the identification space $P^n(\Lambda)$, called the n -dimensional **projective space over Λ** . Let $S^n_\Lambda (= S^{\lambda(n+1)-1})$, the $(\lambda(n+1)-1)$ -sphere be the unit sphere in Λ^{n+1} . Then S^n_Λ is the topological

transformation group of S_Λ^n by the product of Λ , and the orbit space S_Λ^n/S_Λ^0 is $P^n(\Lambda)$. Furthermore, $(S_\Lambda^n, q, P^n(\Lambda), S_\Lambda^0)$ (q is the projection) is a principal bundle called the **Hopf bundle** (or **Hopf fibering**). These comments are valid also for $n = \infty$. When $n = 1$, $P^1(\Lambda)$ is homeomorphic to S^λ , and the Hopf bundle is $(S^{2\lambda-1}, q, S^\lambda, S^{\lambda-1})$ ($\lambda = 1, 2, 4$). A Hopf bundle is defined similarly for $\lambda = 8$ using the \dagger Cayley algebra, and the projection $q: S^{2\lambda-1} \rightarrow S^\lambda$ ($\lambda = 2, 4, 8$) is the **Hopf mapping** (**Hopf map**).

(4) Let G be a topological group, H its closed subgroup, and $r: G \rightarrow G/H$, $r(g) = gH$ the natural projection. If there exist a neighborhood U of $r(H) \in G/H$ and a continuous mapping $f: U \rightarrow G$ such that $r \circ f$ is the identity mapping, then we say that H has a **local cross section** f in G , and $(G/K, p, G/H, H/K, H/K_0)$ is a fiber bundle for any closed subgroup K of H (where p is the natural projection $gK \rightarrow gH$ and K_0 is the largest normal subgroup of H contained in K). The associated principal bundle of the latter fiber bundle is $(G/K_0, p, G/H, H/K_0)$. Any closed subgroup H of a \dagger Lie group G has a local cross section in G ; hence the above bundles can be obtained.

F. Vector Bundles

A system $\xi = (E, p, B)$ of topological spaces E, B and a continuous mapping $p: E \rightarrow B$ is called an n -dimensional real **vector bundle** if the following two conditions are satisfied: (1) $p^{-1}(b)$ is a real vector space for each $b \in B$. (2) There exist an open covering $\{U_\alpha\}$ ($\alpha \in \Lambda$) of B and a coordinate function $\varphi_\alpha: U_\alpha \times F \approx P^{-1}(U_\alpha)$ for each $\alpha \in \Lambda$, where $F = \mathbf{R}^n$; furthermore, the $\varphi_{\alpha,b}: \mathbf{R}^n \approx p^{-1}(b)$ are isomorphisms of vector spaces. In this case, $g_{\beta\alpha}(b) = \varphi_{\beta,b}^{-1} \circ \varphi_{\alpha,b}: \mathbf{R}^n \approx \mathbf{R}^n$ ($b \in U_\alpha \cap U_\beta$) is an element of the \dagger general linear group $GL(n, \mathbf{R})$. Hence a vector bundle is a fiber bundle with fiber \mathbf{R}^n and group $GL(n, \mathbf{R})$, and the converse is also true. A 1-dimensional vector bundle is called a **line bundle**. A vector bundle $\xi' = (E', p', B)$ is called a **subbundle** of a vector bundle $\xi = (E, p, B)$ if $E' \subset E$, $p|_{E'} = p'$, and $p^{-1}(b)$ is a vector subspace of $p^{-1}(b)$ for each $b \in B$.

Let ξ_1 and ξ_2 be two vector bundles of dimension n_1 and n_2 with the same base space B . Let E be the union of the direct sum $p_1^{-1}(b) + p_2^{-1}(b)$ for $b \in B$, and define $p: E \rightarrow B$ by $p(p_1^{-1}(b) + p_2^{-1}(b)) = b$. Take the same coordinate neighborhoods U_α for ξ_1 and ξ_2 , and define $\varphi_\alpha: U_\alpha \times \mathbf{R}^{n_1+n_2} \rightarrow p^{-1}(U_\alpha)$ by $\varphi_\alpha(b, y) = (\varphi_{\alpha,b}^1 + \varphi_{\alpha,b}^2)(y)$ ($y \in \mathbf{R}^{n_1+n_2} = \mathbf{R}^{n_1} + \mathbf{R}^{n_2}$), where the $\varphi_\alpha^i: U_\alpha \times \mathbf{R}^{n_i} \approx p_i^{-1}(U_\alpha)$ are the coordinate functions of ξ_i . Then E is topologized by taking the family $\{\varphi_\alpha(O)\}$ (O is open in $U_\alpha \times \mathbf{R}^{n_1+n_2}$) as the \dagger open base, and we obtain

an $(n_1 + n_2)$ -dimensional real vector bundle (E, p, B) , denoted by $\xi_1 \oplus \xi_2$ and called the **Whitney sum** of ξ_1 and ξ_2 . Similarly, we can define the **tensor product** $\xi_1 \otimes \xi_2$, the **p -fold exterior power** $\wedge^p \xi$ (or **bundle** $\xi^{(p)}$ of p -vectors), and the **bundle of homomorphisms** $\text{Hom}(\xi_1, \xi_2)$, of dimension $n_1 n_2$, $\binom{n}{p}$, and $n_1 n_2$, respectively, using the tensor product $\mathbf{R}^{n_1} \otimes \mathbf{R}^{n_2} = \mathbf{R}^{n_1 n_2}$, the p -fold \dagger exterior power $\wedge^p \mathbf{R}^n = \mathbf{R}^{\binom{n}{p}}$ (the space $(\mathbf{R}^n)^{(p)}$ of p -vectors in \mathbf{R}^n), and the space of homomorphisms $\text{Hom}(\mathbf{R}^{n_1}, \mathbf{R}^{n_2}) = \mathbf{R}^{n_1 n_2}$. (For the last one, we use $\text{Hom}((\varphi_{\alpha,b}^1)^{-1}, \varphi_{\alpha,b}^2)$ instead of $\text{Hom}(\varphi_{\alpha,b}^1, \varphi_{\alpha,b}^2)$.) $\text{Hom}(\xi, \varepsilon^1) = \xi^*$ is called the **dual (vector) bundle** of ξ , where ε^1 is the trivial line bundle. If we use coordinate transformations, \oplus , \otimes , \wedge^p , and ξ^* are obtained by the direct sum, \dagger Kronecker product, matrix of $\dagger p$ -minors, and \dagger transpose of matrices, respectively. If ξ_2 is a subbundle of ξ_1 , the **quotient bundle** ξ_1/ξ_2 of dimension $n_1 - n_2$ is defined by using the quotient vector space $\mathbf{R}^{n_1}/\mathbf{R}^{n_2} = \mathbf{R}^{n_1 - n_2}$, and $\xi_2 \oplus (\xi_1/\xi_2)$ is equivalent to ξ_1 . These operations preserve the equivalence relation of bundles. Also, \oplus and \otimes are commutative up to equivalence and satisfy the associative and distributive laws. For each ξ having a finite-dimensional \dagger CW complex as base space, there is a ξ' such that $\xi \oplus \xi'$ is trivial.

Using the complex number field \mathbf{C} or the quaternion field \mathbf{H} instead of the real number field \mathbf{R} , we can define similarly the **complex vector bundle** or the **quaternion vector bundle** and the operations \oplus , \otimes , etc. For a complex vector bundle ξ , the **complex conjugate bundle** $\bar{\xi}$ is defined by the complex conjugate of matrices.

(5) Tangent bundles, tensor bundles. Let M be an n -dimensional \dagger differentiable manifold of class C^r . Consider the \dagger tangent vector space $T_p(M)$ at $p \in M$, set $T(M) = \bigcup_{p \in M} T_p(M)$, and define $\pi: T(M) \rightarrow M$ by $\pi(T_p(M)) = p$. For a \dagger coordinate neighborhood U_p of p with local coordinate system (x_1, \dots, x_n) , each point of $\pi^{-1}(U_p)$ is represented by $\sum_{i=1}^n f_i \partial/\partial x_i$, and $\pi^{-1}(U_p)$ has a coordinate system $(x_1, \dots, x_n, f_1, \dots, f_n)$. Hence $T(M)$ is a C^{r-1} -manifold, and $\mathfrak{T}(M) = (T(M), \pi, M, \mathbf{R}^n, GL(n, \mathbf{R}))$ is an n -dimensional real vector bundle. $\mathfrak{T}(M)$ is called the **tangent (vector) bundle**, its dual bundle $\mathfrak{T}^*(M)$ the **cotangent (vector) bundle**, and the tensor product $\mathfrak{T}(M) \otimes \dots \otimes \mathfrak{T}^*(M) \otimes \dots$ a **tensor bundle** of M . The line bundle $\wedge^n \mathfrak{T}^*(M)$ is called the **canonical bundle** of M .

For a \dagger complex manifold M , $T(M)$ is a complex manifold and $\mathfrak{T}(M)$ is a complex vector bundle. Therefore these bundles are defined as complex bundles.

(6) Tangent r -frame bundle. In the preceding example, the space of all \dagger tangent r -frames of M is a bundle space with base space M and

group $GL(n, \mathbf{R})$. It is called the **tangent r -frame bundle** (or the bundle of tangent r -frames) of M .

G. The Classification Problem

For a fiber bundle $\xi = (E, p, B, F, G)$ and a continuous mapping $\psi: B' \rightarrow B$, consider the subspace $E' = \{(x, b') \in E \times B' \mid p(x) = \psi(b')\}$ of $E \times B'$ and the projections $p': E' \rightarrow B'$ and $\Psi: E' \rightarrow E$. Then $\psi^* \xi = (E', p', B', F, G)$ is a fiber bundle, and Ψ is a bundle mapping from $\psi^* \xi$ to ξ ; $\psi^* \xi$ is called the **induced bundle** of ξ by ψ . Let $\{U_\alpha\}$ and $\{g_{\beta\alpha}\}$ be the systems of coordinate neighborhoods and transformations of ξ . Then $\{\psi^{-1}(U_\alpha)\}$ and $\{g_{\beta\alpha} \circ \psi\}$ are corresponding systems of $\psi^* \xi$. If $\Psi: E' \rightarrow E$ is a bundle mapping from ξ' to ξ having $\psi: B' \rightarrow B$ as the mapping of base spaces, then $\xi' \equiv \psi^* \xi$. Also, we have $\psi^* \xi_1 \equiv \psi^* \xi_2$ if $\xi_1 \equiv \xi_2$; $(\psi \circ \psi')^* \xi \equiv \psi'^*(\psi^* \xi)$. If ξ is a principal bundle, then $\psi^* \xi$ is also principal, and $\psi^*(\eta \times_G F) \equiv (\psi^* \eta) \times_G F$. For a \dagger paracompact space B' , $\psi_1^* \xi \equiv \psi_2^* \xi$ if $\psi_1, \psi_2: B' \rightarrow B$ are \dagger homotopic.

For a topological group G , a principal bundle $\xi(n, G) = (E(n, G), p, B(n, G), G)$ is called an **n -universal bundle** if $E(n, G)$ is $\dagger n$ -connected ($n \leq \infty$); its base space $B(n, G)$ is called an **n -classifying space** of G . In particular, $\xi(\infty, G) = \xi_G = (E_G, p, B_G, G)$ is called simply a **universal bundle** and B_G a **classifying space** of G . Then we have the **classification theorem**: Let B be a CW complex with $\dim B \leq n$; then the set of equivalence classes of principal G -bundles with base space B is in one-to-one correspondence with the \dagger homotopy set $\pi(B; B(n, G))$ of continuous mappings of B into $B(n, G)$. Such a correspondence is given by associating with the induced bundle $\psi^* \xi(n, G)$ a continuous mapping $\psi: B \rightarrow B(n, G)$, called the **characteristic mapping or classifying mapping (characteristic map or classifying map)** of $\psi^* \xi(n, G)$. Furthermore, if G is an effective left topological transformation group of F , the set of equivalence classes of G -bundles with base space B and fiber F is in one-to-one correspondence with $\pi(B; B(n, G))$. The correspondence is given by associating $\psi^*(\xi(n, G) \times_G F)$ to ψ .

H. Construction of Universal Bundles

For an arbitrary topological group G , J. W. Milnor [6] constructed a universal bundle (E_G, p, B_G, G) in the following manner. The **join** $E_G = G \circ \dots \circ G \circ \dots$ of countably infinite copies of G is defined as follows: A point e of E_G is the symbol $t_1 g_{i_1} \oplus \dots \oplus t_m g_{i_m}$ ($1 \leq i_1 < i_2 < \dots < i_m, m = 1, 2, 3, \dots$), where t_1, \dots, t_m are real numbers satisfying $t_{i_k} \geq 0, t_{i_1} + \dots + t_{i_m} = 1$,

and g_{i_k} is an element of the i_k th copy of G , $k = 1, \dots, m$. Here we can omit $t_{i_k} g_{i_k}$ if $t_{i_k} = 0$. Regard E_G as a topological space with a weak topology such that the coordinate functions $e \mapsto t_i, e \mapsto g_i$ are continuous. Define the right action of G on E_G by $(t_{i_1} g_{i_1} \oplus \dots \oplus t_{i_m} g_{i_m}) \cdot g = t_{i_1} (g_{i_1} \cdot g) \oplus \dots \oplus t_{i_m} (g_{i_m} \cdot g)$. Let B_G and $p: E_G \rightarrow B_G$ be the identification space of E_G by this action of G and the identification mapping. Then (E_G, p, B_G, G) is a **universal bundle** for G , and B_G is called the **classifying space** for G . E_G and B_G are sometimes written as EG and BG . In particular, a classifying space B_G is a countable CW complex for any countable CW group G (i.e., a topological group that is a countable CW complex such that the mapping $g \mapsto g^{-1}$ of G into G and the product mapping $G \times G \rightarrow G$ are both cellular). The following examples of classifying spaces for Lie groups are also useful. Note that every CW complex B_G of a given G has the same \dagger homotopy type.

I. Examples of Universal Bundles

(1) G is either $O(n)$, $U(n)$, or $Sp(n)$: Let Λ and λ be as in (3) of Section E. According as Λ is \mathbf{R} , \mathbf{C} , or \mathbf{H} , we let $U(n, \Lambda)$ be the \dagger orthogonal group $O(n)$, the \dagger unitary group $U(n)$, or the \dagger symplectic group $Sp(n)$. Then the \dagger Stiefel manifold $V_{m+n, m}(\Lambda) = U(m+n, \Lambda)/I_m \times U(n, \Lambda)$ (I_m is the unit element of $U(m, \Lambda)$) is $(\lambda(n+1) - 2)$ -connected. Hence the principal bundle $\xi(\lambda(n+1) - 2, U(m+n, \Lambda)) = (V_{m+n, m}(\Lambda), M_{m+n, m}(\Lambda), U(m, \Lambda))$ from (4) of Section E is a $(\lambda(n+1) - 2)$ -universal bundle of $U(m, \Lambda)$, where the base space $M_{m+n, m}(\Lambda) = U(m+n, \Lambda)/U(m, \Lambda) \times U(n, \Lambda)$ is the \dagger Grassmann manifold.

(2) G is either $O(\infty)$, $U(\infty)$, or $Sp(\infty)$. The examples in (1) are valid for $m, n = \infty$. Consider the \dagger inductive limit group $U(\infty, \Lambda) = \bigcup_n U(n, \Lambda)$ under the natural inclusion $U(n, \Lambda) \subset U(n+1, \Lambda)$, and supply the **infinite classical group** $U(\infty, \Lambda)$ with the weak topology (this means that a set O of $U(\infty, \Lambda)$ is open if and only if each $O \cap U(n, \Lambda)$ is open in $U(n, \Lambda)$). Then the **infinite Stiefel manifold** $V_{m+n, m}(\Lambda)$ and the **infinite Grassmann manifold** $M_{m+n, m}(\Lambda)$ ($m = \infty$ or $n = \infty$) are defined as before, and we have

$$M_{\infty, m}(\Lambda) = \bigcup_n M_{m+n, m}(\Lambda),$$

and so on. Furthermore, these manifolds are CW complexes, and $V_{\infty, m}(\Lambda)$ ($m \leq \infty$) is ∞ -connected. Although $U(\infty, \Lambda)$ is not a Lie group, $U(m, \Lambda) \times U(n, \Lambda)$ has a local cross section in $U(m+n, \Lambda)$ for $m, n \leq \infty$ [7]. Therefore, setting $n = \infty$ in (1), $\xi(\infty, U(m, \Lambda))$ is a universal bundle of $U(m, \Lambda)$, and the infinite Grassmann manifold $M_{\infty, m}(\Lambda)$ is a classifying

space $B_{U(m,\Lambda)}$. Also, $\xi(\lambda(n+1)-2, U(\infty, \Lambda))$ in (1) is a $(\lambda(n+1)-2)$ -universal bundle of $U(\infty, \Lambda)$ ($n \leq \infty$).

(3) G is either $SO(m)$ or a general Lie group. For the rotation group $SO(m)$, we have $\xi(n-1, SO(n)) = (V_{m+n,m}(\mathbf{R}), p, \tilde{M}_{m+n,m}, SO(m))$ and $B_{SO(m)} = \tilde{M}_{\infty,m}$, where $\tilde{M}_{m+n,m} = SO(m+n)/SO(m) \times SO(n)$ is the oriented Grassmann manifold. For any compact Lie group G , we have $\xi(n-1, G) = (V_{m+n,m}(\mathbf{R}), p, O(m+n)/G \times O(n), G)$, where $G \subset O(m)$. For any connected Lie group G , we have $\xi(n, G) = \xi(n, G_1) \times_{G_1} G$, where G_1 is the maximum compact subgroup of G (since G/G_1 is homeomorphic to a Euclidean space, $\xi(n, G)$ reduces to $\xi(n, G_1)$).

J. Reduction of Fiber Bundles

Let G be a topological group and H its closed subgroup. We say that the structure group of a G -bundle ξ is **reduced** to H if ξ is equivalent to a G -bundle whose coordinate transformations take values in H . For a principal H -bundle $\eta_0 = (P, q, B, H)$, the associated H -bundle $\eta_0 \times_H G = (P \times_H G, p, B, G)$ with fiber G is defined, where H operates on G by the product of G ; it is also a principal G -bundle if we define an operation of G on $P \times_H G$ by $\{(x, g)\} \cdot g' = \{(x, gg')\}$. For a principal G -bundle η , we say that η is **reducible** to an H -bundle if there is a principal H -bundle η_0 with $\eta = \eta_0 \times_H G$, and we call η_0 a **reduced bundle** of η . It is easy to see that the group of a G -bundle ξ is reducible to H if and only if the associated principal G -bundle of ξ is reducible to H . Also, if η_0 is a reduced bundle of η , then $\psi^\# \eta_0$ is a reduced bundle of $\psi^\# \eta$.

Now, assume that H has a local cross section in G and G/H is ∞ -connected. Then for an n -universal bundle $\xi(n, H)$ of H , $\xi(n, H) \times_H G$ is an n -universal bundle of G (n -connectedness of $E(n, H) \times_H G$ is shown by the homotopy exact sequence of fiber spaces). Therefore, by the classification theorem, the group of any G -bundle is reducible to H , and the equivalence classes of G -bundles are in one-to-one correspondence with those of H -bundles.

(1) A G -bundle is trivial if and only if its group is reducible to e (identity element). A $2n$ -dimensional differentiable manifold M of class C^∞ has an almost complex structure if and only if the group of the tangent bundle $\mathfrak{T}(M)$ is reducible to $GL(n, \mathbf{C})$, i.e., $\mathfrak{T}(M)$ is considered as an n -dimensional complex vector bundle.

(2) Since $GL(n, \mathbf{R}) \approx O(n) \times \mathbf{R}^{n(n+1)/2}$ and $GL(n, \mathbf{C}) \approx U(n) \times \mathbf{R}^{n^2}$, n -dimensional real (complex) vector bundles can be considered as $O(n)$ ($U(n)$)-bundles with fiber \mathbf{R}^n (\mathbf{C}^n).

K. Homotopy and Homology Theory of Bundles

Since a fiber bundle is a locally trivial fiber space, the exact sequence and the spectral sequence of fiber spaces (\rightarrow 148 Fiber Spaces) are applicable to fiber bundles. For example, the cohomology structures of homogeneous spaces of classical groups have been determined by A. Borel, J.-P. Serre, and others.

(1) Characteristic class. For a classifying space B_G of a topological group G , we have an isomorphism $\pi_n(B_G) \cong \pi_{n-1}(G)$ of homotopy groups and the following classification theorem of fiber bundles over the n -sphere S^n . The set of the equivalence classes of principal G -bundles or G -bundles with fiber F over the base space S^n is in one-to-one correspondence with the set $\pi_{n-1}(G)/\pi_0(G)$ of equivalence classes under the operation of G on $\pi_{n-1}(G)$ given by the inner automorphisms of G ; such a correspondence is given by associating with each principal G -bundle $\eta = (P, q, S^n, G)$ the class (called the **characteristic class** of η) containing the image $\Delta(i_n)$ of a generator $i_n \in \pi_n(S^n)$ by the homomorphism $\Delta: \pi_n(S^n) \cong \pi_n(P, G) \rightarrow \pi_{n-1}(G)$. Take U_1 and U_2 (the open sets of S^n such that the last coordinates t_{n+1} are $> -1/2$ and $< 1/2$, respectively) as coordinate neighborhoods of η . Then the restriction $T = g_{12}|S^{n-1}$ represents the characteristic class of η , where $g_{12}: U_1 \cap U_2 \rightarrow G$ is the coordinate transformation and S^{n-1} is the equator of S^n .

(2) For the principal bundle $\eta = (SO(n+1), q, S^n, SO(n))$, the mapping $T: S^{n-1} \rightarrow SO(n)$ is given by

$$T(t_1, \dots, t_n) = (I_n - 2(t_i t_j)) \begin{pmatrix} I_{n-1} & 0 \\ 0 & -1 \end{pmatrix}$$

(I_n is the unit matrix of degree n). Hence the mapping degree of the composite $q' \circ T: S^{n-1} \rightarrow S^{n-1}$ (of T and the natural projection $q': SO(n) \rightarrow S^{n-1}$) is equal to 0 if n is odd and 2 if n is even. From this fact and the homotopy exact sequence, we have

$$\pi_n(V_{m+n,m}(\mathbf{R})) = \begin{cases} \mathbf{Z} & \text{if } m=1 \text{ or } n \text{ is even} \\ \mathbf{Z}_2 = \mathbf{Z}/2\mathbf{Z} & \text{if } m>1 \text{ and } n \text{ is odd} \end{cases}$$

for the real Stiefel manifold $V_{m+n,m}(\mathbf{R})$, which is $(n-1)$ -connected.

(3) Sphere bundles. An $O(n+1)$ -bundle with fiber S^n is called an **n -sphere bundle**. The set of equivalence classes of n -sphere bundles with base space S^m is in one-to-one correspondence with $\pi_{m-1}(O(n+1))/\pi_0(O(n+1))$. For example, any 1-sphere bundle over S^m ($m \geq 3$) and any n -sphere bundle over S^3 is trivial. Every 3-sphere bundle over S^4 is equivalent to one of $\{\xi_{m,n} | m \text{ an integer, } n \text{ a positive integer}\}$, where

$\xi_{m,n}$ is defined as follows: Let $\rho, \sigma: S^3 \rightarrow O(4)$ be defined by $\rho(q)q' = qq'q^{-1}$, $\sigma(q)q' = qq'$ (q, q' are \dagger quaternions of norm 1). Then these mappings represent generators of $\pi_3(O(4)) \cong \pi_3(S^3 \times S^3) \cong \mathbf{Z} + \mathbf{Z}$, and $\xi_{m,n}$ is the 3-sphere bundle over S^4 corresponding to the element $m\{\rho\} + n\{\sigma\} \in \pi_3(O(4))$ (i.e., to the mapping $f_{m,n}: S^3 \rightarrow O(4)$ defined by $f_{m,n}(q)(q') = q^{m+n}q'q^{-m}$). (Here we use the fact that the operation of the element $r \in O(4)$ ($r(q) = q^{-1}$) is given by $r\rho r^{-1} = \rho$, $r\sigma r^{-1} = \rho\sigma^{-1}$.)

L. Cross Sections

For a fiber bundle $\xi = (E, p, B, F, G)$, a cross section $f: B_0 \rightarrow E$ over a subspace $B_0 (\subset B)$ is a continuous mapping such that $p \circ f$ is the identity mapping of B_0 ; a cross section over B is called a **cross section** of ξ . A bundle ξ is trivial if and only if the associated principal bundle of ξ has a cross section. More generally, given a principal bundle $\eta = (P, q, B, G)$ and a closed subgroup H having a local cross section in G , η is reducible to H if and only if the associated bundle $\eta(\times_G(G/H) = (P/H, q', B), G/H)$ with fiber G/H has a cross section.

Suppose that the base space B of the fiber bundle $\xi = (E, p, B, F, G)$ is a \dagger polyhedron. We denote the $\dagger r$ -skeleton of B by B^r and consider the problem of extending cross sections $f_r: B^r \rightarrow E$ successively for $r = 0, 1, \dots$. Clearly, there is a cross section f_0 . For each r -simplex σ of B , we have $(p^{-1}(\sigma), p, \sigma, F) \equiv (\sigma \times F, p_1, \sigma, F)$ since σ is \dagger contractible. Hence there is a bundle mapping $\varphi_\sigma: \sigma \times F \approx p^{-1}(\sigma)$ with $p \circ \varphi_\sigma = p_1$. Assume the existence of a cross section $f_{r-1}: B^{r-1} \rightarrow E$, and consider the mapping $h_\sigma = p_2 \circ \varphi_\sigma^{-1} \circ (f_{r-1}|_\sigma): \dot{\sigma} \rightarrow F$ ($p_2: \sigma \times F \rightarrow F$ is the projection and $\dot{\sigma}$ is the boundary of σ). Then if h_σ is extensible to $h_\sigma: \sigma \rightarrow F$, an extended cross section $f_\sigma: \sigma \rightarrow E$ of $f_{r-1}|_\sigma$ is defined by $f_\sigma(b) = \varphi_\sigma(b, h_\sigma(b))$ ($b \in \sigma$), and the extension $f_r: B^r \rightarrow E$ of f_{r-1} is defined by $f_r|_\sigma = f_\sigma$, $f_r|_{B^{r-1}} = f_{r-1}$. If $\pi_{r-1}(F) = 0$, for example, there is an extension h_σ of h_σ since $(\sigma, \dot{\sigma}) \approx (V^r, S^{r-1})$, and f_{r-1} is extensible to a cross section f_r .

Now assume that the base space B of a G -bundle $\xi = (E, p, B, F, G)$ is an \dagger arcwise connected polyhedron and F is $\dagger(n-1)$ -connected. Then there is a cross section $f: B^n \rightarrow E$ constructed by the stepwise method of the previous paragraph. But if $\pi_n(F) \neq 0$, we have an obstruction to extending f over B^{n+1} . Now we explain how to measure this obstruction. Suppose that F is $\dagger n$ -simple. Then for each $(n+1)$ -simplex σ of B , the mapping $h_\sigma: \dot{\sigma} \rightarrow F$, defined by f as in the previous paragraph, determines a unique element $c(f)(\sigma)$ of the homotopy group $\pi_n(F)$. Hence we have a \dagger cochain $c(f) \in C^{n+1}(B; \pi_n(F))$, and f is extensible to a cross

section over B^{n+1} if and only if $c(f) = 0$. Thus there is a cross section over B^{n+1} if and only if the set of $c(f)$ for every cross section f over B^n contains the cochain 0; $\{c(f)\}$ is considered as a measure of the obstruction.

Let $w: I \rightarrow B$ be a \dagger path. We consider the space $I \times F$ and the canonical projection $p_1: I \times F \rightarrow I$. Then there is a bundle mapping $\Omega: I \times F \rightarrow E$ with $p \circ \Omega = w \circ p_1$, since $w^\# \xi \equiv (I \times F, p_1, I, F)$; and a homeomorphism $w_\#: F \approx F$ is defined by $w_\# = \varphi_{0, b_0}^{-1} \circ \Omega_0 \circ \Omega_1^{-1} \circ \varphi_{1, b_1}$, where $b_\varepsilon = w(\varepsilon)$ ($\varepsilon = 0, 1$), $\varphi_\varepsilon: U_\varepsilon \times F \approx p^{-1}(U_\varepsilon)$ is a coordinate function of a coordinate neighborhood $U_\varepsilon \ni b_\varepsilon$, and $\Omega_\varepsilon (= \Omega|_{\varepsilon \times F}): F \approx p^{-1}(b_\varepsilon)$. The homeomorphism $w_\#$ induces an isomorphism $w_\#: \pi_n(F) \cong \pi_n(F)$, and $\pi_n(F)$ forms a \dagger local coefficient on B . Then the cochain $c(f)$ is a \dagger cocycle with the local coefficient $\pi_n(F)$, called the **obstruction cocycle** of f . Furthermore, the set $\{c(f)\}$ for every cross section $f: B^n \rightarrow E$ is a cohomology class $c^{n+1}(\xi) \in H^{n+1}(B; \pi_n(F))$ (local coefficient), and $c^{n+1}(\xi)$ is called the **primary obstruction** to the construction of a cross section. There is a cross section over the $(n+1)$ -skeleton B^{n+1} if and only if $c^{n+1}(\xi) = 0$. The local coefficient $\pi_n(F)$ is trivial if B is \dagger simply connected or, for example, if the structure group G of ξ is connected (in which case ξ is called an **orientable fiber bundle**); when this is true, $c^{n+1}(\xi)$ is an element of $H^{n+1}(B; \pi_n(F))$, where $\pi_n(F)$ is not a local coefficient. Furthermore, if $c^{n+1}(\xi) = 0$ and $\pi_i(F) = 0$ ($n < i < m$), then the secondary obstruction $\Omega^{m+1}(\xi) \in H^{m+1}(B; \pi_m(F))$ is defined similarly (\rightarrow 305 Obstructions).

M. Stiefel-Whitney Classes

Let $\xi = (E, p, B, F, O(n))$ be an $O(n)$ -bundle over an arcwise connected polyhedron B and let ξ^0 be its associated principal bundle. Consider the Stiefel manifold $V_{n,n-k} = V_{n,n-k}(\mathbf{R}) = O(n)/I_{n-k} \times O(k)$, which is $(k-1)$ -connected, and the associated bundle $\xi^k = \xi^0 \times_{O(n)} V_{n,n-k}$ with fiber $V_{n,n-k}$. The primary obstruction $W_{k+1}(\xi) = c^{k+1}(\xi^k) \in H^{k+1}(B; \pi_k(V_{n,n-k}))$ ($k = 0, 1, \dots, n-1$) is called the **Stiefel-Whitney class** of ξ . We have $2W_{k+1}(\xi) = 0$ unless $k = n-1$ and k is odd. Hence we usually consider $W_{k+1}(\xi) \in H^{k+1}(B; \mathbf{Z}_2)$. ξ is orientable, i.e., the group of ξ is reducible to $SO(n)$, if and only if $W_1(\xi) = 0$. The **Stiefel-Whitney classes of an n -dimensional \dagger differentiable manifold M** are defined to be those of the tangent bundle $\mathfrak{T}(M)$. Since the orientability of M coincides with that of $\mathfrak{T}(M)$, M is orientable if and only if $W_1(M) = 0$. The condition $W_{k+1}(M) = 0$ is necessary for the existence of a continuous field of orthonormal tangent $(n-k)$ -frames over M (if $k = n-1$ this condition is also suffi-

cient). Also, when M is closed, $W_n(M)$ is equal to $\chi(M)\mu$, where μ is the fundamental cohomology class of M and $\chi(M)$ is the \dagger Euler characteristic of M (\rightarrow 56 Characteristic Classes B).

N. Chern Classes

For a $U(n)$ -bundle $\xi = (E, p, B, F, U(n))$, the primary obstruction $C_{k+1}(\xi) = c^{2k+2}(\xi^k) \in H^{2k+2}(B; \mathbf{Z})$ ($k=0, 1, \dots, n-1$) of the associated bundle $\xi^k = \xi^0 \times_{U(n)} V_{n,n-k}(\mathbf{C})$ is called the **Chern class** of ξ . If we consider ξ as an $O(2n)$ -bundle by $U(n) \subset O(2n)$, then $W_{2k+1}(\xi) = 0$ and $W_{2k}(\xi) = C_k(\xi) \pmod{2}$. The **Chern classes** of a real $2n$ -dimensional almost complex manifold are defined to be those of the tangent bundle $\mathfrak{T}(M)$ (\rightarrow 56 Characteristic Classes C).

O. Bundles of Class C^r , Analytic Bundles

A fiber bundle $\xi = (E, p, B, F, G)$ is called a **fiber bundle of class C^r** ($r=0, 1, \dots, \infty, \omega$) if E, B, F are differentiable manifolds of class C^r , G is a Lie group and a transformation group of F of class C^r , and p and the coordinate functions are differentiable mappings of class C^r . Bundles of class C^0 are usual G -bundles, and those of class C^ω are **real analytic fiber bundles**. Similarly, **complex analytic fiber bundles** are defined by the notions of complex manifolds, \dagger complex Lie groups, and \dagger holomorphic mappings. For example, the universal bundles $\xi(n-1, O(m))$ and $\eta(2n, U(m))$ are real and complex analytic principal bundles, respectively, and the tangent bundle $\mathfrak{T}(M)$ of a C^{r+1} (or complex) manifold is a C^r (or complex analytic) vector bundle. The operations of the Whitney sum, etc., are defined analogously for these vector bundles.

The equivalence of C^r (complex analytic) bundles is defined by means of bundle mappings that are C^r -differentiable (holomorphic). Bundles of class C^r ($r \leq \infty$) are classified by C^r mappings into a classifying space in the same manner as for bundles of class C^0 . Also, the connection of class C^r (\rightarrow 80 Connections) in C^r bundles is an important notion.

For complex analytic bundles, a similar classification has been obtained for restricted spaces by K. Kodaira, Serre, S. Nakano [8], and others. The classification of complex analytic bundles over a \dagger Stein manifold is reduced to that of bundles of class C^0 (**Oka's principle** [9]), and similar results are valid for C^ω -manifolds. The complex analytic (or holomorphic) connection does not necessarily exist, and M. F. Atiyah [10] found the condition for its existence and its relation with Chern classes.

P. Microbundles

A system $x: B \xrightarrow{i} E \xrightarrow{j} B$ of topological spaces E, B and continuous mappings i, j is called an n -dimensional **microbundle** over B if for each $b \in B$, there exist a neighborhood U of b , a neighborhood V of $i(U)$, and a homeomorphism $h: V \approx U \times \mathbf{R}^n$ with $h \circ i|_U = i_1, j|_V = p_1 \circ h$ ($i_1: U \approx U \times 0 \subset U \times \mathbf{R}^n$, and $p_1: U \times \mathbf{R}^n \rightarrow U$ is the projection). Let $H_0(n)$ be the topological group of all homeomorphisms of \mathbf{R}^n onto itself fixing the origin with compact-open topology. Then the equivalence classes of n -dimensional microbundles over B are naturally in one-to-one correspondence with the equivalence classes of $H_0(n)$ -bundles with base space B and fiber \mathbf{R}^n [13].

In the category of polyhedra and PL (\dagger piecewise linear) mappings, the notion of a **PL microbundle** can be defined in the same manner. The structural group of n -dimensional PL microbundles is defined, in a generalized sense, as a complete \dagger semi-simplicial complex [11]. The **tangent PL microbundle** is defined for any \dagger topological (PL) manifold. J. Milnor classified \dagger smoothings of PL manifolds by means of PL microbundles [11] and then showed that the \dagger tangent vector bundles and its \dagger Pontryagin classes of smooth manifolds are not topologically invariant [12].

For a \dagger PL embedding $f: M \rightarrow N$ between PL manifolds, if there is a neighborhood E of $f(M)$ in N and a PL mapping $p: E \rightarrow M$ so that a diagram $v: M \xrightarrow{f} E \xrightarrow{p} M$ is a PL microbundle, then v is called a **normal PL microbundle** of f . In this case, f is \dagger locally flat.

There is a locally flat PL embedding between PL manifolds which admits no normal PL microbundle [14].

Q. Block Bundles

As the normal bundle theory for locally flat PL embeddings of PL manifolds, the concept of block bundle was introduced independently by C. P. Rourke and B. J. Sanderson [15], M. Kato [16], and C. Morlet [17]. Let E be a \dagger polyhedron, and let K be a cell complex. A set $\{E_\sigma | \sigma \in K\}$ of PL balls in E indexed on K is called a **q -block structure** of E if the following three conditions are satisfied: (1) $\bigcup_{\sigma \in K} E_\sigma = E$; (2) for each $\sigma \in K$, there is a \dagger PL homeomorphism $h_\sigma: \sigma \times I^q \rightarrow E_\sigma$ such that $h_\sigma(\tau \times I^q) = E_\tau$ for each face τ of σ , where $I = [-1, 1]$; and (3) if $E_\sigma \cap E_\rho \neq \emptyset$, then $E_\sigma \cap E_\rho = E_\tau$, where $\tau = \sigma \cap \rho$.

For $\sigma \in K$, E_σ is called the **block** over σ , and h_σ in (2) is called a **trivialization** of E_σ . Then a triple $(E, K, \{E_\sigma | \sigma \in K\})$ is referred to as a **q -block bundle** over K and is denoted by ξ/K . Another block bundle $\xi'/K = (E', K, \{E'_\sigma | \sigma \in$

$K\}$ over the same complex K is said to be **isomorphic** with ξ/K if there is a PL homeomorphism $g: E \rightarrow E'$, called an **isomorphism**, such that $g(E_\sigma) = E'_\sigma$ ($\sigma \in K$). A PL embedding $i: |K| \rightarrow E$ is a **zero-section** of ξ/K if for each $\sigma \in K$, there is a trivialization $h_\sigma: \sigma \times I^q \rightarrow E_\sigma$ such that $h_\sigma(x, 0) = i(x)$ ($x \in \sigma$). In this case we say that ξ/K is a block bundle with a zero-section $i: |K| \rightarrow E$. There is a unique zero-section of ξ/K up to isomorphism of ξ/K onto itself. For every \dagger locally flat PL embedding between PL manifolds M and W of codimension q and for any cell division K of M , a \dagger derived neighborhood N of $f(M)$ in W admits a unique q -block bundle $\nu/K = (N, K, \{N_\sigma | \sigma \in K\})$ with $f: M \rightarrow N$ as a zero-section up to isomorphism respecting the zero-section [15]. The block bundle ν/K is called a **normal block bundle** of $f: M \rightarrow W$.

148 (IX.10) Fiber Spaces

A. General Remarks

J.-P. Serre [1] generalized the concept of fiber bundles to that of fiber spaces by utilizing the covering homotopy property (\rightarrow Section B). He applied the theory of \dagger spectral sequences, due to J. Leray, to the (cubic) \dagger singular (co)-homology groups of fiber spaces. These are quite useful for determining (co)homology structures and homotopy groups of topological spaces, and are now of fundamental importance in algebraic topology.

B. Definitions

Let $p: E \rightarrow B$ be a continuous mapping between topological spaces, and let X be a topological space. Then we say that p has the **covering homotopy property** with respect to X if for any mapping $f: X \rightarrow E$ and \dagger homotopy $g: X \rightarrow B$ ($0 \leq t \leq 1$) with $p \circ f = g_0$, there is a homotopy $f_t: X \rightarrow E$ ($0 \leq t \leq 1$) with $f_0 = f$ and $p \circ f_t = g_t$. We call (E, p, B) a **fiber space** (or **fibration**) if p has the covering homotopy property with respect to every cube $I^n = \{(x_1, \dots, x_n) | 0 \leq x_i \leq 1\}$, $n = 0, 1, \dots$ (then p has the covering homotopy property with respect to every \dagger CW complex). Then E is called the **total space**, p the **projection**, B the **base space**, and $F_b = p^{-1}(b)$ the **fiber** over $b \in B$.

Let E, B, F be topological spaces and $p: E \rightarrow B$ a continuous mapping. We call (E, p, B, F) a **locally trivial fiber space** if for each $b \in B$, there exist an open neighborhood U of b and a homeomorphism $\varphi: U \times F \rightarrow p^{-1}(U)$ with $p \circ \varphi(b', y) = b'$ ($b' \in U, y \in F$). In this case, p has the covering homotopy property with respect to each \dagger paracompact space; hence (E, p, B) is a fiber space. A \dagger fiber bundle is clearly a locally trivial fiber space.

C. Path Spaces

Another important example of a fiber space is a path space. A **path** in a topological space X is a continuous mapping $w: I \rightarrow X$ ($I = [0, 1]$). Given subsets A_0 and A_1 of X , the **path space** $\Omega(X; A_0, A_1)$ is the space of all paths $w: I \rightarrow X$ satisfying $w(\varepsilon) \in A_\varepsilon$ ($\varepsilon = 0, 1$) topologized by \dagger compact-open topology. Define $p_\varepsilon: \Omega(X; A_0, A_1) \rightarrow A_\varepsilon$ by $p_\varepsilon(w) = w(\varepsilon)$ ($\varepsilon = 0, 1$). Then $(\Omega(X; A_0, A_1), p_\varepsilon, A_\varepsilon)$ is a fiber space; in fact, p_ε has the covering homotopy property with respect to every topological space. In particular, the total space of the fiber space $(\Omega(X; X, *), p_0, X)$ ($* \in X$) is \dagger contractible, and the fiber $p_0^{-1}(*) = \Omega(X; *, *) = \Omega X$ over $*$ is the \dagger loop space of X with base point $*$. For a continuous mapping $f: Y \rightarrow X$, consider the space $E_f = \{(y, w) \in Y \times \Omega(X; X, X) \mid f(y) = w(0)\}$ and the continuous mapping $p: E_f \rightarrow X$ defined by $p(y, w) = w(1)$. Then $Y \subset E_f$, and Y is a \dagger deformation retract of E_f ; furthermore, (E_f, p, X) is a fiber space with $f = p \mid Y$.

D. Homotopy Groups of Fiber Spaces

For \dagger homotopy groups of fiber spaces, the **Hurewicz-Steenrod isomorphism theorem** holds: Let (E, p, B) be a fiber space and $F = p^{-1}(*)$ the fiber over the base point $* \in B$. Then $p_*: \pi_n(E, F) \rightarrow \pi_n(B)$ is an isomorphism for $n \geq 2$ and a bijection for $n = 1$. By this theorem, we have the **homotopy exact sequence** of a fiber space:

$$\dots \rightarrow \pi_{n+1}(B) \xrightarrow{\Delta} \pi_n(F) \xrightarrow{i_*} \pi_n(E) \xrightarrow{p_*} \pi_n(B) \rightarrow \dots$$

Furthermore, the more general exact sequence

$$\dots \rightarrow \pi(Z; \Omega B)_0 \rightarrow \pi(Z; F)_0 \xrightarrow{i_*} \pi(Z; E)_0 \xrightarrow{p_*} \pi(Z; B)_0$$

is valid for each CW complex Z , where $\pi(Z; X)_0$ denotes the \dagger homotopy set of mappings from Z to X relative to the base point.

Example (1). A **cross section** of a fiber space (E, p, B) is a continuous mapping $f: B \rightarrow E$ with $p \circ f = 1$. If (E, p, B) has a \dagger cross section or the fiber F is a \dagger retract of E , then $\pi_n(E) \cong \pi_n(B) + \pi_n(F)$. If F is contractible in E , then $\pi_n(B) \cong \pi_n(E) + \pi_{n-1}(F)$ ($n \geq 2$).

Example (2). (E, p, B) is called an **n -connective fiber space** if B is \dagger arcwise connected, E is $\dagger n$ -connected, and $p_*: \pi_i(E) \rightarrow \pi_i(B)$ is an isomorphism, for $i > n$. For each arcwise connected space B and integer n , there is such a fiber space.

Example (3). For a CW complex X , there are topological spaces X_n and continuous mappings $f_n: X \rightarrow X_n$, $q_{n+1}: X_{n+1} \rightarrow X_n$ ($n = 0, 1, \dots$) with the following four properties: (i) X_n ($0 \leq n \leq m$) is a point if X is m -connected; (ii) $f_n^*: \pi_i(X) \cong \pi_i(X_n)$ ($i \leq n$); (iii) (X_n, q_n, X_{n-1}) is a fiber

space, and its fiber is an \dagger Eilenberg-MacLane space $K(\pi_n(X), n)$; (iv) $q_n \circ f_n$ is \dagger homotopic to f_{n-1} . Such a system $\{X_n, f_n, q_n\}$ is called the **Postnikov system** of X and is in a sense considered a decomposition of X into Eilenberg-MacLane spaces.

E. Spectral Sequences of Fiber Spaces

The cohomological properties of fiber spaces are obtained mainly from the following results (which are valid similarly for homology except for properties of products). Assume that the base space B of a given fiber space (E, p, B) is \dagger simply connected and the fiber $F = p^{-1}(*)$ is arcwise connected, and let R be a commutative ring with unit. Then the **spectral sequence** (of singular cohomology) **of the fiber space** (E, p, B) (with coefficients in R) is defined to be a sequence $\{E_r, d_r\}$ satisfying the following properties:

- (i) $E_r = \sum_{p,q} E_r^{p,q}$ are bigraded R -modules, and $d_r = \sum_{p,q} d_r^{p,q}$ are R -linear differentials such that $d_r(E_r^{p,q}) \subset E_r^{p+r, q-r+1}$.
- (ii) $E_{r+1}^{p,q} = \text{Ker } d_r^{p,q} / \text{Im } d_r^{p-r, q+r-1}$, which means that $E_{r+1} = H(E_r)$.
- (iii) $E_r^{p,q} = 0$ for $p < 0$ or $q < 0$, $E_r^{p,q} = E_{r+1}^{p,q} = \dots = E_\infty^{p,q}$ for $r > \max(p, q+1)$.
- (iv) E_r has a product for which $E_r^{p,q} \cdot E_r^{p',q'} \subset E_r^{p+p', q+q'}$ and $d_r(u \cdot v) = (d_r u) \cdot v + (-1)^{p+q} u \cdot d_r v$ ($u \in E_r^{p,q}$). Furthermore, the induced product in $H(E_r)$ coincides with the product in E_{r+1} .
- (v) E_∞ is the \dagger bigraded module associated with some filtration of the cohomology module $H^*(E; R)$; that is, $H^n(E; R) = D^{0,n} \supset D^{1,n-1} \supset \dots \supset D^{n,0} \supset D^{n+1,-1} = 0$ and $E_\infty^{p,q} = D^{p,q} / D^{p+1, q-1}$. Furthermore, the \dagger cup product \smile in $H^*(E; R)$ satisfies $D^{p,q} \smile D^{p',q'} \subset D^{p+p', q+q'}$ and coincides with the given product in E_∞ .
- (vi) $E_2^{p,q} = H^p(B; H^q(F; R))$, and the product in E_2 coincides with the cup product in $H^*(B; H^*(F; R))$.
- (vii) The composition of $H^n(B; R) = E_2^{n,0} \rightarrow E_3^{n,0} \rightarrow \dots \rightarrow E_{n+1}^{n,0} = E_\infty^{n,0} = D^{n,0} \subset H^n(E; R)$ is equal to p^* , and the composition of $H^n(E; R) = D^{0,n} \rightarrow E_\infty^{0,n} = E_{n+2}^{0,n} \subset \dots \subset E_3^{0,n} \subset E_2^{0,n} = H^n(F; R)$ is equal to i^* ($i: F \subset E$), where each \rightarrow is the projection onto the quotient module. In the sequence

$$H^{n-1}(F; R) \xrightarrow{\partial^*} H^n(E; R) \xleftarrow{p^*} H^n(B; R),$$

we have $\partial^{*-1}(\text{Im } p^*) = E_\infty^{0, n-1}$, $\text{Coim } p^* = E_\infty^{n,0}$, and $d_n: E_\infty^{0, n-1} \rightarrow E_\infty^{n,0}$ is equal to the **transgression** $\tau^* = p^{*-1} \circ \partial^*: \partial^{*-1}(\text{Im } p^*) \rightarrow \text{Coim } p^*$. Each element of $\partial^{*-1}(\text{Im } p^*)$ is called **transgressive**.

In the following examples, we assume that R is a principal ideal ring.

Example (4). Let k be a commutative

field, and assume that $\dim_k H_*(B; k)$ and $\dim_k H_*(F; k)$ are finite. Then for the \dagger Poincaré polynomial $P_X(t) = \sum_n b_n t^n$, $b_n = \dim_k H_n(X; k)$, we have $P_E(t) = P_B(t)P_F(t) - (1+t)\varphi(t)$, where $\varphi(t)$ is a polynomial with nonnegative coefficients (Leray). In particular, for the \dagger Euler characteristic $\chi(X) = P_X(-1)$, we have $\chi(E) = \chi(B)\chi(F)$. Also, if $i_*: H_n(F; k) \rightarrow H_n(E; k)$ is monomorphic for each $n \geq 0$, then $P_E(t) = P_B(t)P_F(t)$.

Example (5). Isomorphism theorem: If $H_n(B; R) = 0$ ($0 < n < r$) and $H_n(F; R) = 0$ ($0 < n < s$), then $p_*: H_n(E, F; R) \rightarrow H_n(B; R)$ is isomorphic for $0 < n < r + s$ and epimorphic for $n = r + s$, and we have the following **homology exact sequence**:

$$\begin{aligned} \dots \rightarrow H_n(F; R) \xrightarrow{i_*} H_n(E; R) \xrightarrow{p_*} H_n(B; R) \\ \xrightarrow{\tau_*} H_{n-1}(F; R) \rightarrow \dots, \quad n < r + s \end{aligned}$$

(similarly for the cohomology).

Example (6). Assume that $H^n(F; R) \cong H^n(S^r; R)$ (S^r is the r -sphere, $r \geq 1$). Let $\tilde{E} = M_p$ be the \dagger mapping cylinder of $p: E \rightarrow B$ and $\tilde{p}: \tilde{E} \rightarrow B$ be the continuous mapping defined by p . Then the **Thom-Gysin isomorphism** $\tilde{g}: H^{n-r-1}(B; R) \cong H^n(\tilde{E}, E; R)$ ($n \geq 0$) with $\tilde{g}(\alpha) = \tilde{p}^*(\alpha) \smile \tilde{g}(1)$ holds (\rightarrow 114 Differential Topology G). Also, we have the **Gysin exact sequence**:

$$\begin{aligned} \dots \rightarrow H^n(B; R) \xrightarrow{p^*} H^n(E; R) \rightarrow H^{n-r}(B; R) \\ \xrightarrow{g} H^{n+1}(B; R) \rightarrow \dots, \end{aligned}$$

where g satisfies $g(\alpha) = \alpha \smile \Omega = \Omega \smile \alpha$ ($\Omega = g(1) \in H^{r+1}(B; R)$). Here Ω is equal to the image of a generator of $H^r(F; R) = R$ by the transgression τ^* , and $2\Omega = 0$ if r is even. (These results hold also for $r = 0$ and $R = \mathbb{Z}_2$.)

Example (7). Assume that $H^n(B; R) \cong H^n(S^r; R)$ ($r \geq 2$). Then we have $H^{n-r}(F; R) \cong H^n(E, F; R)$ ($n \geq 0$) and the **Wang exact sequence**:

$$\begin{aligned} \dots \rightarrow H^n(E; R) \xrightarrow{i^*} H^n(F; R) \\ \xrightarrow{\theta} H^{n-r+1}(F; R) \rightarrow H^{n+1}(E; R) \rightarrow \dots, \end{aligned}$$

where θ satisfies $\theta(\alpha \smile \beta) = \theta(\alpha) \smile \beta + (-1)^{n(r-1)} \alpha \smile \theta(\beta)$ ($\alpha, \beta \in H^n(F; R)$).

Example (8). For a field k of odd characteristic, if $H^n(E; k) = 0$ ($n > 0$) and the algebra $H^*(F; k)$ is generated by a finite number of elements of odd degree, then $H^*(F; k) \cong \wedge_k(x_1, \dots, x_l)$ (the \dagger exterior algebra) and $H^*(B; k) \cong k[y_1, \dots, y_l]$, where $y_i = \tau^*(x_i)$ (A. Borel).

149 (III.6) Fields

A. Definition

A set K having at least two elements is called a **field** if two operations, called \dagger addition ($+$) and \dagger multiplication (\cdot), are defined in K and satisfy the following three axioms.

(1) For any two elements a, b of K , the sum $a + b$ is defined; the associative law $(a + b) + c = a + (b + c)$ and the commutative law $a + b = b + a$ hold; and there exists for arbitrary a, b a unique element x such that $a + x = b$; that is, K is an \dagger Abelian group with respect to the addition (the \dagger identity element of this group is denoted by 0 and is called the **zero element** of K).

(2) For any two elements a, b of K , the product ab ($= a \cdot b$) is defined; the associative law $(ab)c = a(bc)$ and the commutative law $ab = ba$ hold; and there exists for arbitrary a, b with $a \neq 0$ a unique element x such that $ax = b$, that is, the set K^* of all nonzero elements of K is an Abelian group with respect to multiplication. K^* is called the **multiplicative group** of K , while the identity element of K^* is denoted by 1 and is called the **unity element** (**unit element** or **identity element**) of K .

(3) The distributive law $a(b + c) = ab + ac$ holds. In other words, a field is a \dagger commutative ring whose nonzero elements form a group with respect to multiplication.

A noncommutative ring whose nonzero elements form a group is called a **noncommutative field** (**skew field** or **s-field**). It should be noted that sometimes a field is defined as a ring whose nonzero elements form a group without assuming the commutativity of that group, and in this case our “field” defined before is called a commutative field. (The term “skew field” is sometimes used to mean either a commutative or a noncommutative field.) In this article we limit ourselves to commutative fields (for noncommutative fields \rightarrow 29 Associative Algebras).

B. General Properties

Since a field K is a commutative ring, we have properties such as $a0 = 0a = 0$, $(-a)b = a(-b) = -ab$ for elements a, b in K . If a †subring k of K is a field, we say that k is a **subfield** of K or K is an **overfield** (**extension field** or simply **extension**) of k . If a field K has no subfield other than K , K is called a **prime field**.

A map f of a field K into another field K' is called a (field) **homomorphism** if it is a ring homomorphism, i.e., if it satisfies $f(a + b) = f(a) + f(b)$, $f(ab) = f(a)f(b)$. Since a field is †simple as a ring, every (field) homomorphism is an injection unless it maps everything to zero. A homomorphism of K into K' is called an **isomorphism** if it is a bijection, and K and K' are called isomorphic if there exists an isomorphism of K onto K' . An isomorphism of K onto itself is called an **automorphism** of K .

If there is a natural number n such that the sum $n1 = \overbrace{1 + \dots + 1}^n$ of the unity element 1 is 0 , then the minimum of such n is a prime number p , called the **characteristic** of K . On the other hand, if there is no natural number n such that $n1 = 0$, we say that the characteristic of K is 0 .

C. Examples of Fields

The rational number field \mathbf{Q} consisting of all rational numbers, the real number field \mathbf{R} consisting of all real numbers, and the complex number field \mathbf{C} consisting of all complex numbers, are all fields of characteristic 0 . A subfield of the complex number field \mathbf{C} is called a **number field**. The rational number field is a prime field, and every prime field of characteristic 0 is isomorphic to the rational number field. For the ring \mathbf{Z} of all rational integers, the residue class ring modulo a prime number p is a field $\mathbf{Z}/p\mathbf{Z} = \{0, 1, 2, \dots, p-1 \pmod{p}\}$ of characteristic p , called the **residue class field** for p . Thus $\mathbf{Z}/p\mathbf{Z}$ is a prime field, and every prime field of characteristic p is isomorphic to $\mathbf{Z}/p\mathbf{Z}$. If the number of the elements of a field K is finite, K is called a **finite field**. $\mathbf{Z}/p\mathbf{Z}$ is an example of a finite field.

D. Extensions of a Field

In order to express that K is an extension field of k , we often use the notation K/k . Subfields of K containing k are called **intermediate fields** of K/k . Consider two extensions K_1/k_1 and K_2/k_2 , and let $\varphi: K_1 \rightarrow K_2$ be an isomorphism which induces an isomorphism $\psi: k_1 \rightarrow k_2$. Then we call φ an **extension** of ψ . Suppose that k_1, K_2 are given fields and K_2 contains a subfield k_2 isomorphic to k_1 . Then there exist

an extension field K_1 of k_1 and an isomorphism $\varphi: K_1 \rightarrow K_2$ which is an extension of the given isomorphism $\psi: k_1 \rightarrow k_2$; construction of the field K_1 is often called the embedding of k_1 into K_2 . When K_1 and K_2 are extensions of k , an isomorphism $K_1 \rightarrow K_2$ is called a ***k*-isomorphism** if it leaves every element of k invariant.

In an extension K/k , let S be a subset of K . The smallest intermediate field of K/k containing S is called the field obtained by **adjoining** S to k or the field **generated** by S over k , denoted by $k(S)$. The field $k(S)$ consists of those elements in K each of which is a rational expression in a finite number of elements of S with coefficients in k . An extension field $k(t)$ obtained by adjoining a single element t to k is called a **simple extension** of k , and in this case t is called a **primitive element** of the extension. The †rational function field $k(X)$ with coefficient field k is a simple extension of k with a primitive element X .

When subfields k_λ ($\lambda \in \Lambda$) of a field K are given, the smallest subfield of K containing all these subfields exists and is called the **composite field** of the k_λ .

E. Algebraic and Transcendental Extensions

An element α of an extension field K of a field k is called an **algebraic element** over k if α is a †zero point of a nonzero polynomial, say, $f(X) = a_0 + a_1X + \dots + a_nX^n$ with coefficients in k . If α is not algebraic over k , then α is called a **transcendental element** over k . An algebraic element α is always a root of an irreducible polynomial over k which is uniquely determined up to a constant factor ($\in k^*$) and is called the **minimal polynomial** of α over k . K is called an **algebraic extension** of k if all elements of K are algebraic over k ; otherwise we call K a **transcendental extension** of k . If K_1 is an algebraic extension of K and K is an algebraic extension of k , then K_1 is also an algebraic extension of k . In an arbitrary extension field K of k , the set of all algebraic elements over k forms an algebraic extension field of k . A simple extension $k(t)$ with a transcendental element t is isomorphic to the rational function field of one variable with coefficient field k . If t is an algebraic element over k , $k(t)$ is isomorphic to the †residue class field of the polynomial ring $k[X]$ modulo the minimal polynomial $f(X)$ of t over k .

F. Finite Extensions

An extension field K of a field k is called a **finite extension** if K has no infinite set of elements that are †linearly independent over k ,

i.e., if K is a finite-dimensional linear space over k . The dimension of the linear space over k is called the **degree** of K over k and is denoted by $(K:k)$ (or $[K:k]$). If K is a finite extension of k and L is a finite extension of K , then L is also a finite extension of k and $(L:K)(K:k) = (L:k)$. Every finite extension field of k is an algebraic extension of k and is obtained by adjoining a finite number of algebraic elements to k . Conversely, every field obtained by adjoining a finite number of algebraic elements to k is a finite extension of k . If $K = k(\alpha)$ with an algebraic element α , then $(K:k)$ is equal to the degree of the minimal polynomial of α over k , also called the **degree** of α over k . Every element of $k(\alpha)$ is expressed as a polynomial in α with coefficients in k . On the other hand, for any nonconstant polynomial $f(X)$ of $k[X]$ there exists a simple extension $k(\alpha)$ such that α is a root of $f(X)$.

G. Normal Extensions

An algebraic extension field K of a field k is called a **normal extension** of k if every irreducible polynomial of $k[X]$ which has a root in K can always be decomposed into a product of linear factors in $K[X]$. An extension field K of k is called a **splitting field** of a (nonconstant) polynomial $f(X) \in k[X]$ if $f(X)$ can be decomposed as a product of linear polynomials, i.e., $f(X) = c(X - \alpha_1)(X - \alpha_2) \dots (X - \alpha_n)$, $c \in k$, $\alpha_i \in K$. A splitting field K of $f(X)$ ($f(X) \in k[X]$) is called a **minimal splitting field** of $f(X)$ if any proper subfield L of K ($K \supset L \supset k$) is not a splitting field of $f(X)$. A minimal splitting field of $f(X)$ is obtained by adjoining all the zero points of $f(X)$. A finite extension field of k is a normal extension if and only if it is a minimal splitting field of a polynomial of $k[X]$. For any given (nonconstant) polynomial $f(X) \in k[X]$, there exists a minimal splitting field of $f(X)$, and all minimal splitting fields of $f(X)$ are k -isomorphic.

H. Separable and Inseparable Extensions

An algebraic element α over k is called a **separable element** or an **inseparable element** over k according as the minimal polynomial of α over k is 'separable' or 'inseparable'. An algebraic extension K of k is called a **separable extension** of k if all the elements of K are separable over k ; otherwise, K is called an **inseparable extension**. An element α is separable with respect to k if and only if the minimal polynomial of α over k has no double root in its splitting field. If α is inseparable, then k has nonzero characteristic p , and the minimal polynomial $f(X)$ of α can be decomposed as $f(X) =$

$(X - \alpha_1)^{p^r}(X - \alpha_2)^{p^r} \dots (X - \alpha_m)^{p^r}$, $r \geq 1$, where $\alpha_1, \alpha_2, \dots, \alpha_m$ are distinct roots of $f(X)$ in its splitting field; between the degree n of $f(X)$ and the number m of distinct roots of $f(X)$, the relation $n = mp^r$ holds. In particular, if $\alpha^{p^r} \in k$ for some r , we call α a **purely inseparable element** over k . An algebraic extension of k is called **purely inseparable** if all elements of the field are purely inseparable over k . In an algebraic extension K of k the set of all separable elements forms an intermediate field K_0 of K/k . The field K_0 is called the **maximal separable extension** of k in K . If K is inseparable over k , i.e., if $K \neq K_0$, then the characteristic of k is $p \neq 0$, and K is purely inseparable over K_0 . The degrees $d = [K_0:k]$ and $p^r = [K:K_0]$ are denoted by $[K:k]_s$ and $[K:k]_i$, respectively. A separable extension of a separable extension of k is also separable over k , and every finite separable extension of k is a simple extension.

If no inseparable irreducible polynomial in $k[X]$ exists, we call k a **perfect field**; otherwise, an **imperfect field**. Every field of characteristic 0 is a perfect field. A field of characteristic p ($\neq 0$) is perfect if and only if for each $a \in k$ the polynomial $X^p - a$ has a root in k . Every algebraic extension of a perfect field is a separable extension and a perfect field. Any imperfect field has an inseparable, in fact purely inseparable, proper extension.

I. Algebraically Closed Fields

If every nonconstant polynomial of $k[X]$ can be decomposed into a product of linear polynomials of $k[X]$, or equivalently, if every irreducible polynomial of $k[X]$ is linear, k is called an **algebraically closed field**; k is algebraically closed if and only if k has no algebraic extension field other than k , and hence every algebraically closed field is perfect. For any given field k there exists an algebraically closed algebraic extension field of k unique up to k -isomorphisms (E. Steinitz); hence we call such a field the **algebraic closure** of k . To proceed further, suppose that we are given a field k and its extension K . If there is no algebraic element of K over k outside of k , i.e., if k is the intersection of K and the algebraic closure of k , then we say that k is **algebraically closed** in K . The complex number field is an algebraically closed field (C. F. Gauss's fundamental theorem of algebra; \rightarrow 10 Algebraic Equations).

J. Conjugates

Let k be a field and K an algebraic extension of k . Two elements α, β of K are called **conju-**

gate over k if they are roots of the same irreducible polynomial of $k[X]$ (or equivalently, if the minimal polynomials of α and β with respect to k coincide); in this case we call the subfields $k(\alpha)$, $k(\beta)$ **conjugate fields** over k . The conjugate fields $k(\alpha)$ and $k(\beta)$ are k -isomorphic under an isomorphism σ such that $\sigma(\alpha) = \beta$. In particular, if K is a normal extension of k , the number of conjugate elements of an element α of K is the number of distinct roots of the minimal polynomial $f(X)$ of α , which is independent of the choice of a normal extension K containing k . The element α is separable if and only if the number of conjugate elements in K is the same as the degree of $f(X)$. On the other hand, $k(\alpha)$ is normal over k if and only if $k(\alpha)$ coincides with all its conjugate fields.

Let α be a separable algebraic element over k , and let $\alpha_1 = \alpha, \alpha_2, \dots, \alpha_n$ be conjugate elements of α over k . The product $A = \alpha_1 \alpha_2 \dots \alpha_n$ and sum $B = \alpha_1 + \alpha_2 + \dots + \alpha_n$ are elements of k . Indeed, if $f(X) = X^n + c_1 X^{n-1} + \dots + c_n$ is the minimal polynomial of α with respect to k , we have $A = (-1)^n c_n$, $B = -c_1$, and A and B are called the **norm** and the **trace** of α , respectively, denoted by $A = N(\alpha)$, $B = Tr(\alpha)$. Let K be a finite separable extension of degree n over k , and let α be an element of K . Then the degree m of the minimal polynomial of α is a divisor of n ; that is, $n = mr$ with a positive integer r . We define the norm and the trace of α with respect to K/k by $N_{K/k}(\alpha) = N(\alpha)^r$, $Tr_{K/k}(\alpha) = rTr(\alpha)$, respectively. Then these quantities satisfy $N_{K/k}(\alpha\beta) = N_{K/k}(\alpha)N_{K/k}(\beta)$, $Tr_{K/k}(\alpha + \beta) = Tr_{K/k}(\alpha) + Tr_{K/k}(\beta)$ for $\alpha, \beta \in K$. (For the Galois theory of algebraic extensions \rightarrow 172 Galois Theory.)

K. Transcendental Extensions

Let K be an extension of k and u_1, \dots, u_n be elements of K . An element v of K is said to be **algebraically dependent** on the elements u_1, u_2, \dots, u_n if v is algebraic over the field $k(u_1, u_2, \dots, u_n)$. A subset S of K is called **algebraically independent** over k if no $u \in S$ is algebraically dependent on a finite number of elements of S different from u itself; S is called a **transcendence basis** of K over k if S is algebraically independent and K is algebraic over $k(S)$. Furthermore, if K is separable over $k(S)$, then S is called a **separating transcendence basis** of K over k . There always exists an algebraically independent basis of K over k , and the cardinal number of S depends only on K and k ; this cardinal number is called the **transcendence degree** (or **degree of transcendency**) of K over k . (When S is an infinite set, we sometimes say that the transcendence degree is

infinite.) In particular, if $K = k(S)$ with an algebraically independent S , K is called a **purely transcendental extension** of k .

An extension K of k is called a **separably generated extension**, or simply a **separable extension**, if every finitely generated intermediate field of K/k has a separating transcendence basis over k . If K itself has a separating transcendence basis over k , then K is separably generated, but not conversely.

A purely transcendental extension field of k having a finite transcendence degree n is also called a **rational function field in n variables** over k , and a finite extension of such a rational function field is called an **algebraic function field in n variables** over k .

Let K and L be extension fields of k , both contained in a common extension field. We say that K and L are **linearly disjoint** over k if every subset of K linearly independent over k is also linearly independent over L , or equivalently, if every subset of L linearly independent over k is also linearly independent over K . An algebraic function field $K = k(x_1, x_2, \dots, x_n)$ over k (whose transcendence degree is $\leq n$) is called a **regular extension** of k if K and the algebraic closure \bar{k} of k are linearly disjoint. In order that K be regular over k it is necessary and sufficient that k be algebraically closed in K and that K be separably generated over k .

L. Derivations

A map D of a field K into itself is called a **derivation** of K if it satisfies $D(a+b) = D(a) + D(b)$ and $D(ab) = aD(b) + bD(a)$ for all $a, b \in K$. The set of elements c of K for which $D(c) = 0$ is a subfield. If the characteristic of K is $p (\neq 0)$, then $D(x^p) = 0$ for all $x \in K$. Let k be a subfield of K . A derivation D of K is called a **derivation over k** if $D(c) = 0$ for all $c \in k$; the totality of derivations over k is a ${}^k k$ -module. If $K = k(x_1, x_2, \dots, x_n)$ is an algebraic function field over k , then the k -module of derivations over k has finite dimension $s (\leq n)$ and we can choose s suitable elements u_1, u_2, \dots, u_s of K such that K is separably algebraic over $k(u_1, u_2, \dots, u_s)$. Generally, the transcendence degree r of K over k does not exceed s , and K is separably generated over k if and only if $r = s$.

M. Finite Fields

Finite fields were first considered by E. Galois (1830), so they are also called **Galois fields**. There is no finite noncommutative field (**Wedderburn's theorem**, J. H. M. Wedderburn, *Trans. Amer. Math. Soc.*, 6 (1905)). A simple

proof for this was given by E. Witt (*Abh. Math. Sem. Univ. Hamburg*, 8 (1931)). The characteristic of a finite field is a prime p , and the number of elements of the field is a power of p . Conversely, for any given prime number p and natural number α , there exists a finite field with p^α elements. Such a field is unique up to isomorphism, which we denote by $GF(p^\alpha)$ or $F_q(q=p^\alpha)$. For any positive integer m , $GF(p^{m\alpha})$ is an extension field of $GF(p^\alpha)$ of degree m and a \dagger cyclic extension. Every element a of $GF(p^\alpha)$ satisfies $a^{p^\alpha} = a$; hence a has its p th root in $GF(p^\alpha)$. Therefore every finite field is perfect. The multiplicative group of $GF(p^\alpha)$ is a cyclic group of order $p^\alpha - 1$.

N. Ordered Fields and Real Fields

A field K is called an **ordered field** if there is given a \dagger total order in K such that $a > b$ implies $a + c > b + c$ for all c and $a > b, c > 0$ implies $ac > bc$. The characteristic of an ordered field is always 0. An element a of K is called a **positive element** or a **negative element** according as $a > 0$ or $a < 0$. For an element a of K the **absolute value** of a , denoted by $|a|$, is a or $-a$ according as $a \geq 0$ or $a \leq 0$. If we define neighborhoods of a by the sets $\{x | a - \varepsilon < x < a + \varepsilon\}$ with positive elements ε , K becomes a \dagger Hausdorff space. If, for any two positive elements a, b of K , there exists a natural number n such that $na > b$, then we call K an **Archimedean ordered field**. Two ordered fields are called **similarly isomorphic** if there exists an isomorphism between them under which positive elements are always mapped to positive elements. The rational number field and the real number field are examples of Archimedean ordered fields, while every Archimedean ordered field is similarly isomorphic to a subfield of the real number field. (For the structure of non-Archimedean ordered fields, see [8].) A field k is called a **formally real field** (or simply **real field**) if -1 (1 is the unity element of k) cannot be expressed as a finite sum of squares of elements of k . The real number field is a model of formally real fields. More generally, every ordered field is a formally real field. A formally real field is called a **real closed field** if no proper algebraic extension of it is a formally real field. The real number field is a real closed field. The algebraic closure of a real closed field is obtained by adjoining a root of the polynomial $X^2 + 1$. If a is a nonzero element of a real closed field, then either a or $-a$ can be a square of an element of the field. Every real closed field can be made an ordered field in a unique way, namely, by defining squares of nonzero elements to be positive

150 A Field Theory

elements. Since it is known that every formally real field is a subfield of a real closed field, it follows that every formally real field is an ordered field and therefore is of characteristic 0. The problem of constructing an ordered field out of a formally real field is closely related to the existence of valuations of a certain type [8]. The notion of formally real fields was introduced by E. Artin (*Abh. Math. Sem. Univ. Hamburg*, 5 (1927)). By making use of the theory of formally real fields, Artin succeeded in solving affirmatively \dagger Hilbert's 17th problem, which asked whether every positive definite rational expression (i.e., a rational expression with real coefficients that takes positive values for all real variables) can be expressed as a sum of squares of rational expressions. More precisely, it was shown by A. Pfister that every positive definite function in $\mathbf{R}(X_1, \dots, X_n)$ is a sum of at most 2^n squares.

150 (XX.28) Field Theory

A. History

When a quantity $\psi(x)$, such as velocity, is defined at every point x in a certain region of a space, we say that a field of the quantity ψ is given. This general concept is used in many branches of science. Here we confine ourselves to some branches of physics, in particular to the quantum theory of fields, which describes \dagger elementary particles.

The \dagger theories of elasticity and \dagger hydrodynamics (in particular, concerning \dagger Euler's

equation of motion) deal with displacement and velocity fields, respectively. However, a field in a vacuum (ether), which is quite different from a field in a space filled with matter, first became a subject of physics in [†]electromagnetism. M. Faraday (1837) introduced the electromagnetic field and discovered its fundamental laws, and J. C. Maxwell (1837) completed the mathematical formulation. On the basis of this formalism, A. Einstein (1905) established the theory of [†]relativity and later developed the general theories of relativity and of gravity.

Although quantum theory originated from the problem of blackbody radiation, the quantum theory of the electromagnetic field was first developed by P. A. M. Dirac (1927) after the development of [†]quantum mechanics. Along similar lines P. Jordan and E. P. Wigner (1927) quantized the matter wave (electron field), and W. Heisenberg and W. Pauli (1929) developed the quantum theory of wave fields in general. Subsequently, Jordan and Pauli (1927), Pauli (1939), S. Tomonaga (1943), J. Schwinger (1948), and others reformulated the theory in a relativistically covariant manner. Quantum electrodynamics, dealing with an electromagnetic field interacting with electrons (and positrons), has given excellent agreement with experimental measurements when formulated in this way. Divergence difficulties inherent to quantized field theory were bypassed by the renormalization procedure of Tomonaga, Schwinger, R. P. Feynman, and F. J. Dyson (1947).

On the other hand, H. Yukawa (1934) applied the concept of the quantized field to the interpretation of nuclear force and predicted the existence of π -mesons. Many kinds of new particles have since been found, including π -mesons and muons. The field theory of π -mesons can explain the qualitative features of the meson-nucleon system. Similar theories can be formulated for other types of unstable particles that have been found in cosmic rays since 1949.

During the progress of meson theory, various types of fields were investigated, and a general theory of elementary particles was developed. Dirac (1936) proposed a general wave equation for elementary particles, and Pauli and M. Fierz (1939) proved the connection of spin and statistics (\rightarrow the end of Section D). Schwinger (1951) derived quantum-mechanical equations of motion and commutation relations from a unified variational principle. For the cases where no interaction is present, a general theory of elementary particles consistent with the requirements of relativity and of quantum theory was established as the theory of **free fields**.

B. Relativistically Covariant Classical Fields

Relativistically covariant fields $\varphi_r^\alpha(x)$ on the level of classical theory are functions of the space-time point x with either real or complex values depending on the index α (which distinguishes different fields) [1]. A finite-dimensional representation D^α of $SL(2, C)$ (\rightarrow 258 Lorentz Group) on either a real or complex vector space is assigned to each α , and the index r of $\varphi_r^\alpha(x)$ refers to components in this representation space. Each model is specified in terms of a **Lagrangian density** $\mathcal{L}(x)$ that is a function (typically a polynomial) of $\varphi_r^\alpha(x)$, $\partial_\mu \varphi_r^\alpha(x)$ (∂_μ denoting $\partial/\partial x^\mu$, $\mu=0, \dots, 3$) and their complex conjugates. \mathcal{L} is taken to be invariant under the replacement of $\varphi_r^\alpha(x)$ and $\partial_\mu \varphi_r^\alpha(x)$ by $\sum_s D^\alpha(A)_{rs} \varphi_s^\alpha(x)$ and $\sum_{s,\nu} D^\alpha(A)_{rs} \Lambda(A)_\mu^\nu \partial_\nu \varphi_s^\alpha(x)$ for all $A \in SL(2, C)$ (called the **Lorentz invariance** of \mathcal{L}) and possibly under the replacement of $\varphi_r^\alpha(x)$ and $\partial_\mu \varphi_r^\alpha(x)$ by $\sum_\beta U^{\alpha\beta} \varphi_r^\beta(x)$ and $\sum_\beta U^{\alpha\beta} \partial_\mu \varphi_r^\beta(x)$ (called an **internal symmetry**).

The fields are supposed to satisfy the following partial differential equation, called the **field equation**, and are obtained as the [†]Euler equation of the variational problem for the action integral $I = \int \mathcal{L}(x) dx$:

$$\partial \mathcal{L}(x) / \partial \varphi_r^\alpha(x) - \sum_{\mu=0}^3 (\partial / \partial x^\mu) (\partial \mathcal{L}(x) / \partial (\partial^\mu \varphi_r^\alpha(x))) = 0,$$

$$\partial \mathcal{L}(x) / \partial \bar{\varphi}_r^\alpha(x) - \sum_{\mu=0}^3 (\partial / \partial x^\mu) (\partial \mathcal{L}(x) / \partial (\partial^\mu \bar{\varphi}_r^\alpha(x))) = 0$$

(the bar indicates the complex conjugate), where the second equation is identical to the first for a real field. For complex fields, $\mathcal{L}(x)$ is chosen such that $I = \bar{I}$ (possibly except for a surface term) in order to ensure that the above two equations are complex conjugates of each other.

The invariance of I under a Lie group of (local and/or volume-preserving point) transformations of fields implies a conservation law for a certain quantity (**Noether's theorem**; \rightarrow e.g., E. L. Hill, *Rev. Mod. Phys.*, 23 (1951)). For translational invariance ($x^\mu \rightarrow x^\mu + a^\mu$), the **energy-momentum (stress) tensor**

$$T_{\nu}^{\mu}(x) \equiv -\delta_{\mu\nu} \mathcal{L}(x) + \sum_{\alpha,r} \{ \partial \mathcal{L}(x) / \partial (\partial_\mu \varphi_r^\alpha(x)) \partial_\nu \varphi_r^\alpha(x) + \partial \mathcal{L}(x) / \partial (\partial_\mu \bar{\varphi}_r^\alpha(x)) \partial_\nu \bar{\varphi}_r^\alpha(x) \}$$

(the complex conjugate terms in all equations to be suppressed for real fields) satisfies the differential conservation law $\sum_{\mu=0}^3 \partial_\mu T_{\nu}^{\mu}(x) = 0$ as a consequence of the field equations, which in turn implies the time-independence of the

following quantity provided that $T^\mu_\mu(x)$ vanishes sufficiently fast at spatial infinity:

$$H = \int T^0_0(x) d^3\mathbf{x}, \quad P_k = \int T^0_k(x) d^3\mathbf{x} \quad (x^0 = t).$$

These are the total field Hamiltonian (energy) and momentum.

In a general situation, $T^{\mu\nu} = \sum_\rho g^{\nu\rho} T^\mu_\rho$, where $g^{\mu\nu}$ is the Minkowski metric tensor with the signature 1, -1, -1, -1) is not necessarily symmetric in μ and ν . F. J. Belinfante (*Physica*, 6 (1939); 7 (1940)) has given a formula (by a change of $\mathcal{L}(x)$ via so-called 4-divergence) for obtaining a symmetrized energy-momentum tensor θ^μ_ν for which H and P_k are equal to those defined from the above T^μ_ν and for which the differential conservation law is satisfied.

Lorentz invariance implies the conservation law $\sum_\mu \partial_\mu M^{\mu\nu\lambda}(x) = 0$ for the **angular momentum density**

$$\begin{aligned} M^{\mu\nu\lambda}(x) &= x^\nu T^{\mu\lambda}(x) - x^\lambda T^{\mu\nu}(x) \\ &+ \sum_{\alpha, r, s} \{ \partial \mathcal{L} / \partial (\partial_\mu \varphi_r^\alpha(x)) S_{rs}^{\alpha\nu\lambda} \varphi_r^\alpha(x) \\ &\quad + \partial \mathcal{L} / \partial (\partial_\mu \bar{\varphi}_r^\alpha(x)) \bar{S}_{rs}^{\alpha\nu\lambda} \bar{\varphi}_r^\alpha(x) \} \\ &= x^\nu \Theta^{\mu\lambda}(x) - x^\lambda \Theta^{\mu\nu}(x) \end{aligned}$$

and the time-independence of the total angular momentum

$$M^{\nu\lambda} = \int M^{\nu\lambda} d^3\mathbf{x} \quad (x^0 = t),$$

where $S_{rs}^{\alpha\mu\nu}$ is antisymmetric in μ, ν and $D^\alpha(A)_{rs} = \delta_{rs} + \sum_{\mu, \nu} S_{rs}^{\alpha\mu\nu} \varepsilon_{\mu\nu} / 2$ for $\Lambda(A)_{\mu\nu} = g_{\mu\nu} + \varepsilon_{\mu\nu}$ with an infinitesimal $\varepsilon_{\mu\nu}$. (We have $(\Lambda(A)x)^\mu = \sum_\nu \Lambda(A)^\mu_\nu x^\nu$ and $\Lambda(A)_{\mu\nu} = \sum_\rho g_{\mu\rho} \Lambda(A)^\rho_\nu$.)

A continuous one-parameter group $U(\rho)$ of internal symmetries implies the conservation law $\sum_\mu \partial_\mu J^\mu(x) = 0$ for the **4-current density** (charge ($\mu = 0$) and current ($\mu = 1, 2, 3$) densities)

$$\begin{aligned} J^\mu(x) &= \sum_{\alpha\beta r} \{ \partial \mathcal{L} / \partial (\partial_\mu \varphi_r^\alpha(x)) \lambda^{\alpha\beta} \varphi_r^\beta(x) \\ &\quad + \partial \mathcal{L} / \partial (\partial_\mu \bar{\varphi}_r^\alpha(x)) \bar{\lambda}^{\alpha\beta} \bar{\varphi}_r^\beta(x) \} \end{aligned}$$

and the time-independence of the **charge** $\int J^0(x) d^3\mathbf{x}$ ($x^0 = t$), where $U'(0)^{\alpha\beta} = \lambda^{\alpha\beta}$. An example of $U(\rho)$ is the multiplication by $\exp iQ^z \rho$ (called a **gauge transformation of the first kind**), where Q^z is an integer with $Q^z = 0$ for real fields φ_r^z .

Examples of Lagrangian densities for non-interacting fields (called **free Lagrangian densities**) are:

real scalar field:

$$(\sum_{\mu\nu} g^{\mu\nu} \partial_\mu \varphi(x) \partial_\nu \varphi(x) - m^2 \varphi(x)^2) / 2,$$

complex scalar field:

$$(\sum_{\mu\nu} g^{\mu\nu} \partial_\mu \bar{\varphi}(x) \partial_\nu \varphi(x) - m^2 \bar{\varphi}(x) \varphi(x)),$$

Dirac field:

$$\begin{aligned} &(i/2) \sum_{rs} (\psi_r(x)^\dagger \gamma_{rs}^\mu \partial_\mu \psi_s(x) - \partial_\mu \psi_r(x)^\dagger \gamma_{rs}^\mu \psi_s(x)) \\ &\quad - m \sum_r \psi_r(x)^\dagger \psi_s(x) \\ &(\psi_r(x)^\dagger = \sum_s \bar{\psi}_s(x) \gamma_{sr}^0, \gamma^\mu \equiv (\gamma_{rs}^\mu) \text{ are } \dagger \text{Dirac's } \gamma\text{-matrices}), \end{aligned}$$

massive real vector field:

$$\begin{aligned} &-(1/4) \sum_{\kappa\lambda\mu\nu} g^{\kappa\mu} g^{\lambda\nu} (\partial_\kappa A_\lambda(x) - \partial_\lambda A_\kappa(x)) \\ &\quad \times (\partial_\mu A_\nu(x) - \partial_\nu A_\mu(x)) + \frac{m^2}{2} \sum_{\mu\nu} g^{\mu\nu} A_\mu(x) A_\nu(x), \end{aligned}$$

where D^α is trivial for scalar fields, $[1, 0] \oplus [0, 1]$ for the Dirac field, and $[1, 1]$ for vector fields.

For interacting fields, some interaction parts are added to the sum of such free Lagrangian densities of relevant fields. Some examples are:

$P(\varphi)$ (or $g\varphi^4$) interaction:

$$P(\varphi(x)) \quad (\text{or } g\varphi(x)^4),$$

Yukawa-type interaction:

$$g \sum_{rs} \psi_r(x)^\dagger \gamma_{rs}^\mu \psi_s(x) A_\mu(x),$$

Fermi interactions:

$$\begin{aligned} &g \sum_{kk'} G_{kk'} (\sum_{rs} \psi_r^\alpha(x)^\dagger \mathcal{O}_{rs}^k \psi_s^\beta(x)) \\ &\quad \times (\sum_{r's'} \psi_{r'}^{\alpha'}(x)^\dagger \mathcal{O}_{r's'}^{k'} \psi_{s'}^{\beta'}(x)) \end{aligned}$$

($\mathcal{O}^k = 1$ (scalar, no index k), γ^μ (vector, $G_{kk'} = g_{\mu\mu'}$), $\gamma^\mu \gamma^\nu$ (tensor, $G_{kk'} = g_{\mu\mu'} g_{\nu\nu'}$), $\gamma^5 \gamma^\mu$ (pseudovector, $G_{kk'} = g_{\mu\mu'}$), $\gamma^5 = i\gamma^0 \gamma^1 \gamma^2 \gamma^3$), γ^5 (pseudoscalar, no index k).

C. Heuristic Theory of Quantized Fields

For free fields, a quantization procedure similar to the usual quantum mechanics (\rightarrow 351 Quantum Mechanics; 377 Second Quantization) leads to the following type of canonical commutation or anticommutation relations among fields (and their first time derivatives) at time 0; for example,

real scalar field:

$$\begin{aligned} &[\varphi(0, \mathbf{x}), \dot{\varphi}(0, \mathbf{y})]_- = i\delta^3(\mathbf{x} - \mathbf{y}), \\ &[\varphi(0, \mathbf{x}), \varphi(0, \mathbf{y})]_- = [\dot{\varphi}(0, \mathbf{x}), \dot{\varphi}(0, \mathbf{y})]_- = 0, \end{aligned}$$

Dirac field:

$$\begin{aligned} &[\bar{\psi}_r(0, \mathbf{x}), \psi_s(0, \mathbf{y})]_+ = \delta_{rs} \delta^3(\mathbf{x} - \mathbf{y}), \\ &[\psi_r(0, \mathbf{x}), \psi_s(0, \mathbf{y})]_+ = [\bar{\psi}_r(0, \mathbf{x}), \bar{\psi}_s(0, \mathbf{y})]_+ = 0. \end{aligned}$$

($[A, B]_\pm = AB \pm BA$, $\delta_{rs} = 0$ for $r \neq s$ and $\delta_{rr} = 1$, $\delta^3(\mathbf{x} - \mathbf{y}) = \prod_{k=1}^3 \delta(x^k - y^k)$.) The free-field equations then lead to the following 4-dimensional commutation relations:

real scalar field:

$$[\varphi(x), \varphi(y)]_- = -i\Delta_m(x - y),$$

Dirac field:

$$[\psi_r(x), \psi_s(y)^\dagger]_+ = (\sum_\mu \gamma_{rs}^\mu \partial_\mu - im \delta_{rs}) \Delta_m(x - y),$$

massive real vector field:

$$[A_\mu(x), A_\nu(y)]_- = i(g_{\mu\nu} + m^{-2} \partial_\mu \partial_\nu) \Delta_m(x - y).$$

Here Δ_m is the \dagger invariant distribution. There is a unique representation of such relations for a

field (called the **Fock representation**) with a vector Ω (called the **free vacuum vector**) which is annihilated by $\int \varphi(x)f(x)dx$, by $\int \psi_r(x)f(x)dx$ and $\int \bar{\psi}_r(x)f(x)dx$, or by $\int A_\mu(x)f(x)dx$ whenever $\int e^{ip \cdot x} f(x)dx = 0$ for $p^0 > 0$ (here, $p \cdot x = \sum g_{\mu\nu} p^\mu x^\nu$), and which is cyclic (i.e., polynomials of (smeared-out) fields generate a dense subset of Ω). The free fields in the Fock representation satisfy the Wightman axioms (\rightarrow Section D).

In the Fock representation of canonical fields a translationally invariant vector must be a free vacuum vector, up to multiplication by a complex number. In order to construct a model of a translationally invariant interaction among canonical fields with a unique vector of minimal energy (a vector which is called the true or interacting vacuum and which must be translationally invariant if unique), one must look for some other suitable representation. Such a no-go theorem is called **Haag's theorem**.

The earliest formulation of interacting quantized fields was developed heuristically by formal manipulation in the Fock representation, described in textbooks of **quantum field theory** [2–6]. It can be mathematically justified if the so-called **cutoff** is introduced by limiting the space to a finite volume, possibly changing the space into a lattice and smoothing out fields (effectively cutting off the high-energy part of the interaction) (A. M. Jaffe, O. E. Lanford III, and A. S. Wightman, *Comm. Math. Phys.*, 15 (1969)). The full theory is then expected to be obtained by taking a limit of the true vacuum expectation values as various cutoff parameters are removed. This is the aim of constructive field theory (\rightarrow Section F), which has been achieved for some space-time models of dimension 2 and 3.

In quantum field theory, the S -matrix is given in terms of (the mass-shell restriction of the Fourier transform of) the vacuum expectation value of the time-ordered product of fields, called τ -functions (\rightarrow Section E). In the heuristic approach, it is given in terms of the following Gell-Mann–Low formula (its imaginary time version being mathematically used in constructive field theory): If the field $\varphi(x) = e^{iHx^0} \varphi_0((0, \mathbf{x})) e^{-iHx^0}$ with $H = H_0 + H_I$ (H_0 is the free Hamiltonian as the generator of the time translation for the free field $\varphi_0(x)$ and H_I is the interaction Hamiltonian, such as $P(\varphi_0)$) and $x_1^0 > \dots > x_n^0$, then

$$\begin{aligned} &(\Omega, \varphi(x_1) \dots \varphi(x_n) \Omega) \\ &= \lim_{T \rightarrow \infty} (e^{iHT} \Omega_0, \varphi(x_1) \dots \varphi(x_n) e^{-iHT} \Omega_0) \\ &\quad / (\Omega_0, e^{-2iHT} \Omega_0), \end{aligned}$$

where Ω_0 is the free vacuum. The numerator

can be written as

$$(\Omega_0, U(T, x_1^0) \varphi_0(x_1) U(x_1^0, x_2^0) \dots \varphi_0(x_n) U(x_n^0, T) \Omega_0)$$

in terms of $U(t, s) = e^{iH_0 t} e^{-i(t-s)H} e^{-isH_0}$ and the canonical field φ_0 at time 0. The covariant perturbation series due to Tomonaga, Schwinger, Feynman, and Dyson is obtained by substituting the following expansion, which is the iteration of the Duhamel formula:

$$\begin{aligned} &U(t, s) \\ &= \sum_{n=0}^{\infty} (-i)^n \int_s^t dt_1 \dots \int_s^{t_{n-1}} dt_n H_I(t_1) \dots H_I(t_n). \end{aligned}$$

Here, $H_I(t) \equiv e^{iH_0 t} H_I e^{-iH_0 t}$. Each term can be represented by connected \dagger Feynman diagrams (the denominator canceling out all disconnected graphs) and computed according to the \dagger Feynman rule, yielding \dagger Feynman integrals. Each expression so obtained (formally) may be a divergent integral (in the absence of the cutoff), in which case one tries to cancel it out by modifying the original Hamiltonian with the alteration of parameters such as mass and coupling constant (by an amount called the **renormalization constant**, which is divergent in the absence of the cutoff) or possibly by the addition of terms again involving renormalization constants. If this can be achieved in terms of a finite number of renormalization constants, the model or the Hamiltonian is called **renormalizable** [7]. If the divergent integral appears only in a finite number of graphs (counting the same subgraph of an infinite number of different diagrams as one graph), the model is called **super-renormalizable**.

D. Axiomatic Quantum Field Theory

Relativistically covariant fields $\varphi_\alpha(x)$ on a Hilbert space \mathcal{H} are called **Wightman fields** if the following four **Wightman axioms** are fulfilled [8–10]:

(1) The fields $\varphi_\alpha(x)$ are **operator-valued distributions**: For each C^∞ -function f of rapid decrease on the Minkowski space ($f \in \mathcal{S}(\mathbf{R}^4)$), $\varphi_\alpha(f)$ is an operator defined on a common domain D dense in \mathcal{H} and satisfying $\varphi_\alpha(f)D \subset D$ (the domain of $\varphi_\alpha(f)^*$ contains D), $\varphi_\alpha(f)^*|D = \varphi_{\bar{\alpha}}(\bar{f})$ for another index $\bar{\alpha}$ and $(\Psi, \varphi_\alpha(f)\Phi) = (\Psi, \varphi_\alpha(f)\Phi)$ for any Ψ , and Φ in D is linear and continuous in f relative to the topology of the Schwartz space $\mathcal{S}(\mathbf{R}^4)$.

(2) **Relativistic covariance**: There exists a continuous unitary representation $U(a, A)$ ($a \in \mathbf{R}^4$ and $A \in SL(2, \mathbf{C})$) of the universal covering group $\tilde{\mathcal{P}}_+^\uparrow$ of the \dagger restricted inhomogeneous Lorentz group \mathcal{P}_+^\uparrow on \mathcal{H} such that $U(a, A)D \subset$

D and

$$U(a, A)\varphi_\alpha(f)U(a, A)^* = \sum_\beta D(A)_{\alpha\beta}\varphi_\beta(f_{a,A}),$$

where $f_{a,A}(x) = f(\Lambda(A)^{-1}(x-a))$ and $(D(A)_{\alpha\beta})$ is a finite-dimensional representation of $SL(2, \mathbb{C})$. The index α usually consists of \dagger undotted and dotted indices, interchanged in $\bar{\alpha}$, and of other indices, interchanged among them in $\bar{\alpha}$.)

(3) **Locality:** If the supports of f and g are mutually spacelike, then

$$\varphi_\alpha(f)\varphi_\beta(g) = \varepsilon(\alpha, \beta)\varphi_\beta(g)\varphi_\alpha(f)$$

on D , where $\varepsilon(\alpha, \beta) = \pm 1$. If $\varepsilon(\alpha, \beta) = -1$ exactly when $D(A)_{\alpha\alpha} = D(A)_{\beta\beta} = -1$ for $A = -1$ (i.e., when both φ_α and φ_β are Fermi fields), they are said to satisfy the **normal commutation relations**.

(4) **Spectrum conditions:** Let $U(a, 1) = e^{ia \cdot P}$. The joint spectrum of P^μ ($\mu = 0, 1, 2, 3$) is in the forward cone $\bar{V}_+ = \{p \in \mathbb{R}^4 | p \cdot p \geq 0, p^0 \geq 0\}$, with a point spectrum of multiplicity 1 at $p = 0$. A vector Ω belonging to the point spectrum 0 of P^μ is called the true (or interacting) vacuum and is required to be in D .

Usually D is taken to be minimal, namely, D is the linear hull of Ω and $\varphi_{\alpha_1}(f_1) \dots \varphi_{\alpha_n}(f_n)\Omega$ with all possible $n, \alpha_1, \dots, \alpha_n, f_1, \dots, f_n$. By means of the nuclear theorem, it is possible to define a linear operator $\varphi_{\alpha_1 \dots \alpha_n}(f)$ for $f(x_1, \dots, x_n)$ in $\mathcal{S}(\mathbb{R}^{4n})$, linear and continuous in f on D such that it coincides with $\varphi_{\alpha_1}(f_1) \dots \varphi_{\alpha_n}(f_n)$ if $f(x) = \prod_{j=1}^n f_j(x_j)$. If such operators are introduced, then the linear hull of Ω and $\varphi_{\alpha_1 \dots \alpha_n}(f)\Omega$ is taken to be D .

Under the foregoing axiom, the vacuum expectation values of the products of field operators define tempered distributions $W_\alpha(x) = W_{\alpha_1 \dots \alpha_n}(x_1, \dots, x_n)$, called **Wightman functions**, such that

$$W_\alpha(\prod f_j) = (\Omega, \varphi_{\alpha_1}(f_1) \dots \varphi_{\alpha_n}(f_n)\Omega).$$

The notion of a connected graph in perturbation theory corresponds to the following notion of **truncated Wightman functions** W_α^T :

$$W_\alpha^T(I) = \sum_m (-1)^{m-1} (m-1)! \sum_{\{I_k\}} \prod_{k=1}^m W_\alpha(I_k),$$

$$W_\alpha(I) = \sum_m \sum_{\{I_k\}} \prod_{k=1}^m W_\alpha^T(I_k),$$

where I indicates a set of variables $x_j \in M, j \in I$, $\{I_k\}$ is a partition of I into m subsets, with the order of the x 's in each I_k remaining the same as in I , and the sum over $\{I_k\}$ extending over all possible partitions. If the spectrum of $\{P^\mu\}$ in Ω^\perp is contained in $\bar{V}_+^m = \{p \in M | p \cdot p \geq m^2, p^0 \geq m\}$ for some $m > 0$ (the mass gap), then W_α^T has an exponential clustering property at spatial infinity. For example $W_\alpha^T(x_1 + a_1, \dots, x_n + a_n)e^{m'R} \rightarrow 0$ as a distribution in x if $m' < m$, $a_j^0 = 0$ for all j and $R = \max |a_j - a_k| \rightarrow \infty$.

If the mass operator $(P \cdot P)^{1/2}$ has an isolated point spectrum at m with the eigenspace $\mathcal{H}_1(m)$, then there are sufficiently many $n, \alpha = (\alpha_1, \dots, \alpha_n)$, and $f(x_1, \dots, x_n)$ such that $\varphi_\alpha(f)\Omega \in \mathcal{H}_1(m)$, and the linear hull of such vectors are dense in $\mathcal{H}_1(m)$. In terms of the f_j satisfying $\varphi_{\alpha_j}(f_j)\Omega \in \mathcal{H}_1(m_j)$ (some of the m 's may coincide) and the solutions $g_j(x) = \int \tilde{g}_j(p) \exp i(\mathbf{p}x - \omega_j(\mathbf{p})x^0) d^3\mathbf{p}$, $\omega_j(p) = (p^2 + m_j^2)^{1/2}$, of the Klein-Gordon equation, then the following limits, called **out** and **in states**, exist:

$$\Psi^{\text{out}}(h_1 \dots h_n) = \lim_{t \rightarrow \pm\infty} Q_1(t, g_1) \dots Q_n(t, g_n)\Omega,$$

$$Q_j(t, g_j) = \int \varphi_{\alpha_j}(x_1 + (t, \mathbf{x}), \dots, x_{n_j} + (t, \mathbf{x})) \\ \times f_j(x_1 + \dots + x_{n_j}) g_j(t, \mathbf{x}) dx_1 \dots dx_{n_j} d\mathbf{x},$$

$$h_j = (2\pi)^3 \tilde{g}_j(P) \varphi_{\alpha_j}(f_j)\Omega \in \mathcal{H}_1(m_j).$$

It defines the S -matrix elements as follows:

$$S(h_1 \dots h_n; h'_1 \dots h'_n) \\ = (\Psi^{\text{out}}(h_1 \dots h_n), \Psi^{\text{in}}(h'_1 \dots h'_n)).$$

This is called **Haag-Ruelle scattering theory**, and the existence proof is based on the clustering property of W_α^T and an asymptotic estimate for the behavior of the g 's for large t and all \mathbf{x} (R. Haag, *Phys. Rev.*, 112 (1958); D. Ruelle, *Helv. Phys. Acta*, 35 (1962)). The out and in states can be interpreted in the limit of infinite future and past as the state where n particles are moving at velocities \mathbf{v}_j related to the spectrum p^μ of P^μ through the relation $p^0 = m_j/(1 - \mathbf{v}_j^2)^{1/2}$, $\mathbf{p} = m_j\mathbf{v}_j/(1 - \mathbf{v}_j^2)^{1/2}$ (with probability amplitude proportional to $h_j(p)$) (H. Araki and R. Haag, *Comm. Math. Phys.*, 4 (1967)).

Since

$$(\Psi^{\text{out}}(h_1 \dots h_n), \Psi^{\text{out}}(h'_1 \dots h'_n))$$

$$= \delta_{nn'} \sum_P \prod_{j=1}^n (h_j, h'_{P(j)}),$$

where the sum is over all permutations P , Ψ^{out} can be viewed as a unitary mapping from the \dagger Fock space \mathcal{H}^0 over $\sum_m^\oplus \mathcal{H}_1(m)$ to the closed subspace \mathcal{H}^{out} spanned by $\Psi^{\text{out}}(h_1 \dots h_n)$, $n = 0, 1, 2, \dots$ (Ω for $n = 0$, h_1 itself for $n = 1$). The free fields on \mathcal{H}^{out} and \mathcal{H}^{in} are called (out and in) **asymptotic fields**. Likewise, Ψ^{in} is a unitary mapping from \mathcal{H}^0 to \mathcal{H}^{in} . If $\mathcal{H}^{\text{in}} = \mathcal{H}^{\text{out}}$, then the matrix element S can be viewed as a matrix element of a unitary operator on \mathcal{H}^0 , called an **S -matrix**. Its unitary transform by Ψ^{out} and by Ψ^{in} coincide and define a unitary operator, sometimes called an **S -operator**, on $\mathcal{H}^{\text{in}} = \mathcal{H}^{\text{out}}$. The equality $\mathcal{H} = \mathcal{H}^{\text{in}} = \mathcal{H}^{\text{out}}$ is called the **completeness of the scattering states** or **asymptotic completeness**.

If the scattering states are complete, then the following **LSZ asymptotic condition**, due

to Lehmann, Symanzik, and Zimmermann (*Nuovo Cimento*, 1 (1955)), holds:

$$\text{weak-lim}_{t \rightarrow \pm \infty} Q_j(t, g_j) = a_{\text{out}}^*(h_j),$$

where $a^*(h)$ is the \dagger creation operator ($a^*(h) \cdot \Psi(h_1 \dots h_n) = \Psi(hh_1 \dots h_n)$ for either out or in states), $\varphi_{\alpha(j)}(f_j)\Omega \in \mathcal{H}_1(m_j)$ is not required, and $(\Omega, \varphi_{\alpha(j)}(f_j)\Omega) = 0$ is assumed instead. This leads to an explicit expression for the S -matrix elements in terms of τ -functions, which takes the following simple form if all particles have spin 0, all fields φ_α are scalar ($D(A)_{\alpha\beta} = \delta_{\alpha\beta}$), and all n_j can be taken to be 1. First define the **connected part** $S_c(h_1 \dots h_n; h'_1 \dots h'_n)$ from S by exactly the same equation as truncated Wightman functions with S to be set to 0 if $n=0$, 1 or $n'=0$, 1 except when $n=n'=1$ ($S(h, h') = (h, h')$). Then

$$\begin{aligned} S_c(h_1 \dots h_l; h_{l+1} \dots h_n) \\ = \int \left[\left(\prod_{j=1}^n (p_j \cdot p_j - m_j^2) \right) \tilde{\tau}_\alpha^T(p_1, \dots, p_l, \right. \\ \left. -p_{l+1}, \dots, -p_n) \right] \prod_{j=1}^n (-iZ_j^{-1/2} h_j(\mathbf{p}_j) d\Omega_j(\mathbf{p}_j)), \end{aligned}$$

where $p_j^0 = (\mathbf{p}_j^2 + m_j^2)^{1/2}$ (the set of such p is called the positive mass shell; there the vanishing factors $(p_j \cdot p_j - m_j^2)$ cancel the poles of $\tilde{\tau}_\alpha^T$), $d\Omega_{m_j}(\mathbf{p})$ is the Lorentz invariant measure $(2|p^0|)^{-1} d^3 \mathbf{p} = (\delta(p \cdot p - m_j^2) d^4 p)$ on the positive mass shell, $h \in \mathcal{H}_1(m)$ is represented by a measurable function $h(\mathbf{p})$ with the inner product $(h, h') = \int h(\mathbf{p}) h'(\mathbf{p}) d\Omega_m(\mathbf{p})$, Z_j is defined by $(h, \varphi_{\alpha(j)}(f_j)\Omega) = Z_j^{1/2} (h, \tilde{f}_j)$ for all $h \in \mathcal{H}_1(m_j)$ and $\tilde{f}(p) = (2\pi)^{-3/2} \int e^{ip \cdot x} f(x) dx$, and $\tilde{\tau}_\alpha^T$ is the Fourier transform of the truncated **time-ordered function** (τ -function) defined by

$$\begin{aligned} \tilde{\tau}_\alpha^T(p_1, \dots, p_n) = \int \tau_\alpha^T(x_1, \dots, x_n) \exp i \left(\sum_{j=1}^n p_j \cdot x_j \right) \\ \times \prod_{j=1}^n (2\pi)^{-3/2} d^4 x_j, \\ \tau_\alpha^T(x) = \sum_P \theta(x^0; C_P) W_{P,\alpha}^T(x) \quad (x = (x_1, \dots, x_n)), \end{aligned}$$

$$W_{P,\alpha}^T(x) = (\Omega, \varphi_{\alpha_{P(1)}}(x_{P(1)}) \dots \varphi_{\alpha_{P(n)}}(x_{P(n)}) \Omega)^T,$$

in which the sum is over all permutations P , T indicates the truncated Wightman functions, $\theta(x^0; C_P)$ is the characteristic function of the cone $x_{P(1)}^0 \geq x_{P(2)}^0 \geq \dots \geq x_{P(n)}^0$ (the time ordering) possibly smeared out by convolution with a C^∞ -function of compact support (so that it can multiply a distribution), where the formula does not actually depend on the smearing functions. (Usually fields φ_α are normalized so that $Z_j = 1$.)

The r -functions (O. Steinmann, *Helv. Phys. Acta*, 33 (1960); D. Ruelle, *Nuovo Cimento*, 19 (1961); H. Araki, *J. Math. Phys.*, 2 (1961)) are

defined by

$$\begin{aligned} r_i(x) = \sum_P \theta(x^0; C_P/C_i) W_{P,\alpha}^T(x) \\ \left(= \sum_P \theta(x^0; C_P/C_i) W_{P,\alpha}(x) \right) \end{aligned}$$

(often with an additional factor $(-i)^{n-1}$), where the Fourier-Laplace transform $\tilde{\theta}(q^0; C_P)$ of $\theta(x^0; C_P)$ is a rational function and $\theta(x^0; C_P/C_i)$ is the inverse Fourier transform of its boundary value as $\text{Im } q^0 \in C_i$ tending to 0, and the cone C_i and hence r_i is specified by a consistent choice of signs of $\sum_{j \in I} \text{Im } q_j^0$ for all nonempty proper subsets I of $(1, \dots, n)$. The Fourier transform of $r_i(x)$ is a boundary value of an analytic function common to all r_i and coincides with $\tilde{\tau}_\alpha^T$ for $p^0 \in C_i$. Making use of this relation, some analyticity properties of the S -matrix (including TCP symmetry) have been proved ([11, 12]; J. Bros, H. Epstein, and V. Glaser, *Comm. Math. Phys.*, 1 (1965); Epstein, Glaser, and A. Martin, *Comm. Math. Phys.*, 13 (1969); Epstein, *J. Math. Phys.*, 8 (1967)).

The two-point function for scalar fields has the following simple expression in terms of \dagger invariant distributions, sometimes called the **Källén-Lehmann representation** with the **Källén-Lehmann weight** ρ :

$$(\Omega, \varphi(x) \varphi(y) \Omega) = \int_0^\infty \Delta_\kappa(x-y) d\rho(\kappa^2).$$

Under the Wightman axiom (with the normal commutation relations), there exists an antiunitary operator Θ , called the **TCP operator**, which satisfies the relations

$$\Theta \Omega = \Omega, \quad \Theta U(a, A) \Theta^{-1} = U(-a, A),$$

$$\Theta^2 = U(0, -1),$$

$$\Theta \varphi_\alpha(x) \Theta^{-1} = (-1)^\eta (-i)^N \varphi_\alpha(-x),$$

where η is the number of undotted indices in α , $N=0$ if $D(A)_{\alpha\alpha} = 1$ for $A = -1$ (Bose fields), and $N=1$ if $D(A)_{\alpha\alpha} = -1$ for $A = -1$ (Fermi fields).

The choice of ± 1 for $\varepsilon(\alpha, \alpha)$ in the locality axiom cannot be opposite to the normal commutation relations for any α except for the trivial case $\varphi_\alpha(x) = 0$ ([8–10]; G. Lüders and B. Zumino, *Phys. Rev.*, 110 (1958); N. Burgoyne, *Nuovo Cimento*, 8 (1958)). This is called the **connection of spin and statistics**. For a general choice of ± 1 for $\varepsilon(\alpha, \beta)$, the Wightman axioms imply existence of a certain number of **even-oddness conservation laws** (i.e., the existence of a unitary representation u of a group $(Z_2)^l$ for some l such that $u(g)\Omega = \Omega$, $u(g)\varphi_\alpha(f)u(g)^* = \chi_\alpha(g)\varphi_\alpha(f)$ for some characters χ_α on the group) so that the **Klein transforms** $\hat{\varphi}_\alpha(x) = u(g_\alpha)\varphi_\alpha(x)$ (for some choice of g_α) of the original fields satisfy the Wightman axioms with the normal

commutation relations ([8–10]; H. Araki, *J. Math. Phys.*, 2 (1961)).

E. Theory of Local Observables

Except for the technical assumption of operator-valued distributions, physical contents of the Wightman axioms have been formulated in terms of the von Neumann algebra $\mathcal{A}(\mathcal{O})$ for bounded open sets \mathcal{O} , generated by those observables which can be measured in the space-time region \mathcal{O} , as follows:

(1) **Isotony**: If $\mathcal{O}_1 \supset \mathcal{O}_2$, then $\mathcal{A}(\mathcal{O}_1) \supset \mathcal{A}(\mathcal{O}_2)$.

(2) **Covariance**: $U(a, A)\mathcal{A}(\mathcal{O})U(a, A)^* = \mathcal{A}(\Lambda(A)\mathcal{O} + a)$.

(3) **Locality**: If $Q_j \in \mathcal{A}(\mathcal{O}_j)$ and \mathcal{O}_1 is spacelike to \mathcal{O}_2 , then $[Q_1, Q_2] = 0$. (No signal can propagate faster than the speed of light.)

In addition, the spectrum condition is as before (the stability of the vacuum) and, since we restrict our attention to the closed span of $\mathcal{A}(\mathcal{O})\Omega$ for all \mathcal{O} , Ω is assumed to be cyclic for $\bigcup_{\mathcal{O}} \mathcal{A}(\mathcal{O})$. (Then the latter is irreducible.) By treating $Q(x) = U(x, 1)QU(x, 1)^*$ for $Q \in \mathcal{A}(\mathcal{O})$ as a (noncovariant but localized) field, Haag-Ruelle scattering theory and the analyticity properties of the S -matrix described above for Wightman fields hold in exactly the same way in the theory of local observables. The notion of an algebra of local observables has been a concern of R. Haag since the late 1950s, with the consequent analogy to Wightman fields being demonstrated by Araki in his Zürich lectures of 1961–1962. Hence the above axioms are sometimes called **Haag-Araki axioms**.

With the help of the additional axiom $(\mathcal{A}(\mathcal{O}_1) \cup \mathcal{A}(\mathcal{O}_2))'' = \mathcal{A}(\mathcal{O}_1 \cup \mathcal{O}_2)$, called the **additivity**, the vacuum vector Ω is cyclic and separating for $\mathcal{A}(\mathcal{O})$ for any bounded open \mathcal{O} (**Reeh-Schlieder theorem**) and $\mathcal{A}(\mathcal{O}) = \mathcal{A}(\hat{\mathcal{O}})$, where $\hat{\mathcal{O}}$ is the double cone $\{x \mid |x^0| + |\mathbf{x}| \leq L\}$ if $\mathcal{O} = \{x \mid |x^0| + |\mathbf{x}| \leq L, |\mathbf{x}| < \varepsilon\}$ for any $\varepsilon > 0$, for example (**Borchers theorem**).

A merit of the Haag-Araki axioms is that these axioms have direct physical interpretation. In particular they always imply the commutativity at spacelike separation of supports, in contrast to the anticommutativity for Fermi fields. This then necessitates the consideration of the representations associated with some other states, such as states with an odd number of fermions and representations of the C^* -algebra \mathcal{A} of quasilocal observables (generated by all $\mathcal{A}(\mathcal{O})$), which are nonequivalent to the vacuum representation and are called **superselection sectors**. This viewpoint was introduced by Haag and D. Kastler (*J. Math. Phys.*, 5 (1964)) and the C^* -algebra

version of the Haag-Araki axioms is called the **Haag-Kastler axioms**.

If \mathcal{O}' denotes the causal complement of \mathcal{O} (i.e., the set of all points spacelike to \mathcal{O}), then the assumption $\mathcal{A}(\mathcal{O}) = \mathcal{A}(\mathcal{O}')$ is called **duality** and is proved for a certain type of region, which includes the double cone in the case of free fields. With the assumption of the duality for double cones in the vacuum sector, S. Doplicher, Haag, and J. Roberts (*Comm. Math. Phys.*, 13 and 15 (1969); 24 (1971); 35 (1974)) succeeded in the analysis of superselection sectors and clarified the connection of spin and statistics in a much more satisfactory fashion, as well as the anticommutativity of intertwining operators for superselection sectors for Fermi statistics.

F. Constructive Field Theory

An effort to make mathematical sense out of the heuristic theory of quantized fields and to produce examples of Wightman fields and the associated system of local observables has been pushed forward by J. Glimm and A. Jaffe since the mid 1960s and is known as **constructive field theory**. Since 1972, the **Euclidean methods**, already known in some sense, have become extremely powerful central tools, are collectively known as **Euclidean field theory** [13–16].

The Wightman function $W(z_1 \dots z_n)$ is analytic at the **Schwinger points** $z_j = (ix_j^0, \mathbf{x}_j)$ ($x \in \mathbf{R}^4$) if $x_j \neq x_k$ for $j \neq k$, and its value $S(x_1 \dots x_n) = W(z_1 \dots z_n)$ is called the **Schwinger function**. The axioms for Schwinger functions equivalent to Wightman axioms are known as **Osterwalder-Schrader axioms** (*Comm. Math. Phys.*, 31 (1973); 42 (1975)). The positivity axiom reflecting the positive definite metric of the Hilbert space for Wightman fields is known as **O-S positivity** (or **T-positivity** or **reflection positivity**).

Since the Schwinger function is symmetric in its variables, it can be viewed as the expectation value of the product of (commuting) random fields, called **Euclidean fields**, if an additional positivity holds. This idea was put forward by K. Symanzik in the 1960s. E. Nelson then realized that Euclidean fields for free fields have the Markov property, and he developed **Euclidean Markov field theory**. A work of Guerra in 1972 utilizing **Nelson symmetry** revealed the extreme power of this approach, and the whole of constructive field theory has been studied in Euclidean formulation with remarkable results for super-renormalizable models in space-time of dimension 2 and 3. The key point is the **Feynman-Kac-Nelson formula**, which expresses Schwinger functions

as functional integrals and reveals a mathematical connection between Euclidean field theory and classical statistical mechanics.

G. Gauge Theory

†Electrodynamics in terms of the 4-vector potential $A_\mu(x)$ is invariant under the local gauge transformations $A_\mu(x) \rightarrow A_\mu(x) + \partial_\mu \Lambda(x)$ (and the associated transformation of the charged fields) for Λ satisfying the wave equation $\square \Lambda = 0$. This leads on one hand to complication in the canonical quantization of the fields $A_\mu(x)$ and, on the other hand, to the necessity of an indefinite inner-product space as exemplified by the **Gupta-Bleuler formalism** of quantum electrodynamics. In such a formalism, the **physical Hilbert space** (with positive definite metric) is introduced by considering a specific subspace (physical subspace) of a semidefinite metric and taking the quotient by its null subspace.

The corresponding theory with a non-commutative gauge group is known as the theory of **Yang-Mills fields**. In order to restore the formal unitarity of the S -matrix in the perturbation series in terms of Feynman diagrams, L. D. Faddeev and V. N. Popov (*Phys. Lett.*, 25B (1967)) introduced fictitious particles, called **Faddeev-Popov ghosts**. T. Kugo and I. Ojima (*Prog. Theoret. Phys.*, Suppl., 66 (1979)) developed a canonical quantization scheme for the Yang-Mills field which naturally introduces additional fields corresponding to the Faddeev-Popov ghosts and specifies the physical subspace by means of the simple condition that it be the kernel of the generator of **BRS transformations**, earlier introduced by C. Becchi, A. Rouet, and R. Stora.

Gauge theory can be formulated on a lattice of finite volume as a kind of classical statistical mechanics. This is known as **lattice gauge theory**, and the important issue currently being investigated is whether or not its limit, as the lattice interval tends to 0 (the continuum limit) and the volume tends to infinity, produces a nontrivial quantum theory of gauge fields.

151 (IV.4) Finite Groups

A. The Number of Finite Groups of a Given Order

A group is called a **finite group** if its order is finite (\rightarrow 190 Groups). Since the early years of the theory of finite groups, a major problem has been to find the number of distinct isomorphism classes of groups having a given order. It is almost impossible, however, to find a general solution to the problem unless the values of n are restricted to a (small) subset of the natural numbers. Let $f(n)$ denote the number of isomorphism classes of finite groups of order n . If p is a prime number, then $f(p) = 1$ and any group of prime order is a cyclic group. If p is prime, then any group of order p^2 is an \dagger Abelian group and $f(p^2) = 2$. If p and q are distinct primes and $p > q$, then $f(pq) = 2$ or 1 according as p is congruent to 1 modulo q or not. If $p \equiv 1 \pmod{q}$, there is a non-Abelian group of order pq as well as a cyclic group of order pq . For small n , the value of $f(n)$ is as

00001
170098

follows:

n	8	12	16	18	20	24	27	28	30	32	60
$f(n)$	5	5	14	5	5	15	5	4	4	51	13

For any n , $f(n) \geq 1$. When p is prime, $f(p^m)$ is known for $m \leq 6$: $f(p^3) = 5$, $f(p^4) = 15$ if $p > 2$. For $f(p^5)$ see O. Schreier, *Abh. Math. Sem. Univ. Hamburg*, 4 (1926). For $f(2^6)$ see [11]. Set $f(p^m) = p^l$ and $l = Am^3$. Then $A \rightarrow 2/27$ as $m \rightarrow \infty$ (G. Higman, *Proc. London Math. Soc.*, 10 (1960); C. C. Sims, *Symposium on Group Theory*, Harvard, 1963).

B. Fundamental Theorems on Finite Groups

The following are some fundamental theorems useful in studying finite groups.

(1) The order of any subgroup of a finite group G divides the order of G (J. L. Lagrange). The converse is not necessarily true. If a finite group G contains a subgroup of order n for any divisor n of the order of G , then G is a \dagger solvable group. Furthermore, if G contains a unique subgroup of order n for each divisor n of the order of G , then G is a cyclic group.

Let p be a prime number. Let the order of a finite group G be $p^m m$, where m is not divisible by p . A subgroup of order p^n of G is called a **p -Sylow subgroup** (or simply a **Sylow subgroup**) of G . The importance of this concept may be seen from the next theorem.

(2) A finite group contains a p -Sylow subgroup for any prime divisor p of the order of the group. Furthermore, p -Sylow subgroups are conjugate to each other. The number of distinct p -Sylow subgroups is congruent to 1 modulo p . In general, the number of distinct p -Sylow subgroups of G that contain a given subgroup whose order is a power of p is congruent to 1 modulo p (**Sylow's theorems**).

(3) A p -group is a \dagger nilpotent group (a finite group is called a **p -group** if its order is a power of p). Thus any finite p -group G of order > 1 contains a nonidentity element in the \dagger center of G . Furthermore, any proper subgroup of G is different from its \dagger normalizer. A paper by P. Hall (*Proc. London Math. Soc.*, (2) 36 (1933)) is a classic and fundamental work on p -groups.

A group G of order 8 with 2 generators σ, τ and relations $\sigma^4 = 1$, $\tau\sigma\tau^{-1} = \sigma^{-1}$, $\sigma^2 = \tau^2$ is called the **quaternion group**. This group is isomorphic to the multiplicative group consisting of $\{\pm 1, \pm i, \pm j, \pm k\}$ in the \dagger quaternion field. A **generalized quaternion group** is a group of order 2^n with 2 generators σ, τ and relations $\sigma^{2^{n-1}} = 1$, $\tau\sigma\tau^{-1} = \sigma^{-1}$, $\tau^2 = \sigma^{2^{n-2}}$. A non-Abelian group all of whose subgroups are normal subgroups is called a **Hamilton group**. A Hamilton group is the direct product of a quaternion group, an Abelian group of odd

order, and an Abelian group of exponent 2 (i.e., $\rho^2 = 1$ for each element ρ).

Let G be a finite group, and let $G_0 = G \supset G_1 \supset \dots \supset G_r = \{1\}$ be a \dagger composition series of G . The set of isomorphism classes of the simple groups G_{i-1}/G_i , $i = 1, 2, \dots, r$, is uniquely determined (up to arrangement) by the \dagger Jordan-Hölder theorem. Thus the two most fundamental problems of finite groups are (i) the study of the simple groups and (ii) the study of a group with a given set of composition factors. The first is one of the leading problems of the theory, although it has been in a state of stagnation until rather recently (\rightarrow Section J). As to the second problem, initial works by H. Wielandt and others are under way (particularly in the direction of various generalizations of Sylow's theorems). For the class of finite solvable groups, the first problem has a rather trivial solution; only the second problem is important, and even in this case the theory seems to leave something to be desired.

C. Finite Nilpotent Groups

A finite group is nilpotent if and only if it is the \dagger direct product of its p -Sylow subgroups, where p ranges over all the prime divisors of the order. Any maximal subgroup of a nilpotent group is normal. The converse holds for finite groups; that is, a finite group is nilpotent if and only if all its maximal subgroups are normal.

D. Finite Solvable Groups

One of the most profound results on finite groups, an affirmative answer to the long-standing **Burnside conjecture**, is the **Feit-Thompson theorem** (*Pacific J. Math.*, 13 (1963)): A finite group of odd order is solvable. The index of a maximal subgroup of a finite solvable group is a power of a prime number (E. Galois). But the converse is not true. The unique simple group of order 168 has the property that all maximal subgroups are of prime power index. A finite solvable group contains a self-normalizing nilpotent subgroup (i.e., a nilpotent subgroup H such that $N_G(H) = H$), and any two such subgroups are conjugate (R. W. Carter, *Math. Z.*, 75 (1960); cf. W. Gaschütz, *Math. Z.*, 80 (1963), for a generalization). Such a subgroup is called a **Carter subgroup** and is an analog of a Cartan subalgebra of a Lie algebra. But unlike Cartan subalgebras, most simple groups do not contain any self-normalizing nilpotent subgroups. A finite solvable group of order mn (m, n are relatively prime) contains a subgroup of order m ; two subgroups of order m are conjugate; if l

is a divisor of m , then any subgroup of order l is contained in a subgroup of order m (P. Hall). The converse of the first part of this theorem is also true: A finite group is solvable if it contains a subgroup of order m for any decomposition of the order in the form mn , $(m, n) = 1$ (P. Hall's solvability criterion). This generalizes the famous **Burnside theorem** asserting the solvability of a group of order $p^a q^b$, where both p and q are prime numbers. If the sequence of the quotient groups of a principal series of a finite group G consists of cyclic groups, then the group G is called **supersolvable**. A finite group is supersolvable if and only if the index of any maximal subgroup is a prime number (B. Huppert, *Math. Z.*, 60 (1954)). If p is the largest prime divisor of the order of a finite supersolvable group G , then a p -Sylow subgroup of G is a normal subgroup.

E. Hall Subgroups

A subgroup is called a **Hall subgroup** if its order is relatively prime to its index (see the theorems of P. Hall on finite solvable groups). There is no general theorem known on the existence of a Hall subgroup. If a finite group G has a normal Hall subgroup N , then G contains a Hall subgroup H that is a complement of N in the sense that $G = NH$ and $N \cap H = 1$; furthermore, any two complements are conjugate (**Schur-Zassenhaus theorem**). The analog of Hall's theorem on finite solvable groups fails for nonsolvable groups. But if a finite group, solvable or not, contains a nilpotent Hall subgroup H of order n , then any subgroup of an order dividing n is conjugate to a subgroup of H (Wielandt, *Math. Z.*, 60 (1954); cf. P. Hall, *Proc. London Math. Soc.*, 4 (1954), for a generalization). There are some generalizations of these results for maximal π -subgroups which may not be Hall subgroups.

F. π -Solvable Groups

Let π be a set of prime numbers. Denote the set of prime numbers not in π by π' . A finite group is called a **π -group** if all the prime divisors of the order belong to π . A finite group is called **π -solvable** if any composition factor is either a π' -group or a solvable π -group. If $\pi = \{p\}$ consists of a single prime number p , we use terms such as p -group or p -solvable (instead of $\{p\}$ -solvable). Let G be a π -solvable group. A series of subgroups $P_0 = 1 \subset N_0 \subsetneq P_1 \subsetneq N_1 \subsetneq \dots \subsetneq P_l \subset N_l = G$ defined by the properties that P_i/N_{i-1} is the maximal normal π -subgroup of G/N_{i-1} and N_i/P_i is the maximal normal π' -subgroup of G/P_i is called the **π -series** of G , and the integer l is called the π -

length of G . A solvable group is π -solvable for any set π of prime numbers. A π -solvable group contains a Hall subgroup which is a π -group and also a Hall subgroup which is a π' -group; an analog of Hall's theorem on finite solvable groups holds. Hall and Higman (*Proc. London Math. Soc.*, 7 (1956)) discovered deep relations between the p -length of a p -solvable group and invariants of its p -Sylow subgroup. For example, the p -length is 1 if a p -Sylow subgroup is Abelian.

G. Permutation Groups

The set of all permutations on a set Ω of n elements forms a group of order $n!$ whose structure depends only on n . This group is called the **symmetric group of degree n** , denoted by S_n . Any subgroup of S_n is a **permutation group of degree n** . When it is necessary to mention the set Ω on which permutations operate, S_n may be denoted as $S(\Omega)$, and a subgroup of $S(\Omega)$ is called a permutation group on Ω . The set of n elements on which S_n operates is usually assumed to be $\{1, 2, \dots, n\}$, and an element σ of S_n is written as

$$\sigma = \begin{pmatrix} 1 & 2 & \dots & n \\ 1' & 2' & \dots & n' \end{pmatrix},$$

$$\text{for example, } \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 2 & 3 & 1 & 5 & 4 & 6 \end{pmatrix},$$

where i' is the image of i by σ : $i' = \sigma(i)$. The element σ may be written as $(\dots)(abc\dots z)(\dots)$, which means that σ cyclically maps a into b , b into c , and so on, and finally z back into a . In the example, $\sigma = (1\ 2\ 3)(4\ 5)(6)$. It is customary to omit the cycle with only one letter in it, such as (6) in the example. With this convention, $\sigma = (1\ 2\ 3)(4\ 5)$ may be an element of S_n for any $n \geq 5$, leaving all the letters $i \geq 6$ invariant. A **cycle** of length l is an element σ of S_n which moves l letters a_1, \dots, a_l cyclically and fixes all the rest; i.e., $\sigma = (a_1, \dots, a_l)$. Then an expression such as $\sigma = (1\ 2\ 3)(4\ 5)$ is the same as the product of two cycles $(1\ 2\ 3)$ and $(4\ 5)$. In general, any permutation can be expressed as the product of mutually disjoint cycles (two cycles (a_1, \dots, a_l) and (b_1, \dots, b_m) are said to be disjoint if $a_i \neq b_j$ for all i and j). Furthermore, the expression of the permutation as the product of mutually disjoint cycles is unique up to the order in which these cycles are written. A cycle of length 2 is called a **transposition**. Any permutation may be written as a product of transpositions. This expression is not unique, but the parity of the number of transpositions in the expression is determined by the permutation. A permutation is called **even** if it is the product of an even number of transpositions

and **odd** otherwise. The symmetric group S_n contains the same number of even and odd permutations.

The totality of even permutations forms a normal subgroup of order $(n!)/2$ ($n \geq 2$), called the **alternating group of degree n** and usually denoted by A_n . An even permutation is the product of cycles of length 3. The alternating group A_5 of degree 5 is the nonsolvable group of minimal order. This fact was known to Galois. If $n \neq 4$, then the alternating group A_n is a simple group and a unique proper normal subgroup of S_n . If $n = 4$, A_4 contains a normal noncyclic subgroup V of order 4. In this case A_4 and V are the only proper normal subgroups of S_4 . A noncyclic group of order 4 is called a (**Klein**) **four-group**. If $n \geq 5$, the symmetric group S_n is not a solvable group. This is the group-theoretic ground for the famous theorem, proved by Ruffini, Abel, and Galois, which asserts the impossibility of an algebraic solution of a general algebraic equation of degree more than four. If $n \leq 4$, S_n is solvable. The group S_4 has a composition series with composition factors of orders 2, 3, 2, 2, and S_4 is realized as the group of motions in 3-dimensional space which preserve an octahedron. Hence S_4 is called the **octahedral group**. Similarly, $A_4(A_5)$ is realized as the group of motions in space which preserve a tetrahedron (icosahedron); thus A_4 is called the **tetrahedral group** and A_5 the **icosahedral group**.

These groups have been extensively studied in view of their geometric aspect. The group of motions of a plane which preserve a regular polygon is called a **dihedral group**. If a regular polygon has n sides, then the group has order $2n$. Sometimes a Klein four-group is included in the class of dihedral groups (for $n = 2$). The dihedral groups, octahedral group, etc., are called **regular polyhedral groups**. A finite subgroup of the group of motions in 3-dimensional space is either cyclic or one of the regular polyhedral groups. A dihedral group is generated by two elements of order 2. Conversely, a finite group generated by two elements of order 2 is a dihedral group. This simple fact has surprisingly many consequences in the theory of finite groups of even order [15, ch. 9]. A dihedral group of order $2n$ contains a cyclic normal subgroup of order n , and hence is solvable.

If $n \neq 6$, every automorphism of S_n is inner. The order of the group of automorphisms of S_6 is twice the order of S_6 . The index $(S_n : H)$ of a subgroup H of S_n is at least equal to n unless $H = A_n$. If $(S_n : H) = n$, then H is isomorphic to S_{n-1} . If $n \neq 6$, S_n contains a unique conjugate class of subgroups of index n . But S_6 contains two such classes, which are exchanged by an automorphism of S_6 (\rightarrow Section I).

H. Transitive Permutation Groups

A permutation group G on a set Ω is called a **transitive permutation group** if for any pair (a, b) of elements of Ω , there exists a permutation of G which sends a into b . Otherwise G is said to be **intransitive**. Let G be a transitive permutation group on a set Ω , and let a be an element of Ω . The totality of elements of G which leave a invariant forms a subgroup of G called the **stabilizer of a** (in G). The index of the stabilizer is equal to the number of elements of Ω , the degree of G . Thus the degree of a transitive permutation group G divides the order of G (a fundamental theorem).

The concept of orbits is important. Let G be a permutation group on a set Ω . A subset Γ of Ω is called an **orbit** of G if it is G -invariant and G acts transitively on Γ . In other words, a subset Γ of Ω is an orbit of G if the following two conditions are satisfied: (i) If $a \in \Gamma$ and $g \in G$, the image $g(a)$ also lies in Γ ; and (ii) if a and b are two elements of Γ , there exists an element x of G such that $b = x(a)$. Thus each element x of G induces a permutation $\varphi_x(x)$ on Γ . The set of all these permutations $\varphi_x(x \in G)$ forms a permutation group on Γ , which may be denoted by $\varphi_\Gamma(G)$. Then $\varphi_\Gamma(G)$ is transitive on Γ , and φ_Γ is a homomorphism of G onto $\varphi_\Gamma(G)$. Thus the number of elements in an orbit Γ is a divisor of the order of G . It is clear that the set Ω on which G acts is the union of mutually disjoint orbits $\Gamma_1, \dots, \Gamma_r$ of G . This implies that the degree of G is the sum of the numbers of elements in the orbits Γ_i . The resulting equation often contains non-trivial relations. If φ_i denotes the homomorphism φ_{Γ_i} defined before, then G is isomorphic to a subgroup of the direct product of the groups $\varphi_i(G)$, $i = 1, 2, \dots, r$.

A transitive permutation group is called **regular** if the stabilizer of any letter is the identity subgroup $\{1\}$. A transitive permutation group is regular if and only if its order equals its degree. Any group can be realized as a regular permutation group (**Cayley's theorem**). A transitive permutation group which is Abelian is always regular.

Let G be a transitive permutation group on a set Ω . If the stabilizer of an element a of Ω is a maximal subgroup, G is called **primitive**, and otherwise **imprimitive**. A normal subgroup, which is $\neq \{1\}$, of a primitive permutation group is transitive. An imprimitive permutation group induces a decomposition of the set Ω into the union of mutually disjoint subsets $\Delta_1, \dots, \Delta_s$ ($s > 1$) such that each Δ_i contains at least two elements, and if $x \in G$ maps an element a of Δ_i onto an element b of Δ_j , then x maps every element of Δ_i into Δ_j ; $x(\Delta_i) = \Delta_j$. The set $\{\Delta_1, \dots, \Delta_s\}$ is called a system of im-

primitivity. A subset Δ of Ω is called a **block** if $x(\Delta) \cap \Delta$ equals Δ or the empty set for all x in G . A block is called nontrivial if $\Delta \neq \Omega$ and Δ contains at least two elements. Each member of a system of imprimitivity is a nontrivial block. A transitive permutation group is primitive if and only if there is no nontrivial block.

A permutation group G on a set Ω is called **k -transitive** (or **k -ply transitive**, where k is a natural number) if for two arbitrary k -tuples (a_1, \dots, a_k) and (b_1, \dots, b_k) of distinct elements of Ω , there is an element of G which maps a_i into b_i for all $i = 1, 2, \dots, k$. If $k \geq 2$, G is called **multiply transitive**. A doubly transitive permutation group is always primitive. The symmetric group S_n of degree n is n -transitive, while the alternating group A_n is $(n-2)$ -transitive for $n \geq 3$. Conversely, an $(n-2)$ -transitive permutation group on $\{1, 2, \dots, n\}$ is either S_n or A_n . For multiply transitive permutation groups which are simple, see the list in Section I. If $k \geq 6$, no k -transitive groups are known at present except S_n and A_n . If the Schreier conjecture (\rightarrow Section I) is true, then there are no 6-transitive permutation groups except S_n and A_n (Wielandt, *Math. Z.*, 74 (1960); H. Nagao, *Nagoya J. Math.*, 27 (1964); O'Nan, *Amer. Math. Soc. Notices*, 20 (1973)).

Two 5-transitive permutation groups other than S_n and A_n are known: the groups M_{12} and M_{24} of degrees 12 and 24, respectively, discovered by E. L. Mathieu in 1864 and 1871. The stabilizer of a letter in $M_{12}(M_{24})$ is a 4-transitive permutation group of degree 11 (23), denoted by $M_{11}(M_{23})$. No 4-transitive permutation groups other than S_n , A_n , M_i ($i = 11, 12, 23$, and 24) are known. The groups M_{12} , M_{11} , M_{24} , M_{23} and the stabilizer M_{22} of a letter in M_{23} are called **Mathieu groups**. They are simple groups which have quite exceptional properties. For Mathieu groups, see E. Witt, *Abh. Math. Sem. Univ. Hamburg*, 12 (1938). A k -transitive permutation group G on Ω of degree n and order $n(n-1)\dots(n-k+1)$ has the property that no nonidentity element of G leaves k distinct letters of Ω invariant. If $k \geq 4$, such a group is one of the following: S_k , A_{k+2} , M_{12} , and M_{11} (C. Jordan). For $k = 2$ and 3, see H. Zassenhaus, *Abh. Math. Sem. Univ. Hamburg*, 11 (1936).

A multiply transitive permutation group G contains a normal subgroup S such that S is a non-Abelian simple group and G is isomorphic to a subgroup of the group $\text{Aut } S$ of the automorphisms of S , except when the degree n of G is a power of a prime number and G contains a regular normal subgroup of order n which is an elementary Abelian group (W. S. Burnside). Furthermore, in these exceptional cases,

G is at most 2-transitive if n is odd, while G is at most 3-transitive if n is even but more than 4. The symmetric group S_4 of degree 4 is the only 4-transitive group that contains a proper solvable normal subgroup.

A transitive extension of a permutation group H on Ω is defined as follows. Let ∞ be a new element not contained in Ω . A **transitive extension** G of H is a transitive permutation group on the set $\{\Omega, \infty\}$ in which the stabilizer of ∞ is the given permutation group H on Ω . Transitive extensions do not exist for some H . Suppose that a permutation group H admits a transitive extension G that is primitive. If H is simple, then G is also simple unless the degree of G is a power of a prime number. Constructing transitive extensions has been an effective method for constructing sporadic simple groups.

Permutation groups of prime degree have been studied extensively since the last century, partly because of their connection with algebraic equations of prime degree. Let p be a prime number. A transitive permutation group of degree p is either multiply transitive and nonsolvable or has a normal subgroup of order p with factor group isomorphic to a cyclic group of order dividing $p-1$ (Burnside). Choose two cycles x and y of length p in S_p . If y is not a power of x , then the subgroup $\langle x, y \rangle$ generated by x and y is a multiply transitive permutation group which is simple. The structure of $\langle x, y \rangle$ is not known despite its simple definition. More attention has been paid to groups of degree p , where p is a prime number such that $(p-1)/2 = q$ is another prime number. The problem is to decide if such nonsolvable groups contain the alternating group A_p . The Mathieu groups M_{11} and M_{23} are the only known exceptions for $p > 7$. The search for additional exceptions has been aided by the development of high-speed computers. It is known that there is no exceptional group of degree $p = 2q + 1$ for $23 < p \leq 4079$ (P. J. Nikolai and E. T. Parker, *Math. Tables Aids Comput.*, 12 (1958); see N. Ito, *Bull. Amer. Math. Soc.*, 69 (1963), for further results in this direction).

A **Frobenius group** is a nonregular transitive permutation group in which the identity is the only element leaving more than one letter invariant. A Frobenius group of degree n contains exactly $n-1$ elements which displace all the letters. These $n-1$ elements together with the identity form a regular normal subgroup of order n . This is a theorem of Frobenius; all the existing proofs depend on the theory of characters. The regular normal subgroup of a Frobenius group is nilpotent (J. G. Thompson, *Proc. Nat. Acad. Sci. US*, 45

(1959); [15, ch. 10; 16, ch. 3]). A **Zassenhaus group** is a transitive extension of a Frobenius group.

I. Finite Simple Groups

All simple groups of finite order were completely classified in February 1982 (\rightarrow Section J; [23]). These are divided into the following four classes: (1) cyclic groups of prime order, (2) alternating groups of degree ≥ 5 , (3) simple groups of Lie type, and (4) other simple groups.

The subclass (1) consists of cyclic groups of prime order p for any prime number p . Abelian simple groups belong to this subclass. The subclass (4) consists of twenty-six sporadic simple groups including five Mathieu groups. All sporadic groups, other than the five Mathieu groups, are of recent discovery.

Simple groups of Lie type are analogs of simple Lie groups, and include the classical groups as well as the exceptional groups and the groups of twisted type.

Classical groups are divided into four types: t linear, t unitary, t symplectic, and t orthogonal (\rightarrow 60 Classical Groups). Let $q = p^r$ be a power of a prime number p . Consider a vector space V of dimension $n \geq 2$ over the field \mathbb{F}_q of q elements, except in the unitary case where V is a vector space of dimension $n \geq 2$ over the field \mathbb{F}_{q^2} of q^2 elements. Let f be a nondegenerate form on V which is t Hermitian in the unitary case (with respect to the automorphism of order 2 of \mathbb{F}_{q^2} over \mathbb{F}_q), t skew symmetric bilinear in the symplectic case, and t quadratic in the orthogonal case. In the orthogonal case, the dimension of V is assumed ≥ 3 . Consider the group of all linear transformations of V (linear case) of determinant 1, or the group of all linear transformations of determinant 1 which leave the form f invariant (in other cases). In the orthogonal case, take the commutator subgroup. With each of these groups, the factor group of it by its center is a simple group with a few exceptions.

There are several notations to denote these groups. E. Artin's notation for simple groups, which is reasonably descriptive and simple, follows the name of the simple group: n and q are as described in the preceding paragraph, q is the order of the simple group, and (a, b) denotes the greatest common divisor of two natural numbers a and b .

Linear simple group, $L_n(q)$:

$$g = q^{n(n-1)/2} \prod_{i=2}^n (q^i - 1)/d, \quad d = (n, q-1).$$

Unitary group, $U_n(q)$:

$$g = q^{n(n-1)/2} \prod_{i=2}^n (q^i - (-1)^i)/d, \quad d = (n, q+1).$$

The structure of unitary groups does not depend on the form.

Symplectic group, $S_n(q)$, $n = 2m$:

$$g = q^{m^2} \prod_{i=1}^m (q^{2i} - 1)/d, \quad d = (2, q-1).$$

In the symplectic case, the dimension n of the space V must be even, so $n = 2m$, and the structure does not depend on the form.

Orthogonal group in odd dimension $n = 2m+1$, $O_{2m+1}(q)$:

$$g = q^{m^2} \prod_{i=1}^m (q^{2i} - 1)/d, \quad d = (2, q-1).$$

The structure does not depend on the form in odd dimension.

Orthogonal groups in even dimension $n = 2m$: There are two inequivalent forms, one with index m (which is maximal) and the other with index $m-1$. The two orthogonal groups are denoted by $O_{2m}(\varepsilon, q)$, $\varepsilon = \pm 1$, where $\varepsilon = 1$ if the form is of maximal index and -1 otherwise. Then

$$g = q^{m(m-1)}(q^m - \varepsilon) \prod_{i=1}^{m-1} (q^{2i} - 1)/d, \\ d = (4, q^m - \varepsilon).$$

The value of ε is determined by the form f : $\varepsilon = 1$ if f is equivalent to $\sum_{i=1}^m x_{2i-1} x_{2i}$, and $\varepsilon = -1$ if $f \sim x_1^2 + \gamma x_1 x_2 + x_2^2 + \sum_{i=2}^m x_{2i-1} x_{2i}$, where the polynomial $t^2 + \gamma t + 1$ is irreducible over \mathbb{F}_q .

There are other ways to denote these groups. Let $X = X(*, *)$ be a group of nonsingular linear transformations of a vector space V . Two asterisks indicate two invariants, such as the dimension of V and the number of elements in the ground field. The notation SX stands for the subgroup of X consisting of linear transformations with determinant 1, and the notation PX stands for the factor group of the linear group X by its center. Thus PX is a subgroup of the group of all projectivities of the projective space formed by the linear subspaces of V . The following list is self-explanatory, except the last term in each row, which is the notation of L. E. Dickson [1]:

$$L_n(q) = PSL(n, q) = LF(n, q)$$

$$U_n(q) = PSU(n, q) = HO(n, q^2)$$

$$S_{2n}(q) = PSp(n, q) = A(2n, q).$$

(LF : linear fractional group; HO : hyperorthogonal group; A : Abelian linear group.) If f is a nondegenerate quadratic form, then the sub-

group of $GL(n, q)$ consisting of all the elements leaving the form f invariant may be denoted by $O(n, q, f)$. Let $\Omega(n, q, f)$ denote the commutator subgroup of $O(n, q, f)$. Set $\varepsilon = 1$ if f is of maximal index, and $\varepsilon = -1$ otherwise. Then

$$O_n(\varepsilon, q) = P\Omega(n, q, f).$$

Dickson's notation for orthogonal groups is complicated and seldom used.

Finite simple groups corresponding to Lie groups of some exceptional type were studied by Dickson early in this century, but C. Chevalley (*Tôhoku Math. J.*, (2) 7 (1955)) proved the existence, simplicity, and other properties of groups of any (exceptional) type over any field by a unified method. Simple Lie algebras over the field \mathbb{C} of complex numbers are completely classified, and according to the classification theory they are in one-to-one correspondence with the \dagger Dynkin diagrams. Let L be a simple Lie algebra (over \mathbb{C}) corresponding to the \dagger Dynkin diagram of type X (\rightarrow 248 Lie Algebras). Let $L = L_0 + \sum L_\alpha$ be a Cartan decomposition of L , where α ranges over the \dagger root system Δ of L . It is possible to choose a basis B of L with the following properties (\dagger Chevalley's canonical basis): B consists of $e_\alpha \in L_\alpha$ ($\alpha \in \Delta$) and a basis of L_0 ; the structure constants of L with respect to B are all rational integers; the automorphism $x_\alpha(\xi)$ in the \dagger adjoint group defined by

$$x_\alpha(\xi) = \exp(\xi \operatorname{ad} e_\alpha) \quad (\xi \in \mathbb{C})$$

maps each element of B into a linear combination of elements of B with coefficients which are polynomials in ξ with integer coefficients. Thus the matrix $A_\alpha(\xi)$ representing the transformation $x_\alpha(\xi)$ with respect to B has coefficients which are polynomials in ξ with integer coefficients.

The elements of B span a Lie algebra L_Z over the ring \mathbb{Z} of integers. Let F be a field and form $L_F = F \otimes_{\mathbb{Z}} L_Z$. Then L_F is a Lie algebra over F , and the set B may be identified with a basis of L_F over F . Let t be any element of F , $A_\alpha(t)$ be the matrix obtained from $A_\alpha(\xi)$ by replacing the complex variable ξ by the element t , and finally $x_\alpha(t)$ be the linear transformation of L_F represented by the matrix $A_\alpha(t)$ with respect to B . The group generated by the $x_\alpha(t)$ for each root α and each element t of F is called the **Chevalley group** of type X over F . The commutator subgroups of the Chevalley groups are simple, with a few exceptions which will be stated after the complete list of simple groups of Lie type. Suppose that $X = A_n, D_n$, or E_6 (\rightarrow 248 Lie Algebras S). Then the Dynkin diagram of type X has a nontrivial symmetry; let it be $\alpha \rightarrow \beta$. Suppose that the field F has an automorphism σ of the same order as the order of the symmetry of the

Dynkin diagram. Let θ be the automorphism of the Chevalley group which sends $x_\alpha(t)$ to $x_\beta(t^\sigma)$. Let U (resp. V) be the subgroup of the Chevalley group generated by $x_\alpha(t)$ with $\alpha > 0$, $t \in F$ ($x_\beta(t)$, $\beta < 0$), and let U^1 (V^1) be the subgroup consisting of all the elements of U (V) which are left invariant by θ . The group generated by U^1 and V^1 is called the **group of twisted type**. If the order of σ is i , this group is said to be of twisted type iX . In all but one case, the group of twisted type is simple (see R. Steinberg, *Pacific J. Math.*, 9 (1959)). The value i is 2 except when $X = D_4$. Since D_4 admits symmetries of orders 2 and 3, there are two twisted types. If $X = B_2, G_2$, or F_4 , then the diagram has a symmetry. If the characteristic p of the ground field F is 2, 3, or 2 according as $X = B_2, G_2$, or F_4 and the field F has an automorphism σ such that $(t^\sigma)^\sigma = t^p$ for any $t \in F$, then a procedure similar to the one described before is applicable, and the group of twisted type X' is obtained (R. H. Ree, *Amer. J. Math.*, 83 (1961)). The group of twisted type is simple if the field F has more than three elements.

The following list contains all the simple groups of Lie type. For each classical group, we list the type followed by identification:

$$A_n = L_{n+1}(q) \quad (n \geq 1)$$

$${}^2A_n = U_{n+1}(q) \quad (n \geq 1)$$

$$B_n = O_{2n+1}(q) \quad (n > 1)$$

$$C_n = S_{2n}(q) \quad (n > 2)$$

$$D_n = O_{2n}(1, q) \quad (n > 3)$$

$${}^2D_n = O_{2n}(-1, q) \quad (n > 3)$$

For other groups the type of the group is followed by the customary name or notation, if any, and the order q :

$$B'_2 \quad \textbf{Suzuki group, Sz}(q), q = 2^{2n+1}$$

$$g = q^2(q-1)(q^2+1)$$

$${}^3D_4 \quad g = q^{12}(q^8+q^4+1)(q^6-1)(q^2-1)$$

$$G_2 \quad g = q^6(q^6-1)(q^2-1)$$

$$G'_2 \quad \textbf{Ree group, Re}(q), q = 3^{2n+1}$$

$$g = q^3(q^3+1)(q-1)$$

$$F_4 \quad g = q^{24}(q^{12}-1)(q^8-1)(q^6-1) \\ \times (q^2-1)$$

$$F'_4 \quad q = 2^{2n+1} \quad g = q^{12}(q^6+1)(q^4-1) \\ \times (q^3+1)(q-1)$$

$$E_6 \quad dg = q^{36}(q^{12}-1)(q^9-1)(q^8-1) \\ \times (q^6-1)(q^5-1)(q^2-1)$$

$$d = (3, q-1)$$

$$\begin{aligned}
{}^2E_6 \quad dg &= q^{36}(q^{12}-1)(q^9+1)(q^8-1) \\
&\quad \times (q^6-1)(q^5+1)(q^2-1) \\
d &= (3, q+1) \\
E_7 \quad dg &= q^{63}(q^{18}-1)(q^{14}-1)(q^{12}-1) \\
&\quad \times (q^{10}-1)(q^8-1)(q^6-1)(q^2-1) \\
d &= (2, q-1) \\
E_8 \quad g &= q^{120}(q^{30}-1)(q^{24}-1)(q^{20}-1) \\
&\quad \times (q^{18}-1)(q^{14}-1)(q^{12}-1) \\
&\quad \times (q^8-1)(q^2-1).
\end{aligned}$$

B'_2 : M. Suzuki, *Proc. Nat. Acad. Sci. US*, 46 (1960); G'_2 and F'_4 : Ree, *Amer. J. Math.*, 83 (1961); G_2 : Dickson, *Trans. Amer. Math. Soc.*, 2 (1901), *Math. Ann.*, 60 (1905); other Chevalley groups: Chevalley, *Tôhoku Math. J.*, (2) 7 (1955); twisted types: Steinberg, *Pacific J. Math.*, 9 (1959), J. Tits, *Séminaire Bourbaki* (1958), *Publ. Math. Inst. HES* (1959), D. Hertzig, *Amer. J. Math.*, 83 (1961), *Proc. Amer. Math. Soc.*, 12 (1961).

Nonsimple cases: $L_2(2)$, $L_2(3)$, $U_3(2)$, and $Sz(2)$ are solvable groups of orders 6, 12, 72, and 20, respectively. The groups $O_3(2)$, $G_2(2)$, $G'_2(3)$, and $F'_4(2)$ contain normal subgroups of indices 2, 2, 3, and 2, respectively. These normal subgroups are simple and identified as $L_2(9)$, $U_3(3)$, $L_2(8)$ in the first three cases. The normal subgroup of $F'_4(2)$ is not in the list of simple groups of Lie type and is quite exceptional (**Tits's simple group**, *Ann. Math.*, (2) 80 (1964)).

Isomorphisms between various simple groups: $L_2(q) = U_2(q) = S_2(q) = O_3(q)$; $O_5(q) = S_4(q)$; $O_4(1, q) = L_2(q) \times L_2(q)$; $O_4(-1, q) = L_2(q^2)$; $O_6(1, q) = L_4(q)$; $O_6(-1, q) = U_4(q)$; $O_{2n+1}(q) = S_{2n}(q)$ if q is a power of 2; $L_2(2) = S_3$; $L_2(3) = A_4$; $L_2(4) = L_2(5) = A_5$; $L_2(7) = L_3(2)$; $L_2(9) = A_6$; $L_4(2) = A_8$; $U_4(2) = S_4(3)$. If q is odd and $2n \geq 6$, then $S_{2n}(q)$ and $O_{2n+1}(q)$ have the same order but are not isomorphic. $L_3(4)$ and $L_4(2)$ have the same order but are not isomorphic. There is no other isomorphism or coincidence of orders among the known simple groups (Artin, *Comm. Pure Appl. Math.*, 8 (1955)).

The groups of the automorphisms of simple groups belonging to subclasses (1), (2), and (3) are known. For the simple groups of Lie type, see Steinberg, *Canad. J. Math.*, 10 (1960).

The following list of twenty-six groups consists of all the simple groups that belong to class (4):

Five Mathieu groups whose orders are

$$M_{11}: g = 7,920 = 2^4 \cdot 3^2 \cdot 5 \cdot 11$$

$$M_{12}: g = 95,040 = 2^6 \cdot 3^3 \cdot 5 \cdot 11$$

$$M_{22}: g = 443,520 = 2^7 \cdot 3^2 \cdot 5 \cdot 7 \cdot 11$$

$$M_{23}: g = 10,200,960 = 2^7 \cdot 3^2 \cdot 5 \cdot 7 \cdot 11 \cdot 23$$

$$M_{24}: g = 244,823,040 = 2^{10} \cdot 3^3 \cdot 5 \cdot 7 \cdot 11 \cdot 23.$$

The other twenty-one groups have been discovered since 1964. Each group is identified by the symbol $(x)_i$, indicating that it is the i th group discovered in the year 19x. The list continues with the name or names of discoverers, the order of the group, and a brief description.

$(64)_1$: Z. Janko, $g = 175,560 = 2^3 \cdot 3 \cdot 5 \cdot 7 \cdot 11 \cdot 19$. A subgroup of the Chevalley group $G_2(11)$. See *J. Algebra*, 3 (1966).

$(67)_1$: M. Hall and Z. Janko, $g = 604,800 = 2^7 \cdot 3^3 \cdot 5^2 \cdot 7$, a transitive extension of $U_3(3)$ of degree 100.

$(67)_2$: D. G. Higman and Sims, $g = 44,352,000 = 2^9 \cdot 3^2 \cdot 5^3 \cdot 7 \cdot 11$, a transitive extension of M_{22} of degree 100. It is a normal subgroup of index 2 in the group of automorphisms of a certain graph with 100 vertices.

$(67)_3$: Suzuki, $g = 448,345,497,600 = 2^{13} \cdot 3^7 \cdot 5^2 \cdot 7 \cdot 11 \cdot 13$, a transitive extension of $G_2(4)$; defined from the automorphism group of a graph of 1782 vertices.

$(67)_4$: J. McLaughlin, $g = 898,128,000 = 2^7 \cdot 3^6 \cdot 5^3 \cdot 7 \cdot 11$, a transitive extension of $U_4(3)$; defined from a graph of 275 vertices.

$(68)_1$: G. Higman, Z. Janko, and J. McKay, $g = 50,232,960 = 2^7 \cdot 3^5 \cdot 5 \cdot 17 \cdot 19$, a transitive extension of the group which is obtained from $L_2(16)$ by adjoining the field automorphism of order 2. The existence was verified by using a computer.

$(68)_2$, $(68)_3$, $(68)_4$: J. H. Conway,

$$g = 2^{21} \cdot 3^9 \cdot 5^4 \cdot 7^2 \cdot 11 \cdot 13 \cdot 23$$

$$= 4,157,776,806,543,360,000,$$

$$g = 2^{18} \cdot 3^6 \cdot 5^3 \cdot 7 \cdot 11 \cdot 23,$$

$$g = 2^{10} \cdot 3^7 \cdot 5^3 \cdot 7 \cdot 11 \cdot 23.$$

The big group is obtained from the automorphism group of a lattice in 24-dimensional space, and the two smaller ones are subgroups of it. The lattice was defined by J. Leech in connection with a problem of close packing of spheres in 24 dimensions (*Canad. J. Math.*, 19 (1967)).

$(68)_5$: B. Fischer, $g = 2^{17} \cdot 3^9 \cdot 5^2 \cdot 7 \cdot 11 \cdot 13 = 70,321,751,654,400$, a transitive extension of $U_6(2)$ derived by means of a certain graph.

$(69)_1$: D. Held and others, $g = 2^{10} \cdot 3^3 \cdot 5^2 \cdot 7^3 \cdot 17 = 4,030,387,200$.

$(69)_2$: B. Fischer, $g = 2^{18} \cdot 3^{13} \cdot 5^2 \cdot 7 \cdot 11 \cdot 13 \cdot 17 \cdot 23 = 4,089,470,473,293,004,800$.

$(69)_3$: B. Fischer, $g = 2^{21} \cdot 3^{16} \cdot 5^2 \cdot 7^3 \cdot 11 \cdot 13 \cdot 17 \cdot 23 \cdot 29 = 1,255,205,709,190,661,721,292,800$.

$(71)_1$: R. N. Lyons and C. C. Sims, $g = 2^8 \cdot 3^7 \cdot 5^6 \cdot 7 \cdot 11 \cdot 31 \cdot 37 \cdot 67$.

The existence of $(69)_1$ and $(71)_1$ was verified by

using computers; $(69)_2$ and $(69)_3$ were derived by means of certain graphs. For a more detailed account of these simple groups, see J. Tits, *Séminaire Bourbaki* (1970), No. 375, and the references [18, 19, 20.]

$(72)_1$: A. Rudvalis, $g = 2^{14} \cdot 3^3 \cdot 5^3 \cdot 7 \cdot 13 \cdot 19$, a transitive extension of Tits's simple group, i.e., a normal subgroup of $F'_4(2)$ of index 2. Concerning this group $(72)_1$, see the article of J. H. Conway and D. B. Wales, *J. Algebra*, 27 (1973).

$(73)_1$: M. O'Nan, $g = 2^9 \cdot 3^4 \cdot 5 \cdot 7^3 \cdot 11 \cdot 19 \cdot 31$. This group $(73)_1$ was discovered by O'Nan and the existence was verified by C. Sims, using a computer.

$(73)_2$: B. Fischer, $g = 2^{41} \cdot 3^{13} \cdot 5^6 \cdot 7^2 \cdot 11 \cdot 13 \cdot 19 \cdot 23 \cdot 31 \cdot 47$.

$(73)_3$: B. Fischer and R. Griess, $g = 2^{46} \cdot 3^{20} \cdot 5^9 \cdot 7^6 \cdot 11^2 \cdot 13^3 \cdot 17 \cdot 19 \cdot 23 \cdot 29 \cdot 31 \cdot 41 \cdot 47 \cdot 59 \cdot 71$.

$(74)_1$: J. G. Thompson, $g = 2^{15} \cdot 3^{10} \cdot 5^3 \cdot 7^2 \cdot 13 \cdot 19 \cdot 31$.

$(74)_2$: K. Harada, $g = 2^{14} \cdot 3^6 \cdot 5^6 \cdot 7 \cdot 11 \cdot 19$.

The existence of $(73)_2$ was suggested by B. Fischer, and then that of $(73)_3$ by B. Fischer and R. Griess. Shortly after this, the existence of $(74)_1$ and $(74)_2$ was suggested by J. G. Thompson, and then Thompson and Harada proved the existence of these groups with the aid of P. Smith and S. Norton, using computers. The existence of $(73)_2$ was established in 1976 by Leon and Sims, using a computer. Very recently (July 1980), R. Griess has announced that the group $(73)_3$ is realized as a group of automorphisms of a 196,883-dimensional commutative nonassociative algebra over the rational numbers.

$(75)_1$: Z. Janko, $g = 2^{21} \cdot 3^3 \cdot 5 \cdot 7 \cdot 11^3 \cdot 23 \cdot 29 \cdot 31 \cdot 37 \cdot 43$. This group $(75)_1$ was discovered by Z. Janko. The existence was verified by using a computer.

For a more detailed account of the twenty-six sporadic simple groups, see [21].

Simple groups of order < 1000 are A_5 ($g = 60$), $L_2(7)$ (168), $A_6(360)$, $L_2(8)$ (504), and $L_2(11)$ (660). All simple groups of order $\leq 20,000$ are known.

Among the known simple groups, the following multiply transitive permutation representations are known: Alternating groups A_n (degree n), A_8 and A_7 (degree 15), A_6 (degree 10), A_5 (degree 6), Mathieu groups M_i (degree i), M_{11} (degree 12), $L_n(q)$ (degree $(q^n - 1)/(q - 1)$), $L_2(p)$ (degree p for $p = 5, 7, 11$), $U_3(q)$ (degree $1 + q^3$), $Sz(q)$ (degree $1 + q^2$), $Re(3^n)$ (degree $1 + 3^{3n}$), $S_{2n}(2)$ (degrees $2^{n-1}(2^n \pm 1)$), and the Higman-Sims group $(67)_2$ (degree 176) and, the Conway group $(68)_4$ (degree 276). Among them, A_n (degree n , $n \geq 5$), M_i (degree i), M_{11} (degree 12), $L_2(2^m)$ (degree $1 + 2^m$), and $L_2(5)$ (degree 5) are triply transitive.

There are several remarkable properties of known finite simple groups which have been conjectured to hold for arbitrary finite simple groups. One of the most famous is the **Schreier conjecture**, which asserts that the group of outer automorphisms of a simple group is solvable. This has been verified for all known cases. Another conjecture says that a finite simple group is generated by two elements. This has also been verified for almost all known groups. In many cases, there is a generating set of two elements, one of which has order 2. There is no counterexample known to disprove the universal validity of this property. Except for $Sz(q)$, the orders of known simple groups are divisible by 12.

J. Classification of Finite Simple Groups

The objective of classification theory is to find the complete list of finite simple groups; this was accomplished in February 1982, following the series of important works mentioned below.

The order of a finite non-Abelian simple group is divisible by at least three distinct prime numbers (W. S. Burnside; \rightarrow Section D). The order of a finite non-Abelian simple group is even (W. Feit and J. G. Thompson; \rightarrow Section D). These theorems are special cases of the following theorem: If G is a finite non-Abelian simple group in which the normalizer of any solvable subgroup $\neq \{1\}$ is solvable, then $G = L_2(q)$ ($q > 3$), $Sz(2^{2n+1})$ ($n \geq 1$), A_7 , $L_3(3)$, $U_3(3)$, M_{11} , or Tits's simple group. In particular, a minimal simple group is isomorphic to $L_2(p)$ ($p \equiv 2$ or $3 \pmod{5}$, $p > 3$), $L_2(2^p)$, $L_2(3^p)$, $Sz(2^p)$, or $L_3(3)$, where p is a prime number (a finite non-Abelian simple group is called a minimal simple group if all proper subgroups are solvable). This theorem is proved in a series of papers by J. G. Thompson (*Bull. Amer. Math. Soc.*, 74 (1968), *Pacific J. Math.*, 33 (1970), 39 (1971), 48 (1973), 50 (1974), and 51 (1974)). The method which Thompson used in these papers has since been generalized in various ways by many authors to establish a number of important theorems. There are also some interesting consequences of this theorem concerning solvable groups. For example, a finite group is solvable if and only if every pair of elements generates a solvable subgroup.

Let G be a non-Abelian simple group of even order and S one of its 2-Sylow subgroups. Then S is neither cyclic nor a generalized quaternion group (W. S. Burnside, R. Brauer, and M. Suzuki). If S is a dihedral group, then $G = A_7$ or $L_2(q)$ (q odd ≥ 5) (D. Gorenstein and J. H. Walter). These theorems deal with the

cases where S is "small." The study in this direction has culminated in the classification of finite simple groups all of whose 2-subgroups are generated by at most four elements (D. Gorenstein and K. Harada, *Mem. Amer. Math. Soc.*, 147 (1974)).

If a 2-Sylow subgroup of a finite non-Abelian simple group G is an Abelian group, then $G = L_2(r)$ ($r \equiv 0, 3$ or $5 \pmod{8}$, $r > 3$), or else G possesses an element of order 2 whose centralizer is isomorphic to $Z_2 \times L_2(q)$ ($q \equiv 3$ or $5 \pmod{8}$, $q > 3$) (J. H. Walter). In the latter case, G is called a **group of Janko-Ree type** (J-R type for short), and if $q \neq 5$, it is called a **group of Ree type**. If $q = 5$, then $G = (64)_1$, the Janko's simple group of order 175,560. The Ree groups $Re(q)$ are groups of Ree type. Since the discovery of $Re(q)$, it has long been an open problem to show that there are no other groups of Ree type. Very recently, the combined work of E. Bombieri, J. G. Thompson and others settled the problem (*Inventiones Math.*, 58 (1980)).

A surprisingly short proof of the Walter's theorem above is given by H. Bender (*Math. Z.*, 117 (1970)). Bender's method applies to a much larger class of groups. A subgroup A of a finite group G is said to be **strongly closed** if $A^g \cap N_G(A) \subset A$ for each $g \in G$. D. M. Goldschmidt proved (*Ann. Math.*, 99 (1974)) that if A is a strongly closed Abelian 2-subgroup, then the subgroup G_0 generated by the conjugates of A possesses a normal series $G_0 \supset G_1 \supset G_2$ with the properties: G_2 is of odd order, G_1/G_2 is a 2-group and is contained in the center of G_0/G_2 , and either $G_0 = G_1$ or G_0/G_1 is the direct product of simple groups on the following list: $L_2(q)$ ($q \equiv 0, 3$ or $5 \pmod{8}$, $q > 3$), $Sz(2^{2n-1})$, $U_3(2^n)$ ($n > 1$), and the groups of J-R type. Furthermore, $AG_2/G_2 \supset G_1/G_2$ and AG_1/G_1 is the center of a 2-Sylow subgroup of G_0/G_1 . This theorem generalizes an earlier result of G. Glauberman (the so-called Z^* -theorem) which states that if A is a strongly closed subgroup of order 2, then the image of A in the quotient group G/K by the maximal normal subgroup of odd order is a normal subgroup and hence is contained in the center of G/K . These theorems of Glauberman and Goldschmidt are of fundamental importance in the study of finite simple groups since they provide an effective tool for showing that a given group has a normal Abelian 2-subgroup.

Glauberman obtained a criterion for the existence of a strongly closed Abelian p -subgroup $\neq \{1\}$ for some prime p [15, 22]. For any prime p , the quadratic group $Qd(p)$ is defined to be the semidirect product of the 2-dimensional vector space $V(2, p)$ over the field of p elements by the special linear group

$SL(2, p)$ where the action of $SL(2, p)$ on $V(2, p)$ is taken to be the natural one. A finite group G contains a strongly closed Abelian p -subgroup $A \neq \{1\}$ if no section of G is isomorphic to $Qd(p)$ (a section is a quotient group of a subgroup). Furthermore, if p is odd, then we can choose as A a characteristic subgroup of a p -Sylow subgroup S of G which is determined only by the structure of S . Therefore a finite non-Abelian simple group has a section isomorphic to $Qd(2) = S_4$ except when it is one of the simple groups mentioned in Goldschmidt's theorem. This theorem generalizes an unpublished result of J. G. Thompson to the effect that 3 divides the order of finite non-Abelian simple groups except $Sz(2^{2n+1})$.

Let G be a 2-transitive permutation group on $n+1$ letters, and assume that the stabilizer H of a letter contains a normal subgroup K which is regular on the remaining n letters. Then G contains a normal subgroup N such that G is isomorphic to a subgroup of the automorphism group of N and either $N = L_2(q)$, $U_3(q)$, $Sz(q)$ or a group of Ree type, or else N is 2-transitive on the $n+1$ letters and no nonidentity element of N leaves two distinct letters invariant (the structure of N in the latter case is also known (H. Zassenhaus; — Section H). This theorem is proved by E. Shult for n even (*Illinois J. Math.*, 16 (1972)) and by C. Hering, W. M. Kantor, and G. M. Seitz for n odd (*J. Algebra*, 20 (1972)). Its proof depends on the work of many authors who considered various special cases, especially the work of H. Zassenhaus, W. Feit, N. Ito, and M. Suzuki on the classification of Zassenhaus groups, and the work of M. Suzuki on the case where n is even and H/K is of odd order (*Ann. Math.*, 79 (1964)). In this special case which Suzuki handles, the stabilizer H is of even order and $H \cap H^g$ is of odd order for any $g \in G - H$. If a proper subgroup H of an arbitrary finite group G has this property, then H is called a **strongly embedded subgroup**. Extending the work of Suzuki, H. Bender proved the following theorem (*J. Algebra*, 17 (1971)): If a finite group G possesses a strongly embedded subgroup, then either (i) a 2-Sylow subgroup of G is cyclic or a generalized quaternion group, or (ii) G possesses a normal series $G = G_0 \supset G_1 \supset G_2$ such that G_0/G_1 and G_2 are of odd order and $G_1/G_2 = L_2(2^n)$, $U_3(2^n)$, or $Sz(2^{2n-1})$ ($n > 1$). This theorem generalizes another theorem of Suzuki who reached the same conclusion under the assumption that two distinct 2-Sylow subgroups have only the identity element in common. Bender's theorem is of fundamental importance in the classification theory of finite simple groups, since a strongly embedded subgroup often appears as an obstacle to the proofs of classification

theorems. For a generalization of Bender's theorem, see a paper by M. Aschbacher (*Proc. Amer. Math. Soc.*, 38 (1973)), which also contains an alternative proof of Shult's theorem.

The theorem of Shult, Hering, Kantor, and Seitz may be interpreted as a classification of finite groups having a split (B, N) -pair of rank 1. Let G be a finite group and let B and N be subgroups of G such that (i) B and N generate G , (ii) $T = B \cap N$ is a normal subgroup of N , and (iii) $W = N/T$ is generated by a set S of elements of order 2 such that $sBs \neq B$ and $sBw \subset BwB \cup BswB$ for each $s \in S$ and each $w \in W$. The subgroups B and N are called a (B, N) -pair of G (the quadruplet (G, B, N, S) is called a **Tits system**), and the cardinality of the set S is called the rank of the (B, N) -pair. The (B, N) -pair is said to be split if B has a normal subgroup U such that $B = TU$ and $T \cap U = \{1\}$, and is said to be saturated if $T = \bigcap_{n \in N} B^n$. If a finite group G has a split saturated (B, N) -pair of rank 1, and if $Z = \bigcap_{g \in G} B^g$, then G/Z is a 2-transitive permutation group satisfying the assumption of the theorem of Shult, Hering, Kantor, and Seitz, and information is obtained on the structure of G . In general, the simple groups of Lie type are characterized as simple groups with certain (B, N) -pairs. For (B, N) -pairs of rank 2, see papers by P. Fong and G. M. Seitz (*Inventiones Math.*, 21 (1973), 24 (1974)). J. Tits has developed a satisfactory theory on finite groups having a (B, N) -pair of rank at least 3 (Lecture notes in math. 386, Springer).

Let G be a finite group generated by a conjugate class D of elements of order 2, and let π be the set of positive integers consisting of the orders of the products of two distinct elements of D . Furthermore, assume that G has no nontrivial solvable normal subgroup. B. Fischer proved (*Inventiones Math.*, 13 (1971)) that if $\pi = \{2, 3\}$, then G contains a normal subgroup isomorphic to one of the following groups: A_n , $S_{2n}(2)$, $O_{2n}(\pm 1, 2)$, $O_n(\pm 1, 3)$, $U_n(2)$, and the three Fischer's simple groups $(68)_5$, $(69)_2$, $(69)_3$. For a generalization of this theorem, see papers by M. Aschbacher (*Math. Z.*, 127 (1972), *J. Algebra*, 26 (1973)). The most powerful result in this direction is given by F. Timmesfeld (*J. Algebra*, 33 (1975), 35 (1975)): Suppose π consists of 2, 4, and odd positive integers. Furthermore, assume that if d and e are in D and de is of order 4, then $(de)^2 \in D$. Then $G = A_6$, $U_3(3)$, the Hall-Janko group $(67)_1$, $L_n(q)$ ($n \geq 3$), $O_{2n+1}(q)$ ($n \geq 3$), $O_{2n}(\pm 1, q)$ ($n \geq 4$), $G_2(q)$, ${}^3D_4(q)$, $F_4(q)$, ${}^2E_6(q)$, $E_6(q)$, $E_7(q)$, or $E_8(q)$, where $q = 2^m$.

Let G be a simple group of even order and let H be the centralizer of an element of order 2. Then the order of G is bounded by a function f of the order h of H (for example, we can

choose $f(h) = \{h(h+1)\}!$; R. Brauer and K. A. Fowler, *Ann. Math.*, 62 (1955)). In particular, there exist only finitely many isomorphism classes of finite simple groups which contain an element of order 2 with a given centralizer H . This fact is a ground for Brauer's program of studying simple groups of even order in terms of the structure of the centralizers of elements of order 2. There are a number of important results concerning Brauer's program [20]. For example, nine sporadic simple groups were discovered in related works. Since 1973, Brauer's program has been improved greatly by M. Aschbacher, D. Gorenstein, and others, and the classification of finite simple groups was finally completed in February 1982 [21, 23].

152 (VII.18) Finsler Spaces

A. Definitions

Let $T(M)$ be the \dagger tangent vector bundle of an n -dimensional \dagger differentiable manifold M . An element of $T(M)$ is denoted by (x, y) , where x is a point of M and y is a \dagger tangent vector of M at x . Given a \dagger local coordinate system (x^1, \dots, x^n) of M , we can obtain a local coordinate system of $T(M)$ by regarding $(x^1, \dots, x^n, y^1, \dots, y^n) = (x^i, y^j)$ as coordinates of the pair $(x, y) \in T(M)$, where (x^1, \dots, x^n) are coordinates of a point x of M and $y = \sum y^j \partial / \partial x^j$. A continuous real-valued function $L(x, y)$ defined on $T(M)$ is called a **Finsler metric** if the following conditions are satisfied: (i) $L(x, y)$ is differentiable at $y \neq 0$; (ii) $L(x, \lambda y) = |\lambda| L(x, y)$ for any element (x, y) of $T(M)$ and any real number λ ; and (iii) if we put $g_{ij}(x, y) = (1/2) \partial^2 L(x, y)^2 / \partial y^i \partial y^j$, the symmetric matrix $(g_{ij}(x, y))$ is positive definite. A differentiable manifold with a Finsler metric is called a **Finsler space**. There exists a Finsler metric on a manifold M if and only if M is \dagger paracompact. We call $F(x, y) = L(x, y)^2$ the **fundamental form** of the Finsler space. When $F(x, y)$ is a quadratic form of (y^1, \dots, y^n) , $L(x, y)$ is a \dagger Riemannian metric, and $F(x, y) = \sum_{i,j} g_{ij}(x) y^i y^j$. Therefore a Finsler space is a Riemannian space if and only if g_{ij} does not depend on y . The matrix g_{ij} is also called the **fundamental tensor** of the Finsler space $(i, j = 1, \dots, n)$.

Thus the notion of a Finsler metric is an extension of that of Riemannian metric. The study of differentiable manifolds utilizing such generalized metrics was considered by B. Riemann, but he stated that a Riemannian

metric is more convenient for the purpose since “only nongeometrical results can be obtained” by using Finsler metrics [7]. P. Finsler initiated the systematic study of Finsler metrics and extended to a Finsler space many concepts and theorems valid in the classical theory of curves and surfaces [5].

B. The Finsler Metric

In a Finsler space, the arc length of a curve $x = x(t)$ ($a \leq t \leq b$) is given by $\int_a^b L(x, dx/dt) dt$. Therefore a \dagger geodesic in a Finsler space is defined as a \dagger stationary curve for the problem of \dagger variation $\delta \int_a^b L(x, dx/dt) dt = 0$, and the differential equation of the geodesic is given by

$$\frac{d^2 x^i}{dt^2} + \sum_{j,k} \gamma_{jk}^i \left(x, \frac{dx}{dt} \right) \frac{dx^j}{dt} \frac{dx^k}{dt} = 0,$$

where $\gamma_{jk}^i(x, y)$ is the \dagger Christoffel symbol of g_{ij} , i.e.,

$$\gamma_{jk}^i(x, y) = \frac{1}{2} \sum_a g^{ia} \left(\frac{\partial g_{ja}}{\partial x^k} + \frac{\partial g_{ak}}{\partial x^j} - \frac{\partial g_{jk}}{\partial x^a} \right),$$

where $(g^{ij}(x, y))$ is the inverse matrix of $(g_{ij}(x, y))$.

The distance between two points in a Finsler space is defined, as in a Riemannian space, as the infimum of the lengths of curves joining the two points. Many properties of Riemannian spaces as metric spaces can be extended to Finsler spaces. The topology defined by the Finsler metric coincides with the original topology of the manifold. A Finsler space M is said to be \dagger complete if every Cauchy sequence of M as a metric space is convergent. The following three conditions are equivalent: (i) M is complete; (ii) each bounded closed subset of M is compact; (iii) each geodesic in M is infinitely extendable. In a complete Finsler space, any two points can be joined by the shortest geodesic.

A diffeomorphism φ of a Finsler space M preserves the distance between an arbitrary pair of points if and only if the transformation on $T(M)$ induced by φ preserves the Finsler metric $L(x, y)$. Such a transformation is called an \dagger isometry of the Finsler space. In the \dagger compact-open topology the set of all isometries of a Finsler space is a \dagger Lie transformation group of dimension at most $n(n+1)/2$. If a Finsler space admits the isometry group of dimension greater than $(n(n-1)+2)/2$, it is a Riemannian space of constant curvature [8].

C. The Theory of Connections

An important difference between a Finsler space and a Riemannian space relates to their

properties with respect to the theory of \dagger connections. In the case of a Riemannian space, the Christoffel symbols constructed from the fundamental tensor are exactly the coefficients of a connection, whereas in the case of a Finsler space, the Christoffel symbols $\gamma_{jk}^i(x, y)$ do not define a connection, for the fundamental tensor g_{ij} depends not only on the points of the space but also on the directions of tangent vectors at these points.

When we consider notions such as tensors, etc., in a Finsler space M , it is generally more convenient to take the whole tangent vector bundle $T(M)$ into consideration rather than restricting ourselves to the space M . For example, let P be the \dagger tangent n -frame bundle over a Finsler space M and $Q = p^{-1}(P)$ be the \dagger principal fiber bundle over $T(M)$ induced from P by the projection p of $T(M)$ onto M . We call the elements of fiber bundles associated with Q tensors. In this sense, the fundamental tensor g_{ij} in a Finsler space is the covariant tensor field of order 2. Therefore it is natural to consider a connection in a Finsler space as a connection in the principal fiber bundle Q . The connection in a Finsler space defined by E. Cartan is exactly of this type [3]. Namely, he showed that by assigning to a connection in Q certain conditions related to the Finsler metric, we can determine uniquely a connection from the fundamental tensor so that the covariant differential of the fundamental tensor vanishes.

Cartan's introduction of the notion of connection produced a development in the theory of Finsler spaces that parallels the development in the theory of Riemannian spaces, and many important results have been obtained. O. Varga (1941) succeeded in obtaining a Cartan connection in a simpler way by using the notion of osculating Riemannian space. S. S. Chern (1943) studied general Euclidean connections that contain Cartan connections as a special case. Noticing that the tangent space of a Finsler space is a \dagger normed linear space, H. Rund (1950) obtained many notions different from those of Cartan. However, as far as the theory of connections is concerned, the two theories do not seem to be essentially different. The theory of curvature in a Finsler space is more complicated than that in a Riemannian space because we have three curvature tensors in the Cartan connection. Using the fact that, in a local cross section of the tangent vector bundle of a Finsler space, a Riemannian metric can be introduced by the Finsler metric, L. Auslander (1955) [2] extended to Finsler spaces the results of J. L. Synge and S. B. Myers on the curvature and topology of Riemannian spaces. A. Lichnérowicz extended the \dagger Gauss-Bonnet formula to

Finsler spaces by considering an integral on the subbundle of the tangent vector bundle satisfying $L(x, y) = 1$ [6]. M. H. Akbar-Zadeh studied \dagger holonomy groups and transformation groups of Finsler spaces by using the theory of fiber bundles.

Connections of Finsler spaces have been investigated by many geometers, but most of them used methods considerably different from those of the modern theory of connections in principal fiber bundles. J. H. Taylor and Synge (1925) defined the covariant differential of a vector field along a curve. L. Berwald (1926) defined a connection from the point of view of the **general geometry of paths**. A curve on a manifold satisfying the differential equation

$$\frac{d^2 x^i}{dt^2} + 2G^i\left(x, \frac{dx}{dt}\right) = 0$$

is called a **path**. The theory was originated by O. Veblen and T. Y. Thomas and generalized as above by J. Douglas. Characteristically, with respect to a Berwald connection, the covariant differential of the fundamental tensor does not vanish.

A Finsler space is a space endowed with a metric for line elements. As a dual concept, we have a **Cartan space**, which is endowed with a metric for **areal elements** [4]. A. Kawaguchi (1937) extended these notions further and studied a **space of line elements of higher order** (or **Kawaguchi space**).

153 (IX.7) Fixed-Point Theorems

A. General Remarks

Given a mapping f of a space X into itself, a point x of X is called a **fixed point** of f if $f(x) = x$. When X is a topological space and f is a continuous mapping, we have various theorems concerning the fixed points of f .

B. Fixed-Point Theorems for Polyhedra

(1) Brouwer Fixed-Point Theorem. Let X be a \dagger simplex and $f: X \rightarrow X$ a continuous mapping. Then f has a fixed point in X (*Math. Ann.*, 69 (1910), 71 (1912)).

(2) Lefschetz Fixed-Point Theorem. Let $H_p(X)$ be the p -dimensional \dagger homology group of a \dagger finite polyhedron X (with integral coefficients), $T_p(X)$ the \dagger torsion subgroup of $H_p(X)$, and $B_p(X) = H_p(X)/T_p(X)$. The continuous mapping $f: X \rightarrow X$ naturally induces a homomorphism f_* of the free \mathbb{Z} -module $B_p(X)$ into itself. Let α_p be the \dagger trace of f_* and $\Lambda_f = \sum_{p=0}^n (-1)^p \alpha_p$ ($n = \dim X$). We call this integer Λ_f the **Lefschetz number** of f .

We have the **Lefschetz fixed-point theorem**:

(i) Let f, g be continuous mapping sending X into itself. If f, g are \dagger homotopic ($f \simeq g$), then $\Lambda_f = \Lambda_g$. (ii) If $\Lambda_f \neq 0$, then f has at least one fixed point in X (*Trans. Amer. Math. Soc.*, 28 (1926)).

The condition $\Lambda_f \neq 0$ is, however, not necessary for the existence of a fixed point of f . The Brouwer fixed-point theorem is obtained immediately from (i) and (ii). In particular, if the mapping f is homotopic to the identity mapping 1_X , then α_p is the p th \dagger Betti number of X , and Λ_f is equal to the \dagger Euler characteristic $\chi(X)$ of X . Hence, in this case, if $\chi(X) \neq 0$, then f has a fixed point.

When X is a compact oriented manifold without boundary the Lefschetz number Λ_f of f can be interpreted as the \dagger intersection number of the graph of f and the diagonal of X .

More generally, let X and Y be compact oriented n -dimensional manifolds without boundary. If f and $g: X \rightarrow Y$ are continuous mappings, a point x of X such that $f(x) =$

$g(x)$ is called a **coincidence point** of f and g . The intersection number $\Lambda_{f,g}$ of the graph of f and that of g is called the **coincidence number** of f and g . If $\Lambda_{f,g} \neq 0$, then f and g have at least one coincidence point. The coincidence number $\Lambda_{f,g}$ is also expressed as $\sum_{p=0}^n (-1)^p \text{tr}(f^* \circ g_! | H^p(X))$, where $g_!: H^p(X) \rightarrow H^p(Y)$ is the \dagger Gysin homomorphism of g .

Suppose that a finite group G acts on the manifolds X and Y . If $f: X \rightarrow Y$ is a mapping, a point x of X such that $\tau f(x) = f\tau(x)$ for all $\tau \in G$ is called an **equivariant point** of f . When G is a group of order 2 and acts on X nontrivially, the **equivariant point index** $\hat{\Lambda}_f$ is employed. This index was introduced by Nakaoka (*Japan. J. Math.* 4 (1978)), using the \dagger equivariant cohomology. It has the property that $\hat{\Lambda}_f \neq 0$, implying that f admits an equivariant point. The prototype of this theorem is the Borsuk-Ulam theorem (*Fund. Math.* 20 (1933)), which states that a continuous mapping $f: S^n \rightarrow \mathbb{R}^n$ always admits a point $x \in S^n$ such that $f(x) = f(-x)$.

(3) Lefschetz Number and Fixed-Point Indices. Suppose that $|K|$ is an n -dimensional homogeneous polyhedron (i.e., any simplex of K that is not a face of another simplex of K is of dimension n), and $f: |K| \rightarrow |K|$ is a continuous mapping. Then there exists a continuous mapping $g: |K| \rightarrow |K|$ homotopic to f and admitting only isolated fixed points $\{q_1, \dots, q_r\}$, each of which is an inner point of an n -dimensional simplex of K . The \dagger local degree λ_i of a mapping g at q_i is called the **fixed-point index** of g at q_i . Then $J_f = \sum_{i=1}^r \lambda_i$ does not depend on the choice of g and is equal to $(-1)^n \Lambda_f$.

(4) Singularities of a Continuous Vector Field.

Let X be an n -dimensional \dagger differentiable manifold and F a \dagger continuous vector field on X that assigns a tangent vector x_p to each point p of X . A point p is called a **singular point** of F if x_p is the zero vector. The vector field F induces in a natural manner a continuous mapping $f: X \rightarrow X$ that is homotopic to the identity mapping 1_X . Then a fixed point of f is a singular point of F , and vice versa. When such a singular point p is isolated, there exists a \dagger coordinate neighborhood N of p that is homeomorphic to an n -dimensional open ball such that x_q is nonzero for every point q in N except for $q = p$. Let N' be the boundary of N . Then we may consider $N' \cong S^{n-1}$ and a mapping $F|N'$ from S^{n-1} to $\mathbb{R}^n \setminus \{0\} \simeq S^{n-1}$. The \dagger degree of a mapping $S^{n-1} \xrightarrow{F|N'} \mathbb{R}^n \setminus \{0\} \xrightarrow{\cong} S^{n-1}$ is called the **index of the singular point** p . This index is equal to the fixed-point index λ_p of f at p . Hence, when X is compact and has no

boundary, the sum of indices of (isolated) singular points of F is equal to $(-1)^n \chi(X)$. In particular, a compact manifold X without boundary admits a continuous vector field with no singular point if and only if $\chi(X) = 0$ (Hopf's theorem, *Math. Ann.*, 96 (1927)).

(5) Poincaré-Birkhoff Fixed-Point Theorem. In certain cases, a continuous mapping $f: X \rightarrow X$ of a finite polyhedron X into itself has fixed points even if $\Lambda_f = 0$. For example, let X be the annular space $\{(r, \theta) | \alpha \leq r \leq \beta\}$ ((r, θ) are the polar coordinates of points in a Euclidean plane) and let $f: X \rightarrow X$ be a homeomorphism satisfying the following conditions: (i) there exist continuous functions $g(\theta)$, $h(\theta)$ such that $g(\theta) < \theta$, $h(\theta) > \theta$, $f(\alpha, \theta) = (\alpha, g(\theta))$, $f(\beta, \theta) = (\beta, h(\theta))$; (ii) there exists a continuous positive function $\rho(r, \theta)$ defined for $\alpha < r < \beta$ such that

$$\iint_D \rho(r, \theta) dr d\theta = \iint_D \rho(f(r, \theta)) dr d\theta$$

for all measurable sets D .

Then f has at least two fixed points. This theorem was conjectured in 1912 by Poincaré, who hoped to apply it to solve the \dagger restricted three-body problem. The theorem was later proved by G. D. Birkhoff (*Trans. Amer. Math. Soc.*, 14 (1913); see also M. Brown and W. D. Neumann, *Michigan Math. J.* 24 (1977)) and is called the **Poincaré-Birkhoff fixed-point theorem** or the **last theorem of Poincaré**.

C. Atiyah-Bott and Atiyah-Singer Fixed-Point Theorems

There is a far-reaching generalization of the Lefschetz formula given by Atiyah and Bott (*Ann. Math.*, (2) 86 (1967), 88 (1968)). Let M be a compact differentiable manifold without boundary and $f: M \rightarrow M$ a differentiable mapping with only simple fixed points; that is, it is assumed that $\det(1 - df_p) \neq 0$ for each fixed point $p \in M$ of f , where df_p is the differential of f at the point p . The fixed points of f are finite in number. Suppose that an \dagger elliptic complex over M

$$\mathcal{E}: 0 \rightarrow \Gamma(E_0) \xrightarrow{d_0} \Gamma(E_1) \xrightarrow{d_1} \dots \xrightarrow{d_{l-1}} \Gamma(E_l) \rightarrow 0$$

and a sequence of smooth vector bundle homomorphisms $\varphi_i: f^*E_i \rightarrow E_i$ ($i = 0, \dots, l$) are given such that $d_i T_i = T_{i+1} d_i$ for each i , where $T_i: \Gamma(E_i) \rightarrow \Gamma(E_i)$ is defined by $T_i s(x) = \varphi_i s(f(x))$ for $s \in \Gamma(E_i)$. The sequence $T = (T_i)$ induces endomorphisms $H^i T$ of the homology groups $H^i(\mathcal{E})$ of the elliptic complex \mathcal{E} . We define the Lefschetz number $L(T)$ by $L(T) = \sum_{i=0}^l (-1)^i \text{tr } H^i T$. On the other hand, for a fixed point p of f , let $\varphi_{i,p}: E_{i,p} \rightarrow E_{i,p}$ denote the restriction of φ_i on the fiber $E_{i,p}$ of E_i over

p . Under the circumstances mentioned above the Lefschetz number $L(T)$ is given by the formula

$$L(T) = \sum_p \sum_{i=0}^l \frac{(-1)^i \text{tr } \varphi_{i,p}}{|\det(1 - df_p)|},$$

where the summation is over the fixed points of f .

Here are some examples of the above formula. First, take as \mathcal{E} the \dagger de Rham complex and as φ_i the obvious one, i.e., the i th exterior power of the transpose of df . In this case, the formula reduces to the classical Lefschetz formula. As a second example consider the \dagger Dolbeault complex

$$0 \rightarrow \Lambda^{0,0}(M) \xrightarrow{\bar{\partial}} \Lambda^{0,1}(M) \xrightarrow{\bar{\partial}} \dots \xrightarrow{\bar{\partial}} \Lambda^{0,n}(M) \rightarrow 0$$

of a compact complex manifold M and a holomorphic mapping $f: M \rightarrow M$ with only simple fixed points. In this case the formula above reduces to one giving the Lefschetz number of the induced endomorphisms $f^*: H^{0,*}(M) \rightarrow H^{0,*}(M)$ of the \dagger Dolbeault cohomology:

$$L(f^*) = \sum_p \frac{1}{\det_C(1 - df_p)},$$

where df_p is regarded as a holomorphic differential.

If the assumption that the mapping f has only simple fixed points is replaced by the one that f is a diffeomorphism of M contained in a compact \dagger transformation group G , then there is also a generalized Lefschetz formula, given by Atiyah and Singer (*Ann. Math.*, (2) 87 (1968)). The fixed-point set of such a diffeomorphism is a closed submanifold of M (consisting of several components). Suppose that we are given an elliptic complex \mathcal{E} over M and a lift of the G -action on M to \mathcal{E} . The latter implies that, if we define $T_i: \Gamma(E_i) \rightarrow \Gamma(E_i)$ by $T_i s(x) = f^{-1} s(f(x))$ for $s \in \Gamma(E_i)$, then $d_i T_i = T_{i+1} d_i$ holds for each i . Under these circumstances, the Lefschetz number $L(T)$ can be expressed in the form

$$L(T) = \sum_{F_i} v(F_i),$$

where the summation is over the components $\{F_i\}$ of the fixed-point set M^f of f and where the number $v(F_i)$ is written explicitly in terms of the \dagger symbol of the elliptic complex \mathcal{E} with G -action, the characteristic classes of the manifold F_i , the characteristic classes of the normal bundle of F_i in M , and the action of $g = f^{-1}$ on the normal vectors. The formula is essentially a reformulation of the \dagger Atiyah-Singer index theorem. In fact, $L(T)$ is the \dagger analytic index of \mathcal{E} evaluated on g and the number $v(F_i)$ is deduced from the \dagger topological index of \mathcal{E} using

the localization theorem. The most useful elliptic complexes are de Rham complexes, Dolbeault complexes, signature operators and Dirac operators. In the case of Dolbeault complexes, f is assumed to be an analytic automorphism, and the number $v(F_i)$ takes the form

$$v(F_i) = \frac{\prod_0 \mathcal{Q}^\theta \mathcal{T}(F_i)}{\det(1 - g|N^*)} [F_i].$$

Here, the normal bundle N of F_i has a decomposition $N = \sum_\theta N(\theta)$ into the sum of complex vector bundles such that g acts on $N(\theta)$ as $e^{i\theta}$, and \mathcal{Q}^θ is the characteristic class defined by

$$\mathcal{Q}^\theta = \prod_j \frac{1 - e^{-i\theta}}{1 - e^{-x_j - i\theta}},$$

where the \dagger Chern class of $N(\theta)$ is written as $c(N(\theta)) = \prod_j (1 + x_j)$; moreover $\mathcal{T}(F_i)$ denotes the \dagger Todd class of the complex manifold F_i , and N^* denotes the dual bundle of N (\rightarrow 237 K-Theory H).

D. Fixed-Point Theorems for Infinite-Dimensional Spaces

Birkhoff and O. D. Kellogg generalized Brouwer's fixed-point theorem to the case of function spaces (*Trans. Amer. Math. Soc.*, 23 (1922)). Their result was utilized to show the existence of solutions of certain differential equations, and has led to a new method in the theory of functional equations.

J. P. Schauder obtained the following theorem: Let A be a closed convex subset of a Banach space, and assume that there exists a continuous mapping T sending A to a \dagger countably compact subset $T(A)$ of A . Then T has fixed points (*Studia Math.*, 2 (1930)). This theorem is called the **Schauder fixed-point theorem**.

A. Tikhonov generalized Brouwer's result and obtained the following **Tikhonov fixed-point theorem** (*Math. Ann.*, 111 (1935)): Let R be a locally convex \dagger topological linear space, A a compact convex subset of R , and T a continuous mapping sending A into itself. Then T has fixed points.

This theorem may be applied to the case where R is the space of continuous mappings sending an m -dimensional Euclidean space E^m into a k -dimensional Euclidean space E^k to show the existence of solutions of certain differential equations. For example, when $m = k = 1$, consider the differential equation

$$dy/dx = f(x, y), \quad y(x_0) = y_0.$$

We set $T(y) = y_0 + \int_{x_0}^x f(t, y(t)) dt$ to determine a continuous mapping $T: R \rightarrow R$. Then the fixed points of T are the solutions of the differential

154 A Foliations

equation. Now we can apply the theorem of Tikhonov to show the existence of solutions.

On the other hand, when we are given problems of functional analysis, Schauder's fixed-point theorem is usually more convenient to apply than Tikhonov's theorem.

The following theorem, written in terms of functional analysis, is useful for applications: Let D be a subset of an n -dimensional Euclidean space, F the family of continuous functions defined on D , and $T: F \rightarrow F$ a mapping. Suppose that the following three conditions are satisfied: (i) For $f_1, f_2 \in F$, $0 < \lambda < 1$ implies $\lambda f_1 + (1 - \lambda)f_2 \in F$. (ii) If a series $\{f_k\}$ of functions in F converges uniformly in the wider sense to a function f , then $f \in F$; and furthermore, the series $\{Tf_k\}$ converges uniformly in the wider sense to Tf . (iii) The family $T(F)$ is a \dagger normal family of functions on D . Then there exists a function $f \in F$ such that $Tf = f$.

Let R be a topological linear space and T a mapping assigning a closed convex subset $T(x)$ of R to each point x of R . A point x of R is called a **fixed point** of T if $x \in T(x)$. The mapping T is called **semicontinuous** if the condition $x_n \rightarrow a$, $y_n \rightarrow b$ ($y_n \in T(x_n)$) implies that $b \in T(a)$. In particular, if K is a bounded closed convex subset of a finite-dimensional Euclidean space R and T a semicontinuous mapping sending points of K into convex subsets of K , then T admits fixed points (**Kakutani fixed-point theorem**, *Duke Math. J.*, 8 (1941)). This result was further generalized to the case of locally convex topological linear spaces by Ky Fan (*Proc. Nat. Acad. Sci. US*, 38 (1952)).

154 (IX.21) Foliations

A. Introduction

A foliation is a kind of geometric structure on manifolds, such as a differentiable or complex structure. The study of foliations evolved from

investigation of the behavior of orbits of a vector field and also of the solutions of total differential equations. Through the early works of C. Ehresmann, G. Reeb, and A. Haefliger, together with the development of manifold theory in 1960s, it became an established field of mathematics. Since then, great progress has been made in this field, especially in its topological aspects. At the same time it turns out that many problems in foliation theory are deeply related not only to the geometry of manifolds but also to various other branches of mathematics, such as the theory of differential equations, functional analysis, and group theory.

B. Definitions and General Remarks

A **foliation** on a manifold can be defined within various categories: topological, C^r -differentiable ($1 \leq r \leq \infty$), real analytic, and holomorphic. For definiteness, however, we restrict ourselves to the C^r -differentiable category in what follows. Furthermore, all manifolds are assumed to be paracompact.

Let M be an n -dimensional C^∞ -manifold, possibly with boundary. A **codimension** q , C^r -**foliation** of M ($0 \leq q \leq n, 0 \leq r \leq \infty$) is a family $\mathcal{F} = \{L_\alpha \mid \alpha \in A\}$ of arcwise connected subsets, called **leaves**, of M with the following properties: (i) $L_\alpha \cap L_{\alpha'} = \emptyset$ if $\alpha \neq \alpha'$; (ii) $\bigcup_{\alpha \in A} L_\alpha = M$; (iii) Every point in M has a local coordinate system (U, ψ) of class C^r such that for each leaf L_α the arcwise connected components of $U \cap L_\alpha$ are described by $x^{n-q+1} = \text{constant}, \dots, x^n = \text{constant}$, where x^1, x^2, \dots, x^n denote the local coordinates in the system (U, ψ) . In particular, every leaf of \mathcal{F} is an $(n-q)$ -dimensional submanifold of M . The totality of integral submanifolds of a completely integrable nonsingular system of Pfaffian equations on \mathbf{R}^n , $\omega_i = a_{i1}(x)dx_1 + a_{i2}(x)dx_2 + \dots + a_{in}(x)dx_n = 0$ ($i = 1, 2, \dots, q$) forms a codimension q foliation, and the totality of integral curves of a nonsingular vector field of class C^r on M ($r \geq 1$) constitutes a codimension $n-1$ C^r -foliation.

Let \mathcal{F} be a codimension q , C^r -foliation of M ($r \geq 1$). Then M admits a C^{r-1} p -plane field consisting of all vectors tangent to the leaves of \mathcal{F} , and, dually, a C^{r-1} q -plane field ($p+q=n$). Denote the former by $\tau(\mathcal{F})$ and the latter by $\nu(\mathcal{F})$, and call them the **tangent bundle** and the **normal bundle** of \mathcal{F} , respectively. $\nu(\mathcal{F})$ is isomorphic to the quotient bundle $T(M)/\tau(\mathcal{F})$. \mathcal{F} is called **transversely orientable** if $\nu(\mathcal{F})$ is an orientable vector bundle. A C^r -mapping $f: N \rightarrow M$ is said to be **transverse to the foliation** \mathcal{F} if the composite mapping $T(N) \xrightarrow{df} T(M) \rightarrow T(M)/\tau(\mathcal{F})$ is epimorphic at each point of N .

In this case, f induces a codimension q , C^r -foliation $f^{-1}(\mathcal{F})$ of N whose leaves are the arcwise connected components of $f^{-1}(L)$ ($L \in \mathcal{F}$).

In particular, if Q is a q -dimensional C^r -manifold and $f: N \rightarrow Q$ is a C^r -submersion, f induces a codimension q , C^r -foliation of N whose leaves are the arcwise connected components of $f^{-1}(x)$ ($x \in Q$).

A C^r p -plane field \mathcal{X} on M is called **involutive** if, for any C^r vector fields X, Y on M such that $X_x, Y_x \in \mathcal{X}_x$ ($x \in M$), the Lie bracket $[X, Y]$ satisfies $[X, Y]_x \in \mathcal{X}_x$. This condition is known as the **Frobenius integrability condition** for \mathcal{X} . If \mathcal{X} is defined locally by q Pfaffian equations $\omega_1 = \dots = \omega_q = 0$, the above condition is equivalent to the condition that there are C^{r-1} 1-forms θ_{ij} ($i, j = 1, \dots, q$) such that $d\omega_i = \sum_{j=1}^q \theta_{ij} \wedge \omega_j$. A C^r p -plane field \mathcal{X} is said to be **completely integrable** if it is a tangent bundle of some foliation. When $r \geq 2$, \mathcal{X} is completely integrable if and only if it is involutive (**Frobenius theorem**) (\rightarrow 428 Total Differential Equations). There is a topological obstruction to the complete integrability of \mathcal{X} (\rightarrow Section F).

A closed C^∞ -manifold M admits a codimension 1, C^r -plane field if and only if the Euler number of M vanishes. In 1944, Reeb constructed a codimension 1, C^∞ -foliation of the 3-sphere S^3 as follows [1]. Let $f(x)$ be a C^∞ -even function defined on the open interval $(-1, 1)$, such that

$$\lim_{|x| \rightarrow 1} \frac{d^{(k)}}{dx^{(k)}} \frac{1}{f'(x)} = 0 \quad (k = 0, 1, 2, \dots).$$

The graphs of the equations $y = f(x) + c$ ($-1 < x < 1, c \in \mathbf{R}$) together with the lines $x = \pm 1$ constitute a codimension 1, C^∞ -foliation of $[-1, 1] \times \mathbf{R}$. Then by rotating it around the y -axis in \mathbf{R}^3 , we obtain a codimension 1, C^∞ -foliation of $D^2 \times \mathbf{R}$, where D^2 denotes the closed 2-disk. The foliation is invariant under vertical translations and therefore defines a codimension 1, C^∞ -foliation of $D^2 \times S^1$. This foliation is called the **Reeb component** of $D^2 \times S^1$. Since S^3 is a union of two solid tori intersecting in the common toroidal surface, the Reeb components of each solid torus constructed above define the so-called **Reeb foliation** of S^3 (Fig. 1).

Fig. 1

Generalizing the above construction into a differential topological method, one obtains the following results: Every closed 3-dimensional manifold admits a codimension 1, C^∞ -foliation (S. P. Novikov [3], W. Lickorish, J. Wood); every odd-dimensional sphere admits a codimension 1, C^∞ -foliation (I. Tamura, A. Durfee, B. Lawson). On the other hand, every open manifold has a codimension 1, C^∞ -foliation induced by a submersion over \mathbf{R} (\rightarrow Section F).

Let M be a total space of a C^r -bundle over a C^∞ -manifold B with fiber F . If F is a C^∞ -manifold and the \dagger structure group reduces to a totally disconnected subgroup of $\text{Diff}^r F$, the group of all C^r -diffeomorphisms of F , then the local sections, which are defined in an obvious manner using the local triviality of this bundle, fit together to give leaves of a codimension q , C^r -foliation ($q = \dim F$). In this case, M is called a **foliated bundle** or a **flat F -bundle** over B . Each leaf of this foliation is diffeomorphic to a covering manifold of B and transverse to the fibers of the bundle $M \rightarrow B$. Foliated bundles exhibit a class of foliations; this is especially important in connection with the characteristic classes of foliations (\rightarrow Section G).

C. Holonomy

The notion of the holonomy of a leaf, given by Ehresmann, is a generalization of the \dagger Poincaré mapping in \dagger dynamical systems. Let \mathcal{F} be a codimension q , C^r -foliation of M and L be a leaf of \mathcal{F} . Let $N(L)$ denote the total space of the normal disk bundle of L in M . Choose a C^r -immersion $i: N(L) \rightarrow M$ such that i restricted to the zero section of $N(L)$ is the natural inclusion and i maps the fibers of $N(L)$ transversely to the foliation \mathcal{F} . Then the induced foliation $i^{-1}(\mathcal{F})$ of $N(L)$ has the properties that the leaves are transverse to the fibers of $N(L)$ and the zero section of $N(L)$ is a leaf. If γ is an oriented loop in L based at a point $x_0 \in L$, then there is a neighborhood U of 0 in the fiber over x_0 satisfying the following: for each point $x \in U$ there is a curve $\gamma_x: [0, 1] \rightarrow N(L)$ having the properties: (i) $\gamma_x(0) = x$, (ii) $\text{Im}(\gamma_x)$ lies on a leaf of $i^{-1}(\mathcal{F})$, and (iii) $\pi \circ \gamma_x(t) = \gamma(t)$ for any $t \in [0, 1]$, where $\pi: N(L) \rightarrow L$ is the bundle projection. The family of curves $\{\gamma_x | x \in U\}$ gives a C^r -diffeomorphism H_γ from U to another open set of $\pi^{-1}(x_0)$, which assigns $\gamma_x(1)$ to x . Let G_q^r denote the group of \dagger germs at 0 of all local C^r -diffeomorphisms of \mathbf{R}^q which fix 0. The germ at 0 of the mapping H_γ depends only on the \dagger homotopy class of γ , and, by identifying $\pi^{-1}(x_0)$ with \mathbf{R}^q , we obtain a homomorphism $h_L: \pi_1(L, x_0) \rightarrow G_q^r$. h_L is determined by L up to conjugacy and is called the **holonomy homo-**

morphism, or simply the **holonomy**, of the leaf L . The image of h_L is called the **holonomy group** of L . For $r \geq 1$, by differentiating each element of G_q^r , one has a homomorphism $dh_L: \pi_1(L, x_0) \rightarrow GL(q; \mathbf{R})$, called the **linear holonomy** of L . The holonomy of a proper leaf (\rightarrow Section D) completely characterizes the foliation of a neighborhood of it (Haefliger).

D. Topology of Leaves

Let \mathcal{F} be a codimension q foliation of M . The **leaf topology** is a topology of M defined by requiring each connected component of the set of the form $U \cap L$ to be open, where U is an open set in M and $L \in \mathcal{F}$. Leaves are nothing but the connected components of M with respect to this topology. A leaf $L \in \mathcal{F}$ is called a **compact leaf** if L is compact in the leaf topology. In general, L is called **proper** if two topologies on L induced from the original and the leaf topologies on M coincide. Any compact leaf is proper. A leaf L is called **locally dense** if $\text{Int } \bar{L} \neq \emptyset$. If a leaf is neither proper nor locally dense, it is called **exceptional**. Since we are assuming that M is paracompact, a leaf that is a closed subset of M is proper (Haefliger). There exists a codimension 1, C^1 -foliation of the 2-torus T^2 that contains exceptional leaves. But in the C^r category ($r \geq 2$), such a foliation does not exist on T^2 (A. Denjoy, C. Siegel). In higher dimensions, there are examples of C^∞ -foliations with exceptional leaves (R. Sacksteder). The following result is called the **Novikov closed leaf theorem** [3]: Any codimension 1, C^r -foliation ($r \geq 2$) of a closed 3-dimensional manifold M contains a Reeb component if either $\pi_1(M)$ is finite or $\pi_2(M) \neq 0$ ($M \neq S^1 \times S^2, S^1 \times RP^2$). In particular, every C^2 -foliation of S^3 contains a compact leaf homeomorphic to T^2 . The question of whether every codimension 2, C^r -foliation of S^3 has a compact leaf is known as the **Seifert conjecture**. There is a counterexample in the C^1 case (P. Schweitzer [7]), but it remains unsolved for $r \geq 2$ (\rightarrow 126 Dynamical Systems N).

A compact leaf L is said to be **stable** if it has an arbitrarily small open neighborhood that is a union of compact leaves. The following results are called the **Reeb stability theorems**: (1) Let L be a compact leaf of a C^r -foliation ($r \geq 0$). If the holonomy group of L is finite, then it is stable (Reeb [1]). (2) Let \mathcal{F} be a transversely orientable codimension 1, C^r -foliation ($r \geq 1$) of a compact manifold M (tangent to the boundary). If there exists a compact leaf L with $H^1(L; \mathbf{R}) = 0$, then M is a fiber bundle over S^1 or $[0, 1]$, and the leaves of \mathcal{F} are the fibers of this bundle. In particular,

every leaf is compact and stable (Reeb [1], Thurston [8]).

The generalization of the stability theorem for proper leaves has been investigated by T. Inaba and P. Dippolito.

E. Haefliger Structures

Let \mathcal{G}_q be the \dagger pseudogroup consisting of all C^r -diffeomorphisms g of an open subset of \mathbf{R}^q to another open subset of \mathbf{R}^q . We write Γ_q^r for the set of all germs $[g]_x$ of g at x , $x \in \text{domain of } g$, $g \in \mathcal{G}_q$. The sheaf topology of Γ_q^r is the topology whose open base is the family of subsets of the form $\bigcup_{x \in \text{domain of } g} \{[g]_x\}$. With this topology and the multiplication induced from the composition of \mathcal{G}_q , Γ_q^r is a **topological groupoid**, i.e., a \dagger groupoid whose multiplication and inverse mappings are continuous. If one identifies a point x in \mathbf{R}^q with $[\text{id}_{\mathbf{R}^q}]_x$, Γ_q^r contains \mathbf{R}^q as a subspace.

A codimension q , C^r -**Haefliger structure** or a Γ_q^r -**structure** \mathcal{H} on a topological space X is a maximal covering of X by open sets $\{U_i | i \in J\}$, such that for each pair $i, j \in J$, there is a continuous mapping $\gamma_{ij}: U_i \cap U_j \rightarrow \Gamma_q^r$ satisfying

$$\gamma_{ik}(x) = \gamma_{ij}(x) \circ \gamma_{jk}(x) \text{ for } x \in U_i \cap U_j \cap U_k. \quad (*)$$

Since $\gamma_{ii}(x)$ is the germ of the identity mapping for $x \in U_i$, the correspondence $x \rightarrow \gamma_{ii}(x)$ defines a continuous mapping $f_i: U_i \rightarrow \mathbf{R}^q \subset \Gamma_q^r$. A codimension q , C^r -foliation of a C^∞ -manifold M is the same as a Γ_q^r -structure on M such that each f_i is a C^r -submersion (Haefliger [5]).

If $f: Y \rightarrow X$ is continuous and \mathcal{H} is a Γ_q^r -structure on X , there is an induced Γ_q^r -structure $f^{-1}\mathcal{H}$ on Y which is defined by $\{f^{-1}(U_i), \gamma_{ij} \circ f | i, j \in J\}$. Two Γ_q^r -structures \mathcal{H}_0 and \mathcal{H}_1 on X are said to be **homotopic** if there exists a Γ_q^r -structure \mathcal{H} on $X \times [0, 1]$ such that $\mathcal{H}|_{X \times \{t\}} = \mathcal{H}_t$ ($t = 0, 1$).

Let $\Gamma_q^r(X)$ be the set of homotopy classes of Γ_q^r -structures on X . There exists a space $B\Gamma_q^r$, called the **classifying space for Γ_q^r -structures**, such that there is a natural one-to-one correspondence between $\Gamma_q^r(X)$ and $[X, B\Gamma_q^r]$ for any paracompact space X , where $[A, B]$ denotes the set of homotopy classes of continuous mappings from A to B . By condition (*) above, if $r > 0$, the differentials $\{d\gamma_{ij}(x) | x \in U_i \cap U_j, i, j \in J\}$ define a q -dimensional vector bundle $\nu(\mathcal{H})$ over X , which is called the **normal bundle** of \mathcal{H} . The correspondence $\mathcal{H} \rightarrow \nu(\mathcal{H})$ gives a continuous mapping $\nu: B\Gamma_q^r \rightarrow BGL(q, \mathbf{R})$ among classifying spaces. If $r = 0$, there is also a similar mapping $\nu: B\Gamma_q^0 \rightarrow B\text{Top}_q$. Let $B\Gamma_q^0$ be the homotopy fiber of the mapping ν . $B\Gamma_q^0$ is a classifying space for the Γ_q^0 -structures with trivialized normal bundles.

There is a tight connection between the

topology of $B\Gamma_q^r$ and the group structure of $\text{Diff}^r(\mathbf{R}^q)$, which is stated below. Let $\text{Diff}_K^r(\mathbf{R}^q)$ be the topological group of all C^r -diffeomorphisms of \mathbf{R}^q that are identities outside some compact sets with the C^r topology. Let $\text{Diff}_{K,\delta}^r(\mathbf{R}^q)$ denote $\text{Diff}_K^r(\mathbf{R}^q)$ with the discrete topology and $B\overline{\text{Diff}}_K^r(\mathbf{R}^q)$ denote the homotopy fiber of the natural mapping $B\text{Diff}_{K,\delta}^r(\mathbf{R}^q) \rightarrow B\text{Diff}_K^r(\mathbf{R}^q)$. Then there exists a continuous mapping $B\overline{\text{Diff}}_K^r(\mathbf{R}^q) \rightarrow \Omega^q B\Gamma_q^r$ that induces an isomorphism in the homology group with integer coefficient for $0 \leq r \leq \infty$ and $q \geq 1$, where Ω^q denotes the q th \dagger loop space functor (J. N. Mather [12], Thurston [10]). Further, it has been proved that $\text{Diff}_{K,\delta}^r(\mathbf{R}^q)$ is a \dagger simple group (if $r \neq q + 1$) and that $B\Gamma_q^r$ is $\dagger(q + 1)$ -connected for $r \neq q + 1$ (Mather and Thurston, Haefliger [5]). The group $\text{Homeo}_{K,\delta}\mathbf{R}^q$ is \dagger acyclic (Mather), and hence $B\Gamma_q^0$ is \dagger contractible.

F. Existence and Classification of Foliations

Not every plane field on a manifold is isomorphic to a completely integrable field (R. Bott). Thus, in general, the existence of a foliation of a manifold. Haefliger and Thurston solved the existence and classification problems in foliation in terms of Haefliger structures as follows. Two codimension q foliations \mathcal{F}_0 and \mathcal{F}_1 of a C^∞ -manifold M are said to be **concordant** if there is a codimension q foliation \mathcal{F} on $M \times [0, 1]$, that is transverse to $M \times \{t\}$ ($t = 0, 1$) and induces there the given foliation \mathcal{F}_t ($t = 0, 1$). They are said to be **integrably homotopic** if one further requires that the foliation \mathcal{F} be transverse to $M \times \{t\}$ for all $t \in [0, 1]$ in the definition above. Similarly, two subbundles ξ_0, ξ_1 of $T(M)$ are said to be **concordant** if there is a subbundle ξ of $T(M \times [0, 1])$ such that $\xi|_{M \times \{t\}} = \xi_t$ for $t = 0, 1$, and they are said to be **homotopic** if one further assumes that $\xi|_{M \times \{t\}}$ is a subbundle of $T(M \times \{t\})$ for all $t \in [0, 1]$. The following theorem is of fundamental importance.

Theorem: Let M be an open (resp. closed) C^∞ -manifold. Then for each $r = 0, 1, \dots, \infty$, the integrable homotopy classes (resp. concordance classes) of codimension q , C^r -foliations of M are in a natural one-to-one correspondence with homotopy classes of Γ_q^r -structures \mathcal{H} on M together with homotopy classes (resp. concordance classes) of subbundles of $T(M)$ isomorphic to $\nu(\mathcal{H})$. (M. L. Gromov, A. Phillips, Haefliger [5], Thurston [9]).

The following are consequences of the theorem: (i) A closed manifold M admits a codimension 1, C^∞ -foliation if and only if the Euler number of M vanishes. (ii) If a manifold

admits a ${}^{\dagger}q$ -frame field, then the associated q -plane field is homotopic to the normal bundle of a codimension q foliation of M . (iii) Every dimension q plane field on a C^{∞} -manifold is homotopic to the normal bundle of a C^0 -foliation with C^{∞} leaves.

G. Characteristic Classes of Foliations

Let $B\Gamma_q^r$ be the classifying space of Γ_q^r -structures. An element of the cohomology group $H^*(B\Gamma_q^r; \mathbf{R})$ is called a (real) **characteristic class of codimension q , C^r -foliations**. If \mathcal{F} is a codimension q , C^r -foliation of M and $f: M \rightarrow B\Gamma_q^r$ is the classifying mapping for \mathcal{F} , then an element $\alpha(\mathcal{F}) = f^* \alpha \in H^*(M; \mathbf{R})$, $\alpha \in H^*(B\Gamma_q^r; \mathbf{R})$, is called the characteristic class of \mathcal{F} corresponding to α . The first nontrivial characteristic classes of foliations are known as the **Godbillon-Vey classes** (C. Godbillon and J. Vey [13]) and can be defined as follows. Let \mathcal{F} be a transversely oriented, codimension q , C^{∞} -foliation of M . Then there exists a ${}^{\dagger}q$ -form Ω on M such that on a neighborhood U of each point of M , Ω is written as $\omega_1^U \wedge \dots \wedge \omega_q^U$, where $\omega_1^U, \dots, \omega_q^U$ are linearly independent 1-forms that vanish on leaves of \mathcal{F} . By the integrability condition, there is a 1-form η such that $d\Omega = \eta \wedge \Omega$. Then the Godbillon-Vey class $\Gamma_{\mathcal{F}}$ of \mathcal{F} is the de Rham cohomology class in $H^{2q+1}(M; \mathbf{R})$ represented by the closed $2q+1$ form $\eta \wedge (d\eta)^q$.

The following construction provides a wide class of characteristic classes of foliations (Bott and Haefliger [14], I. Bernstein and B. Rosenfeld [15]). Let J_k be the set of ${}^{\dagger}k$ -jets at 0 of local C^{∞} -diffeomorphisms of \mathbf{R}^q keeping 0 fixed. The set $\{J_k\}_{k=0}^{\infty}$ forms an † inverse system of † Lie groups with respect to the natural homomorphism $p_k: J_{k+1} \rightarrow J_k$, and each J_k ($k \geq 1$) contains $O(q)$ as a † maximal compact subgroup. Let P_k be the differentiable fiber bundle of k -jets at 0 of local diffeomorphisms of \mathbf{R}^q whose domains contain 0. It is a † principal J_k -bundle over \mathbf{R}^q . Denote by $A(P_{\infty})$ the † direct limit of the de Rham complexes of $\{P_k\}_{k=0}^{\infty}$, and let A be the subcomplex of $A(P_{\infty})$ consisting of invariant forms with respect to the natural action of \mathcal{G}_q^{∞} . A is canonically isomorphic to the † cochain complex $A(A_q)$ of continuous alternating forms on A_q , where A_q is the topological Lie algebra of † formal vector fields on \mathbf{R}^q (\rightarrow 105 Differentiable Manifolds AA).

Now let \mathcal{F} be a codimension q , C^{∞} -foliation of M . Let $P_k(\mathcal{F})$ denote the differentiable fiber bundle over M whose fiber over $x \in M$ is the space of k -jets at x of the C^{∞} -submersion $f: U \rightarrow \mathbf{R}^q$ from an open neighborhood U of x to \mathbf{R}^q , satisfying (i) $f(x) = 0$, (ii)

$\text{Ker } df = \tau(\mathcal{F})|_U$. This is a principal J_k -bundle over M , and its restriction to U is isomorphic to the pullback by f of the bundle P_k . Hence there are homomorphisms from the set of invariant forms on P_k to $A(P_k(\mathcal{F}))$ that induce a homomorphism $A \cong A(A_q) \rightarrow \varinjlim A(P_k(\mathcal{F}))$. This homomorphism is compatible with the action of $O(q)$ and hence induces a homomorphism of $O(q)$ -basic subcomplexes. Thus one obtains a homomorphism $\varphi_{\mathcal{F}}: H^*(A_q; O(q)) \rightarrow \varinjlim H^*(A(P_k(\mathcal{F})); O(q)) \cong H^*(M; \mathbf{R})$. In fact, $\varphi_{\mathcal{F}}$ depends only on the 2-jet of the foliation \mathcal{F} , and one can think of it as a homomorphism $\varphi: H^*(A_q; O(q)) \rightarrow H^*(B\Gamma_q^r; \mathbf{R})$ ($r \geq 2$). The elements in $\text{Im } \varphi$ are called the **smooth characteristic classes of foliations**.

Let WO_q be the differential graded algebra:

$$WO_q = E(u_1, u_3, \dots, u_{2[(q+1)/2]-1}) \otimes \hat{\mathbf{R}}[c_1, \dots, c_q],$$

where $du_i = c_i$, $dc_i = 0$, $\deg(u_i) = 2i - 1$, $\deg(c_i) = 2i$, and E denotes the exterior algebra over \mathbf{R} generated by the u_i 's, and $\hat{\mathbf{R}}$ denotes the † polynomial algebra of the c_i 's truncated by the † ideal generated by elements of degree $> 2q$. There exists a homomorphism of differential graded algebras $WO_q \rightarrow A(A_q; O(q))$ which induces an isomorphism in cohomology (I. M. Gel'fand and D. B. Fuks). For a codimension q foliation \mathcal{F} of M , the cohomology class determined by c_{2i} corresponds to the i th Pontryagin class of the normal bundle $\nu(\mathcal{F})$ of \mathcal{F} , and the cohomology class $u_1 c_q^q$ corresponds to the Godbillon-Vey class of \mathcal{F} . In particular, the subring of the cohomology ring $H^*(M; \mathbf{R})$ generated by the † Pontryagin classes of $\nu(\mathcal{F})$ is trivial for degree $> 2q$ (Bott's vanishing theorem).

Let N^{q+1} be a closed $(q+1)$ -dimensional Riemannian manifold of † constant negative curvature. The total space $T_1 N$ of the unit tangent sphere bundle of N admits a codimension q , C^{∞} -foliation associated with the † geodesic flow of $T_1 N$ († Anosov foliation). It has been shown that the Godbillon-Vey class of this foliation is nontrivial (R. Roussarie, F. Kamber and P. Tondeur, K. Yamato). It is known that many of the smooth characteristic classes are also nontrivial (Bott and Haefliger, Thurston, J. Heitsch).

A smooth characteristic class $\alpha \in H^*(B\Gamma_q^r; \mathbf{R})$ is called **rigid** if for any smooth one-parameter family $\{\mathcal{F}_t\}$ of codimension q foliations on a C^{∞} -manifold M , $d(\alpha(\mathcal{F}_t))/dt = 0$ holds. The elements in the image of the natural homomorphism

$$H^*(WO_{q+1}) \rightarrow H^*(WO_q) \rightarrow H^*(B\Gamma_q^r; \mathbf{R})$$

are rigid (Heitsch). On the other hand, the Godbillon-Vey class is not rigid. In fact, Thurston constructed a one-parameter family of codimension q foliations of a certain

$(2q+1)$ -dimensional manifold for which the Godbillon-Vey class varies continuously. The characteristic classes of a simple foliation are often trivial. For example, the Godbillon-Vey class of a codimension 1 foliation of a closed manifold vanishes if it is almost without holonomy (i.e., no noncompact leaves have non-trivial holonomy) (M. Herman [16]; T. Mizutani, S. Morita, and T. Tsuboi [17]).

H. Further Topics

(1) **Transverse structures.** Let B be a q -dimensional manifold and \mathcal{S} a geometric structure on it, and let $\mathcal{G}_{\mathcal{S}}$ denote the \dagger pseudo-group generated by the local diffeomorphisms that preserve the structure \mathcal{S} . Replacing \mathcal{G}_q by $\mathcal{G}_{\mathcal{S}}$ in the definition of a C^r -Haefliger structure, one obtains definitions of a $\Gamma_{\mathcal{S}}$ -structure and a $\Gamma_{\mathcal{S}}$ -foliation. A $\Gamma_{\mathcal{S}}$ -foliation is called a **Riemannian foliation**, a transversely **real analytic foliation**, or a transversely **holomorphic foliation** if \mathcal{S} is a Riemannian, real analytic, or complex structure on \mathbf{R}^q ($\mathbf{C}^{q/2}$), respectively. The theories for many such foliations are analogous to those for C^r -foliations. For example, many results are known about the characteristic classes of Riemannian or holomorphic foliations. Haefliger showed that there is no codimension 1 real analytic foliation on a simply connected closed manifold and that the classifying space $B\bar{\Gamma}_1^w$ for codimension 1 transversely oriented transversely real analytic foliations has the homotopy type of a $\dagger K(\pi, 1)$ -space for some uncountable \dagger perfect group π [5].

(2) **Foliated cobordism.** Two closed oriented n -dimensional C^∞ -manifolds M_0 and M_1 with codimension q , C^r -foliations are said to be **foliated cobordant** if there exist a compact oriented $(n+1)$ -dimensional C^∞ -manifold W with boundary $\partial W = M_1 \cup (-M_0)$ and a codimension q , C^r -foliation of W which is transverse to ∂W and induces the given foliations of M_0 and M_1 . The resulting foliated cobordism classes $\{\mathcal{F}\}$ form a group $\mathcal{F}\Omega_{n,q}^r$ with respect to the disjoint union. It is known that $\mathcal{F}\Omega_{2,1}^\infty = \{0\}$ and that the Reeb foliation of S^3 is cobordant to zero. The characteristic classes of foliations provide invariants of foliated cobordisms. In particular the Godbillon-Vey number $\Gamma_{\mathcal{F}}[M]$ is an invariant of $\mathcal{F}\Omega_{2q+1,q}^r$ ($r \geq 2, q \geq 1$), and a result of Thurston mentioned in Section G implies that the homomorphism $\mathcal{F}\Omega_{2q+1,q}^r \rightarrow \mathbf{R}$ defined by $\{\mathcal{F}\} \mapsto \Gamma_{\mathcal{F}}[M]$ is surjective.

(3) **Growth of leaves, transverse invariant measure.** Let \mathcal{F} be a C^∞ -foliation of a compact manifold. Fix a \dagger Riemannian metric on M . Then each leaf L of \mathcal{F} has the induced metric, and one has a function $f_L(r) =$

$\text{vol}(D(x, r))$, where $D(x, r)$ is the set of points $y \in L$ whose distance along L from a fixed point $x \in L$ is not greater than r . The growth type of the function f_L is determined only by L . Many papers have been published that deal with the relation between the behavior of leaves and their growth types in codimension 1 foliations (J. Cantwell and L. Conlon, G. Hector, T. Nishimori, N. Tsuchiya). On the other hand, as a generalization of the notion of asymptotic cycles in dynamical systems, the notion of **foliation cycles**, or equivalently a **transverse invariant measure**, has been defined (J. Plante [18], D. Ruelle, D. Sullivan [19]). The existence of a transverse invariant measure for a foliation is closely connected to the growth types of the leaves. The example of Denjoy in Section D leads to the study of \dagger minimal sets of foliations and the structures of foliations (Hector, Cantwell and Conlon). The structure of a codimension 1 foliations which are almost without holonomy has been fairly well investigated (Sacksteder, Hector, H. Imanishi, R. Moussou, Roussaire).

(4) **Compact foliation.** A foliation whose leaves are all compact is called a **compact foliation**. D. Epstein proved that if \mathcal{F} is a codimension 2, C^2 -compact foliation of a closed 3-manifold, then the leaves of \mathcal{F} are the fibers of a \dagger Seifert fibration of M . In higher dimensions, the situation is more complicated (Sullivan, R. Edwards and K. Millett).

(5) **Foliated bundles.** There are many results on foliated bundles. In particular J. W. Milnor [20] and J. Wood obtained a condition for a circle bundle ξ over a closed surface Σ to have a foliation transverse to fibers. More precisely, if ξ and Σ are orientable, then ξ admits such a foliation if and only if $|X(\xi)| \leq -\min\{0, \chi(\Sigma)\}$, where X denotes the Euler number and χ the Euler-Poincaré characteristic. Kamber and Tondeur made an extensive study of characteristic classes of foliated bundles [21].

(6) **Transverse foliations.** Two foliations \mathcal{F} and \mathcal{G} of M are said to be **transverse** to each other if any two leaves K and L of \mathcal{F} and \mathcal{G} are transverse to each other. A foliated bundle has such foliations. D. Hardorp proved that on every orientable closed 3-manifold, there exists a triple of codimension 1 foliations that are pairwise transverse. Tamura and A. Sato classified the codimension 1 foliations that are transverse to the Reeb component of $D^2 \times S^1$.

155 (VI.2) Foundations of Geometry

A. Introduction

Geometry deals with figures. It depends, therefore, on our spatial intuition, but our intuition lacks objectivity. The Greeks originated the idea of developing geometry logically, based on explicitly formulated axioms, without resorting to intuition. From this intention resulted Euclid's *Elements*, which was long considered the perfect model of a logical system. As time passed, however, mathematicians came to notice its imperfections. Since the 19th century especially, with the awakening of a more rigorous critical spirit in science and philosophy, more systematic criticism of the *Elements* began to appear. Non-Euclidean geometry was formulated after reexamination of Euclid's axiom of parallels; but it was also discovered that even as a foundation of Euclidean geometry, Euclid's system of axioms was far from perfect. Various systems of axioms for Euclidean geometry were proposed by mathematicians in the latter half of the 19th century, among them one by D. Hilbert [1], which became the basis of far-reaching studies.

B. Hilbert's System of Axioms

Hilbert took as undefined elements **points** (denoted by A, B, C, \dots), **straight lines** (or simply **lines**, denoted by a, b, c, \dots), and **planes** (denoted by $\alpha, \beta, \gamma, \dots$). Between these objects there exist incidence relations (expressed in phrases such as " A lies on a ," " a passes through A ," etc.); order relations (" B is between A and C "); congruence relations; and parallel relations. The relations are subject to the following five groups of axioms:

- (I) **Incidence axioms:** (1) For two points A, B , there exists a line a through A and B . (2) If $A \neq B$, the line a through A, B is uniquely determined. We write $a = A \cup B$ and call a the **join** of A, B . (3) Every line contains at least two different points. There exist at least three points that do not lie on a line. (4) If A, B, C are points not on a line, there exists a plane α through A, B, C . (We also say that A, B, C lie on α .) For every plane α , there exists at least one point A on α . (5) If A, B, C are points

not on a line, the plane α through A, B, C is uniquely determined. We write $\alpha = A \cup B \cup C$ and call α the **join** of A, B, C . (6) If A, B are two different points on a line a and if A, B lie on a plane α , then every point on a lies on α . (We say that a lies on α or α passes through a .) (7) If a point A lies on two planes α, β , there exists at least one other point B on α and β . (8) There exist at least four points not lying on a plane.

(II) **Ordering axioms:** (1) If B is between A and C , then A, B, C are three different points lying on a line; also, B is between C and A . (2) If A, C are two different points, then there exists a point B such that C is between A and B . (3) If B is between A and C , then A is not between B and C .

We define a **segment** as a set of two different points A, B , denoted as AB or BA , and we call A and B **ends** of this segment. The set of points between A, B is called the **interior** of AB , and the set of points of $A \cup B$ that are neither ends nor interior points of AB is called the **exterior** of AB .

(4) Let A, B, C be three points not lying on a line. If a line a on the plane $A \cup B \cup C$ does not pass through A, B , or C , but passes through a point of the interior of AB , then it also passes through a point of the interior of BC or CA (**Pasch's axiom**).

The following propositions are proved from the above axioms. Given n points A_1, A_2, \dots, A_n on a line ($n > 2$), we can rearrange them, if necessary, so that the point A_j is between A_i and A_k whenever we have $1 \leq i < j < k \leq n$. There are exactly two ways of arranging the points in this manner (**theorem of linear ordering**). Let O be a point on a line a , and let A, B be two points on the line different from O . Write $A \sim B$ when $A = B$ or O is not between A and B ; write $A \not\sim B$ otherwise. Then \sim is an equivalence relation between points on the line different from O ; from $A \sim B, A \sim C$ it follows that $B \sim C$. We say that A, B are on the same **side** or on different sides of O on a depending on whether $A \sim B$ or $A \not\sim B$. Two subsets a' and a'' of a defined by $a' = \{A' | A \sim A'\}, a'' = \{A'' | A \not\sim A''\}$ are called **half-lines** or **rays** on a with O as the extremity (or starting from O). Denoting by a , for simplicity, the set of points on a , we have $a = a' \cup \{O\} \cup a''$ (disjoint union).

Using axiom II.4, we can also prove the following: Let a be a line on α , and let A, B be two points on α not lying on a . If $A = B$ or if the interior of the segment AB has no point in common with a , we say that A, B are on the same **side** of a on α , and write $A \sim B$. Otherwise, we say that A, B are on different sides of a on α and write $A \not\sim B$. Then \sim is an equivalence relation between points on α not lying on a , and from $A \sim B, A \sim C$ follows $B \sim C$. The

subsets $\alpha' = \{A' | A \sim A'\}, \alpha'' = \{A'' | A \not\sim A''\}$ of α are called **half-planes** on α **bounded** by a . Again, denoting by α and a the set of points on α and the set on a , respectively, we obtain $\alpha = \alpha' \cup a \cup \alpha''$ (disjoint union).

(III) **Congruence axioms:** Two segments $AB, A'B'$ can be in a relation of **congruence**, expressed symbolically as $AB \equiv A'B'$. (Segments AB and $A'B'$ are then said to be **congruent**. Since the segment AB is defined as the set $\{A, B\}$, the four relations $AB \equiv A'B', BA \equiv A'B', AB \equiv B'A', BA \equiv B'A'$ are equivalent.) This relation is subject to the following three axioms: (1) Let A, B be two different points on a line a , and A_1 a point on a line a_1 (a_1 may or may not be equal to a). Let a'_1 be a ray on a_1 starting from A_1 . Then there exists a unique point B_1 on a'_1 such that $AB \equiv A_1B_1$. (2) From $A_1B_1 \equiv AB$ and $A_2B_2 \equiv AB$ follows $A_1B_1 \equiv A_2B_2$. (Hence it follows that \equiv is an equivalence relation between segments.) (3) Let A, B, C be three points such that B is between A and C , and let A_1, B_1, C_1 be three points such that B_1 is between A_1 and C_1 . Then from $AB \equiv A_1B_1, BC \equiv B_1C_1$ follows $AC \equiv A_1C_1$.

Now let h, k be two different lines in a plane α and through a point O , and let h', k' be the rays on h, k starting from O . The set of two such rays h', k' is called an **angle** in α , denoted by $\angle(h', k')$ or $\angle(k', h')$. This angle is also denoted by $\angle AOB$, where A, B are points of h', k' , respectively. The rays h', k' are called the **sides** and the point O is called the **vertex** of this angle. Then h' is a subset of a half-plane on α bounded by k , and k' is a subset of a half-plane on α bounded by h . The intersection of these two half-planes is called the **interior** of this angle, and the subset of $\alpha - O$ consisting of points belonging to neither the inside nor the sides of the angle is called the **exterior** of the angle. Between two angles $\angle(h', k'), \angle(h'_1, k'_1)$ there may exist the relation of congruence, again expressed by the symbol \equiv , as in the case of segments, and subject to the following two axioms: (4) Let $\angle(h', k')$ be an angle on a plane α and h_1 be a line on α_1 (α_1 may or may not be equal to α). Let O_1 be a point on h_1, h'_1 a ray on α_1 starting from O_1 , and α'_1 a half-plane on α_1 bounded by h_1 . Then there exists a unique ray k'_1 starting from O_1 and lying in α'_1 such that $\angle(h', k') \equiv \angle(h'_1, k'_1)$. Moreover, $\angle(h', k') \equiv \angle(h', k')$ always holds. (Hence it follows that \equiv is an equivalence relation between angles.) (5) Let both A, B, C and A_1, B_1, C_1 be triples of points not lying on a line. Then from $AB \equiv A_1B_1, AC \equiv A_1C_1$, and $\angle BAC \equiv \angle B_1A_1C_1$, it follows that $\angle ABC \equiv \angle A_1B_1C_1$.

(IV) **Axiom of parallels:** Suppose that a, b are two different lines. Then it follows from axiom I.2 that if a and b share a point P , such a point is the unique point lying on both a and

b . In this case we say that a, b **intersect** at P and write $a \cap b = P$. On the other hand, if a and b have no point in common and if a, b are on the same plane, we say that a, b are **parallel** and write $a \parallel b$. If A, a are on a plane α and A is not on a , we can prove (utilizing axioms I, II, and III) that there exists a line b passing through A in α such that $a \parallel b$. The axiom of parallels postulates the uniqueness of such a b .

(V) **Axioms of continuity**: (1) Let AB, CD be two segments. Then there exist a finite number of points A_1, A_2, \dots, A_n on $A \cup B$ such that $CD \equiv AA_1 \equiv A_1A_2 \equiv \dots \equiv A_{n-1}A_n$ and B is between A and A_n (**Archimedes' axiom**). (2) The set of points on a line a (again denoted for simplicity by a) is "maximal" in the following sense: It should satisfy axioms II.1–II.3, III.1, V.1, and the theorem of linear ordering. If \bar{a} is a set of points satisfying these axioms such that $\bar{a} \supset a$, then \bar{a} should be $= a$ (**axiom of linear completeness**). Hence follows the **theorem of completeness**: the set of points, lines, and planes is maximal in the sense that it is not possible to add further points, lines, or planes to this set with the resulting set still satisfying axioms I–IV and V.1.

C. Consistency

In formulating the above axioms and proving their consistency, Hilbert assumed the consistency of the theory of real numbers (\rightarrow 156 Foundations of Mathematics). To prove consistency, Hilbert constructed a model for the above axioms using the method of analytic geometry. He defined points as triples of real numbers (x_1, x_2, x_3) , lines and planes as sets of points satisfying suitable systems of linear equations, and relations of ordering, congruence, and parallelism in the usual way. It is easy to verify that such a system satisfies all the axioms I–V. Thus the consistency of these axioms is reduced to the consistency of the theory of real numbers (\rightarrow 35 Axiom Systems).

A model for I–IV and V.1 can be obtained in the countable field \mathbf{R}_0 of all real \dagger algebraic numbers instead of \mathbf{R} . Then \mathbf{R}_0 can be further restricted to its subfield \mathbf{P}_0 defined as follows: Let F be an arbitrary field. An \dagger extension of F of the form $F(\sqrt{1+\lambda^2})$ with $\lambda \in F$ is called a **Pythagorean extension** of F , and F is said to be a **Pythagorean field** if any Pythagorean extension of F coincides with F (e.g., \mathbf{R}_0 and \mathbf{R} are Pythagorean). It is easily verified that I–IV are satisfied in the "analytic geometry over any Pythagorean field." On the other hand, we can construct a minimal Pythagorean field containing a given field (the **Pythagorean closure** of the field) in the same way as we construct the \dagger algebraic closure of a field. The field \mathbf{P}_0 is

defined as the Pythagorean closure of the field \mathbf{Q} of rational numbers.

D. Independence of Axioms

In Hilbert's system, the axioms I and II are used to formulate further axioms. On the other hand, it can be shown that each of the groups III, IV, and V is independent from other axioms.

The independence of IV is shown by the consistency of non-Euclidean geometry (\rightarrow 285 Non-Euclidean Geometry). The following model shows the independence of III.5: In the analytic model for I–V, we replace the definition of distance between two points

$(x_1, x_2, x_3), (y_1, y_2, y_3)$ by

$$((x_1 - y_1 + x_2 - y_2)^2 + (x_2 - y_2)^2 + (x_3 - y_3)^2)^{1/2}.$$

Then III.5 does not hold, while all other axioms remain satisfied. The independence of V.2 is shown by the geometry over \mathbf{R}_0 or \mathbf{P}_0 . The independence of V.1 follows from the existence of the non-Archimedean Pythagorean field: the Pythagorean closure of any \dagger non-Archimedean field (e.g., the field of rational functions of one variable over \mathbf{Q} with a \dagger non-Archimedean valuation) is such a field. A geometry in which V.1 does not hold is called a **non-Archimedean geometry**.

E. Completeness of the System of Axioms and Relations between Axioms

The \dagger completeness of the system of axioms I–V can be shown by introducing coordinates in the geometry with these axioms and representing it as \dagger Euclidean geometry of three dimensions. Axiom group V is essential for the introduction of coordinates over \mathbf{R} . Moreover, we have the following results:

(i) The geometry with the axioms I–IV can be represented as "Euclidean geometry" of three dimensions over a Pythagorean field, and the geometry with axioms I.1–I.3, II–IV can be represented as "Euclidean geometry" of two dimensions over a Pythagorean field.

(ii) The geometry with II, and a stronger axiom of parallels IV* (given a line a and a point A outside a , there exists one and only one line a' passing through A that is parallel to a) can be represented as an \dagger affine geometry over a field K that is not necessarily commutative.

(iii) The field K is commutative if and only if the following holds: Suppose that in Fig. 1 $A' \cup B \parallel A \cup B'$, $B' \cup C \parallel B \cup C'$. Then it follows that $A' \cup C \parallel A \cup C'$ (**Pascal's theorem**).

Fig. 1

(iv) The “two-dimensional geometry” with I.1–I.3, II, and IV* can be embedded in the “three-dimensional geometry” with axioms I, II, and IV* if and only if the following holds: Suppose that in Fig. 2 we have $AUB \parallel A'UB'$, $BUC \parallel B'UC'$. Then it follows that $CUA \parallel C'UA'$ (Desargues's theorem).

Fig. 2

(v) From I.1–I.3, II, IV*, and Pascal's theorem follows Desargues's theorem.

(vi) Desargues's theorem is independent of I.1–I.3, II, III.1–III.4, IV*, and V; that is, we can construct a **non-Desarguesian geometry** (a geometry in which Desargues's theorem does not hold) in which these axioms are satisfied.

Axioms I, II, and IV*, as well as the theorems of Pascal and Desargues, are propositions in affine geometry. Each has a corresponding proposition in [†]projective geometry, and the results concerning them can be transferred to the case of projective geometry (\rightarrow 343 Projective Geometry).

F. Polygons and Their Areas

Suppose that we are given a finite number of points A_i ($i=0, 1, \dots, r$) in the geometry with axioms I and II. Then the set of segments (or, more precisely, the union of segments together with their interiors) A_iA_{i+1} ($i=0, 1, \dots, r-1$) is called a **broken line** joining A_0 with A_r . In particular, if $A_0 = A_r$, then this set is called a **polygon** with **vertices** A_i and **sides** A_iA_{i+1} . A polygon with r vertices is called an r -gon. (For $r=3, 4, 5, 6$, r -gons are called **triangles**, **quadrangles**, **pentagons**, and **hexagons**, respectively.) A **plane polygon** is a polygon whose vertices all lie on a plane. A polygon is called **simple** if any three consecutive vertices do not lie on a line, and two sides A_iA_{i+1} and A_jA_{j+1} ($i \neq j$) meet only when $j=i+1$ or $i=j+1$. In this article,

we consider only simple plane polygons, and refer to them simply as polygons.

[†]Jordan's theorem implies that a polygon in the sense just defined divides the plane into two parts, its **interior** and its **exterior**. This special case of Jordan's theorem can be proved by I.1–I.3 and II only. A polygon P is divided into two polygons P_1, P_2 by a broken line joining two points on sides of P and lying in the interior of P (Fig. 3). In this case, we say that P is **decomposed** into P_1, P_2 and write $P = P_1 + P_2$. We may again decompose P_1, P_2 and thereby arrive at a decomposition of the form $P = P_1 + \dots + P_k$. Axiom III is used to introduce the congruence relation \equiv between polygons. Two polygons P, Q are called **decomposition-equal** if there exist decompositions $P = P_1 + \dots + P_k, Q = Q_1 + \dots + Q_k$ such that $P_1 \equiv Q_1, \dots, P_k \equiv Q_k$. This is expressed by PzQ . We call P, Q **supplementation-equal** if there exist two polygons P', Q' such that $(P + P')z(Q + Q'), P'zQ'$. This will be expressed by PeQ . If we assume IV, we can use result (i) of Section E. Let K be the ground field of the geometry (K is Pythagorean, hence [†]ordered). The **area** of polygon P is defined as the positive element $m(P)$ of K assigned to P such that $m(P + Q) = m(P) + m(Q)$, and $m(P) = m(P')$ if $P \equiv P'$. From PzQ or PeQ , it follows that $m(P) = m(Q)$. Under these axioms, it is proved that $m(P) = m(Q)$ implies PeQ . If we also assume V.1, then $m(P) = m(Q)$ implies PzQ . Thus the theory of area of polygons can be constructed without assuming axiom V.2, though this result cannot be generalized to higher-dimensional cases. For the case of three dimensions, we can construct two solids of the same volume that are not supplementation-equal [2, 7].

Fig. 3

G. Geometric Construction by Ruler and a Transferrer of Constant Lengths

The geometry with I–IV can be represented as 3-dimensional Euclidean geometry over a Pythagorean field. Conversely, all these axioms are valid in 3-dimensional Euclidean geometry over any Pythagorean field. Thus the minimal system of “quantities” whose existence is assured in geometry with these axioms is the field P_0 , the Pythagorean closure of Q . Hilbert noticed that the existence of a

geometric object under axioms I–IV can be expressed as its constructibility by **ruler** (i.e., an instrument to draw a straight line joining two points) and a **transferrer of constant lengths**. The latter, for a constant length x , is an instrument that permits finding the point X on the given ray AB such that $AX = x$. It is not possible to construct by ruler and transferrer all the points that can be constructed by means of ruler and compass (\rightarrow 179 Geometric Construction). However, it is possible to construct all the lengths λx , where λ is any element of P_0 . Hilbert conjectured that an element of P_0 can be characterized as a †totally positive algebraic number of degree 2^v , $v \in \mathbb{N}$. This conjecture was proved by Artin [3].

H. Related Topics

While Hilbert's foundations are concerned with 3-dimensional Euclidean geometry, it is easy to generalize these results to the case of n -dimensional Euclidean geometry (\rightarrow 139 Euclidean Geometry). Also, for affine and projective geometries, there are well-organized systems of axioms (at least for the case of dimensions ≥ 3). Hilbert [1, Appendix III] showed that plane †hyperbolic geometry can be constructed on a modified system of axioms, but for other non-Euclidean geometries (in particular, telliptic geometries) there are no known systems of axioms as good as Hilbert's for the Euclidean case. On the other hand, Hilbert [1, Appendix IV] gives another method of constructing Euclidean geometry in characterizing the group of motions as the topological group with certain properties. G. Thomsen [4] rewrote Hilbert's system of axioms in group-theoretical language utilizing the fact that the group of motions is generated by symmetries with respect to points, lines, and planes. Finally, Hilbert's study of the foundations of geometry led him to research in the †foundations of mathematics.

156 (I.1) Foundations of Mathematics

A. General Remarks

The notion of †set, introduced toward the end of the 19th century, has proved to be one of the most fundamental and useful ideas in mathematics. Nonetheless, it has given rise to well-known †paradoxes. Based on this notion, R. Dedekind developed the theories of natural numbers [2] and real numbers [3], defining the latter as “cuts” of the set of rational numbers. Thus set theory served as a unifying principle of mathematics.

It has been noted, however, that some of the most commonly utilized arguments in set theory, which are at the same time the most useful in mathematics and belong almost to the basic framework of formal logic itself, resemble very much those which give rise to paradoxes. This fact has caused many critical mathematicians to question the very nature of mathematical reasoning. Thus a new field, **foundations of mathematics**, came into being at the beginning of this century. This field was divided at its inception into different doctrines according to the views of its initiators: **logicism** by B. Russell, **intuitionism** by L. E. J. Brouwer, and **formalism** by D. Hilbert. In set theory, which was the origin of this controversy, it was pointed out that the “definition” of set as given by G. Cantor was too naive, and axiomatic treatments of this theory were proposed (\rightarrow 33 Axiomatic Set Theory).

B. Logicism

Russell asserted that mathematics is a branch of logic and that paradoxes come from neglecting the “types” of concepts. According to his opinion, mathematics deals formally with structures independently of their concrete meanings. Science of this character has been called logic from antiquity. According to him, logic is the youth of mathematics, and mathematics is the manhood of logic. To construct mathematics from this standpoint, asserted Russell, ordinary language is lengthy and inaccurate, and some proper system of symbols should be used instead. Thus he tried to reconstruct mathematics using †symbolic logic.

Attempts to reorganize mathematics using logical symbols had formerly been made by G. Leibniz, who wrote *Dissertatio de arte combinatoria* in 1666, as well as by A. de Morgan, G. Boole, C. S. Peirce, E. Schröder, G. Frege, G. Peano, and others. Symbols used by the last two authors resemble those of today. Russell studied these works and published his own theory in a monumental joint work with A. N. Whitehead: *Principia mathematica* (3 vols., 1st ed. 1910–1913, 2nd ed. 1925–1927), in which the theories of natural numbers and real numbers as well as analytic geometry are developed from the fundamental laws of logic.

If this work had been completely successful, it could have eliminated any possibility of the intrusion of paradoxes into mathematics. However, the authors were forced to postulate an “unsatisfactory” axiom in order to construct mathematics. They introduced the notion of †type as follows: An object M defined as the set of all objects of a certain type belongs to a higher type than the types of the elements of M . This serves to eliminate certain paradoxes but brings about inconveniences such as the following. Suppose that we are trying to construct the theory of real numbers from that of rational numbers. Each real number can then be considered a †predicate about rational numbers. If this predicate contains only †quantifiers relating to variables running over all rational numbers, then the corresponding real number is said to be **predicative**, otherwise **impredicative**. According to Russell, the latter should have a higher type than the former, which makes the theory of real numbers exceedingly complicated. To avoid this difficulty, Russell proposed the **axiom of reducibility**, which says that every predicate can be replaced by a predicative one. With this rather artificial axiom Russell himself expressed dissatisfaction. Russell also postulated the †axiom of infinity and the †axiom of choice, which are also problematic. After examining the philosophical background of the book, H. Weyl wrote about *Principia mathematica*, “Mathematics is no more based on logic than the utopia built by the logician.” Nevertheless, logic as formulated in this book, as well as the theory of types as developed by F. P. Ramsay in the school of Russell and Whitehead, is still an important subject of mathematical logic.

C. Intuitionism

The intuitionist claims that mathematical objects or truths do not exist independently from mathematically thinking spirit or intuition, and that these objects or truths should be directly seized by mental or intuitional activ-

ity. The philosophical standpoints of mathematicians such as L. Kronecker and H. Poincaré in the 19th century or E. Borel, H. Lebesgue, and N. N. Luzin at the turn of this century can be assimilated to intuitionism, but those of the latter three are often said to belong to **semi-intuitionism** or to **French empiricism**. Brouwer took a narrower standpoint, strongly antagonistic to Hilbert’s formalism. Today the word “intuitionism” is generally interpreted in Brouwer’s sense.

Brouwer sharply criticized the usual way of reasoning in mathematics and claimed that indiscriminate use of the **law of excluded middle** (or **tertium non datur**) $P \vee \neg P$ cannot be permitted. According to him, the proposition “Either there exists a natural number with a given property P , or else no such number exists” is to be regarded as proved only when an actual construction of a natural number with the property P is given or when the absurdity of the existence of such a natural number can be constructively proved. When neither of these two results can be shown, then one can say nothing about the truth of the above proposition. Thus the usual method of proof, known as the method of **reductio ad absurdum**, i.e., of proving a proposition P by proving its double negation $\neg \neg P$, is not generally considered valid. It is a difficult but important problem of mathematical logic to determine which parts of usual mathematics can be reconstructed intuitionistically, though it does not seem easy to reconstruct any part of mathematics elegantly from this standpoint.

D. Formalism

To eliminate paradoxes, Hilbert tried to apply his axiomatic method. From Hilbert’s standpoint, any part of mathematics is a deductive system based on its axioms. In the deductive development, however, “logic,” including set theory and elementary number theory, is used. Paradoxes appear already in such logic. Hilbert’s idea was to axiomatize such logic and to prove its consistency. Thus one must first formalize the most elementary part of mathematics, including logic proper.

Hilbert proved the consistency of Euclidean geometry by assuming the consistency of the theory of real numbers. This is an example of a **relative consistency** proof, which reduces the consistency proof of one system to that of another. Such a proof can be meaningful only when the latter system can somehow be regarded as based on sounder ground than the former. To carry out the **consistency proof** of logic proper and set theory, one must reduce it to that of another system with sounder

ground. For this purpose, Hilbert initiated **metamathematics** and the **finitary standpoint**.

The finitary standpoint recognizes as its foundation only those facts that can be expressed in a finite number of symbols and only those operations that can be actually executed in a finite number of steps. Essentially, it does not differ from the standpoint of intuitionism. The methods based on this standpoint are also called **constructive methods**.

Metamathematics is also called **proof theory**. Its subject of research is mathematical proof itself. Hilbert was the first to insist on its importance. The theory is indispensable for consistency proofs of mathematical systems, but it may also be used for other purposes. In fact, the same idea can be seen in the †duality principle of projective geometry, which dates from long before Hilbert's proclamation of formalism. This is not a theorem of projective geometry deduced from its axioms; rather, it is a proposition about the theorems in projective geometry, based on the type of axioms and proofs in this subject.

According to Hilbert's method, one must develop proof theory from the finitary standpoint with the aim of proving the consistency of axiomatized mathematics. For this purpose, one must formalize the mathematical theory in question by means of symbolic logic. A theory thus formalized is called a **formal system**.

E. Some Results of Formalist Theory

One of the most remarkable results hitherto obtained with Hilbert's method is the consistency proof of pure number theory by G. Gentzen [7]. This consistency proof covers the largest domain for which an explicit consistency proof has so far been obtained. However, the methods of formalist proof theory have proved to be most effective in studying the logical structure of mathematical theories and have led to various results on the consistency of formalized mathematical systems, on symbolic logic, and on axiomatic set theory. We give some examples.

(1) Gödel's Incompleteness Theorem. K. Gödel [6] showed that if a system obtained by formalizing the theory of natural numbers is consistent, then this system contains a †closed formula A such that neither A nor its negation $\neg A$ can be proved within the system. He originally proved this under the assumption that the system is ω -consistent. This is a stronger condition for the system than simple consistency, but J. B. Rosser [13] succeeded in replacing this by the latter. This result shows the incompleteness not only of the usual

theory of natural numbers but of any consistent theory (from the finitary standpoint) containing the theory of these numbers.

At the same time, Gödel also obtained the following important result: Let S be any consistent formal system containing the theory of natural numbers. Then it is impossible to prove the consistency of S by utilizing only arguments that can be formalized in S . This means that a consistency proof from the finitary standpoint of a formal system S inevitably necessitates some argument that cannot be formalized in S .

(2) Consistency Proofs for Pure Number Theory. Gentzen [7] called **pure number theory** the theory of natural numbers not depending on the free use of set theory (differing consequently from the usual theory of natural numbers based on †Peano axioms; → 294 Numbers) and proved its consistency. W. Ackermann [14] proved the consistency of a similar theory admitting the use of Hilbert's † ε -symbol. G. Takeuti [15] showed that Gentzen's result can be obtained as a corollary to his theorem extending †Gentzen's fundamental theorem on †predicate logic of the first order to a †theory of types of a certain kind.

According to the result of Gödel mentioned in (1) above, some reasoning outside pure number theory must be used to prove its consistency. In all consistency proofs of pure number theory mentioned above, †transfinite induction up to the first † ε -number ε_0 is used, but all the other reasoning used in these proofs can be presented in pure number theory. This shows that the legitimacy of transfinite induction up to ε_0 cannot be proved in this latter theory. A direct proof of this fact was given by Gentzen [13]. On the other hand, the legitimacy of transfinite induction up to an ordinal number $< \varepsilon_0$ can be proved within pure number theory.

Again, transfinite induction is not the only method by which to prove the consistency of pure number theory. Actually, Gödel [17] carried out the proof utilizing what he called computable functions of finite type on natural numbers and what we call primitive recursive functionals of finite type.

By restricting pure number theory further, one obtains weaker theories of natural numbers whose consistency can be proved with finitary methods without recourse to such methods as transfinite induction up to ε_0 . M. Presburger [18] proved the consistency of a theory in which only the addition of numbers is considered an operation. Ackermann [19], J. von Neumann [20], J. Herbrand [21], and K. Ono [22] proved the consistency of theories in which some restrictions are placed

on the use of the axiom of \dagger mathematical induction.

On the other hand, K. Schütte [23] gave a consistency proof for number theory including what he called “infinite induction” from a stronger standpoint than Hilbert’s finitary one; he attempted to find a basis that makes such a proof possible.

(3) The Consistency of Analysis. No definitive result has yet been obtained from the standpoint of formalism, though many attempts are being made, among which a recent one by C. Spector [24] should be mentioned.

(4) Axiomatic Set Theory. There are different kinds of axiom systems (\rightarrow 33 Axiomatic Set Theory). To give a consistency proof for any of these systems is considered a very difficult problem today, but many interesting results are known concerning the relative consistency or independence of these axioms.

(5) The Skolem-Löwenheim Theorem. The metamathematical Skolem-Löwenheim theorem states: Given a consistent system of axioms stated in the first-order predicate logic whose cardinality is at most countable, there always exists an \dagger object domain consisting of countable objects satisfying all these axioms.

For example, axiomatic set theory is stated in predicate logic of the first order, and the cardinality of its axioms is countable. Thus there exists an object domain consisting of countable objects satisfying all these axioms, provided that they are consistent. Such a domain is called a **countable model** of axiomatic set theory. On the other hand, from the axioms of this theory one can prove that there exists a family of sets that is more than countable. This should also hold in a model of the theory, in which each object represents a set. This situation is known as the **Skolem paradox**.

This does not imply, however, the inconsistency of axiomatic set theory. In fact, the term “countable” is to be interpreted in its mathematical sense when one says “there exists a family of sets that is more than countable,” while it should be interpreted in its metamathematical sense when one speaks of a countable model of the theory. It is the confusion of these two different interpretations that leads to the “paradox.”

(6) Skolem’s Theorem on the Impossibility of Characterizing the System of Natural Numbers by Axioms. T. Skolem [27] proved that it is not possible to characterize the system of natural numbers by a countable system of axioms stated in the predicate logic of the first order. More precisely, given any consistent

countable system of axioms satisfied by the system of natural numbers, there always exists another \dagger linearly ordered system satisfying all these axioms and yet not isomorphic to the system of natural numbers as an ordered system.

Gödel’s incompleteness theorem and the Skolem paradox, as well as this result, seem to indicate that there is a certain limit to the effectiveness of the formalist method. On the other hand, nonstandard analysis has originated in this result.

157 (VI.22) Four-Color Problem

A. Brief History

It is obvious that four colors are necessary to color some geographical maps on a sphere (or plane), but are four colors sufficient to color every map? This is the so-called four-color problem. The precise formulation of this problem will be given in Section B. The conjecture was made by Francis Guthrie and communicated through his brother Frederick Guthrie to A. De Morgan in 1852 [4]. A. Cayley called attention to the problem in 1878. It became famous after J. P. Heawood pointed out a mistake in the proof by A. B. Kempe (1879). Heawood also studied the problem of coloring maps on arbitrary surfaces (→ Section E).

Though there have been various approaches to the four-color problem, the main stream of investigation has concentrated on obtaining an unavoidable set consisting of reducible arrangements (→ Section D) in order to correct the mistake made by Kempe. G. D. Birkhoff [7] first discovered the simplest nontrivial reducible arrangement, nowadays called Birkhoff's diamond (Fig. 1). Using all reducible arrangements known up to that time, P. Franklin showed that every map with up to 25 countries must contain a reducible arrangement, so that such a map is four-colorable [8]. This limit has been gradually increased; in 1975 a reducible arrangement for 25 countries was found.

Fig. 1
Birkhoff's diamond.

H. Heesch invented the method of discharging (→ Section D), found criteria for reducibility, and finally conjectured the existence of an unavoidable set of reducible arrangements with several thousand elements, but this was too large to construct by hand. W. Haken and K. Appel with J. Koch worked with high-speed computers for a total of 1,200 CPU hours over a period of four and a half years and finally succeeded in constructing and checking an avoidable set of reducible arrangements with 1,834 elements, which proved the four-color problem affirmatively (1976; [9, 10]). For early investigations of the four-color problem → [5]; for results up to the 1930s → [3].

B. Precise Formulation of the Problem

To formulate the problem precisely, we must state the following two conditions: (i) Every country on a map is a †connected domain; a connected part of the sea is considered to be a country. (ii) Two countries sharing boundary lines must be colored differently. On the other hand, if two countries share only a finite number of points, then they may share the same color.

Actually we can modify the map so that no more than three countries meet at the same point. A map with this condition is called a **trivalent** or **cubic map**. In the study of the four-

color problem, we can restrict ourselves to trivalent maps without two-sided countries. In the remainder of this article, we shall assume that the maps considered have these properties.

In recent investigations, it has become customary to convert maps into their \dagger dual graphs, where each country is replaced by its capital lying inside, and for each adjacent pair A, B (Fig. 2), the boundary is replaced by a line connecting the representative points of A and B in such a way that it meets the boundary only once.

Fig. 2
Dual graph.

The formal extension of the four-color problem to higher dimensions is trivial, since we can easily construct arrangements needing arbitrary many colors for coloring. By converting to a dual graph, one can see that this is not surprising, since the planarity of a graph is a strong restriction, while the condition of representability of a linear graph in 3-dimensional space imposes no restriction.

C. Tait's Algorithm

Suppose that a planar trivalent map M is four-colored. Denote the four colors by 0, 1, 2, and 3. (In Fig. 3, we use A, B, C , and D instead of 0, 1, 2, and 3, respectively). Here we take the operation $a \oplus b \rightarrow c$. Represent the integers $a, b = 0, 1, 2, \text{ or } 3$ in the binary (2-adic) number system as 2-digit numbers $a_1 a_0$ and $b_1 b_0$, where a_i and b_i are 0 or 1. For each digit we take the operation $a_i \oplus b_i = c_i$ to be binary

Fig. 3
An example of Tait's algorithm. At the vertices, ● stands for + and ○ for -. Within the domains, A, B, C, and D stand for four colors corresponding to 0, 1, 2, and 3, respectively.

addition without carrying, i.e., the operation is that of the logical (exclusive) "or." The number $c = c_1 c_0$ in the binary system represents the result of the operation. To each boundary line, we give the number corresponding to $a \oplus b$, where a and b are the colors for the two countries meeting at the boundary. Then we have the numbering 1, 2, and 3 for each edge, where 1, 2, and 3 are labeled once and only once for each triple of edges emanating from each vertex. Such numbering for edges is called **Tait coloring** for edges. Then we give the signature + or - to each vertex, according as the order of the edge numbering is counterclockwise or clockwise. Then the algebraic sum of the signatures along the boundary of each country in the map is always a multiple of 3. Conversely, if we give the signature + or - to each vertex in such a way that the algebraic sum of the signatures is always a multiple of 3 along the boundary of each country, then we get a four-coloring of the map by reversing the above procedure. This is called **Tait's algorithm**, which shows that the four-coloring of a planar map is an \dagger NP problem. As for five-coloring, it is known that an algorithm of polynomial complexity exists.

Tait's algorithm also shows that the four-color problem is equivalent to the following apparently elementary geometric proposition: "For any convex polyhedron, we can always cut near some of its vertices in such a way that the resulting polyhedron has only faces such that the number of sides is a multiple of 3." Many other equivalent statements of the four-color problem are known [1, 2].

D. Solution of the Four-Color Problem

For a given planar trivalent map, denote by V_n the number of the countries with n sides ($n \geq 3$). From Euler's theorem on polyhedra, we have immediately the relation

$$\sum_{n \geq 3} (6 - n) V_n = 12. \tag{1}$$

We easily see from this that every planar map must contain 3-, 4-, or 5-sided countries. A family F of the arrangements of countries with the property that every planar map must contain at least one arrangement belonging to F is called an **unavoidable set**. The family consisting of 3-, 4-, and 5-sided countries is the simplest example. In order to obtain an unavoidable set, Heesch invented the method of **discharging**. Let us assume the existence of a map M that contains no arrangement of a family F . We give a signed charge of $(6 - n)$ to every n -gon in M . Next we divide and move the charges so that the pluses and the minuses cancel out. If all positive charges disappear,

according to the assumption of the existence of the map M , then we have a contradiction of (1), so we can conclude that no such map M exists.

A 3-sided country can be ignored in four-coloring. As for a 4-sided country A , Kempe proved (by means of a definite modification procedure) that after four-coloring outside A , we also have a total four-coloring including A . An arrangement of a country or countries A is called **reducible** if, as in the above case, after four-coloring outside A , we get a total four-coloring including A by suitable modifications. If we have an unavoidable set consisting only of reducible arrangements, then by definition, every planar map will be four-colorable.

Kempe believed that he had proved the reducibility of a pentagon (5-sided country), but unfortunately, he missed a particular case. Even though the pentagon is not reducible, much effort has been given to finding other reducible arrangements. Many useful criteria for reducibility have also been studied. If we have enough reducible arrangements, then we can either eventually obtain an unavoidable set, which proves the four-color problem affirmatively, or find a “minimal counter-example” without reducible arrangements, which disproves it.

Haken obtained an unavoidable set consisting of arrangements without certain kinds of reduction obstructions. (He called these “geographically good arrangements.”) He firmly believed that, applying certain “probabilistic conjectures” to such arrangements, he would conquer the problem by considering arrangements of up to 14 countries. With repeated improvements on the discharging process and on the criteria for reducibility, he finally was able to conclude that his speculation was correct, as recounted in Section A. His investigation is not only an example of the use of high-speed computation in pure mathematics, but also one inviting reassessment of the meaning of mathematical proof.

E. Coloring Maps on Arbitrary Surfaces

On a \dagger torus, seven colors are sufficient to color any map and that many colors are necessary to color some maps. Heawood (1890) investigated the problem of coloring maps on closed surfaces with \dagger Euler characteristic $\chi < 2$, orientable or not. The least number of colors sufficient to color any map on a surface is called the **chromatic number** of the surface. Heawood proved that the chromatic number is less than or equal to

$$p = [(7 + \sqrt{49 - 24\chi})/2] \quad (\chi < 2), \tag{2}$$

where $[x]$ means the largest integer $a \leq x$. After this was proved in various special cases, J. W. T. Youngs and G. Ringel finally proved in 1968 that the number p equals the chromatic number except for a Klein bottle (a non-orientable surface with $\chi = 0$) [6]. Franklin proved in 1934 that the chromatic number for a Klein bottle is 6.

158 (XXI.24)
Fourier, Jean Baptiste Joseph

Jean Baptiste Joseph Fourier (March 21, 1768–May 16, 1830) was born in Auxerre, France, the son of a tailor, and was orphaned at the age of eight. In 1790, he was appointed professor at the Ecole Polytechnique. In 1798, Napoleon took him on his Egyptian campaign together with G. Monge. On his return to France, he was made governor of the department of Isère. With the downfall of Napoleon, he lost his position; however, he was later appointed to the French Academy of Science as a result of his research on the transmission of heat. In 1826 he was elected a member of the Académie Française.

His research on heat transmission was begun in 1800. In 1811, he presented a prize-

winning solution to a problem put forth by the Academy of Science. He solved the equation for heat transmission under various †boundary conditions. Fourier also stated (without rigorous proof) that an arbitrary function could be represented by †trigonometric series (→ 159 Fourier Series), a statement that gave rise to subsequent developments in analysis.

159 (X.22) Fourier Series

Throughout this article, we assume that $f(x)$, $g(x)$, ... are real-valued functions and that integrals are always Lebesgue integrals.

A. Introduction

The set of functions

$$1/\sqrt{2\pi}, \quad \cos x/\sqrt{\pi}, \quad \sin x/\sqrt{\pi}, \dots, \\ \cos kx/\sqrt{\pi}, \quad \sin kx/\sqrt{\pi}, \dots,$$

which is called the **trigonometric system**, is an †orthonormal system in $(-\pi, \pi)$ (→ 317 Orthogonal Functions). Let $f(x)$ be an element of $L_1(-\pi, \pi)$ (i.e., †Lebesgue integrable in $(-\pi, \pi)$). We put

$$a_k = \frac{1}{\pi} \int_{-\pi}^{\pi} f(t) \cos kt \, dt, \\ b_k = \frac{1}{\pi} \int_{-\pi}^{\pi} f(t) \sin kt \, dt, \quad k=0, 1, \dots, \quad (1)$$

and call a_k, b_k the **Fourier coefficients** of f . The formal series

$$\frac{1}{2}a_0 + \sum_{k=1}^{\infty} (a_k \cos kx + b_k \sin kx) \quad (2)$$

is called the **Fourier series** of f and is often denoted by $\Xi(f)$. To indicate that a formal series $\Xi(f)$, as above, is the Fourier series of a function f , we write

$$f(x) \sim \frac{1}{2}a_0 + \sum_{k=1}^{\infty} (a_k \cos kx + b_k \sin kx).$$

The sign \sim means that the numbers a_k, b_k are connected with f by the formula (1); it does not imply that the series is convergent, still less that it converges to f . Generally, **trigonometric series** are those of form (2), where the a_k, b_k are arbitrary real numbers. Since the trigono-

metric series have period 2π , we assume that the functions considered are extended for all real x by the condition of periodicity $f(x+2\pi)=f(x)$. The study of the properties of the series $\Xi(f)$ and the representation of f by $\Xi(f)$ are major objects of the theory of Fourier series. Since $e^{ix} = \cos x + i \sin x$, if we set $2c_k = a_k - ib_k$, $c_{-k} = \bar{c}_k$ ($k=0, 1, 2, \dots$), we have

$$c_k = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(t) e^{-ikt} \, dt, \quad k=0, \pm 1, \dots$$

Then $\Xi(f)$ is represented by the **complex form** $\sum_{k=-\infty}^{\infty} c_k e^{ikx}$, and $\{e^{ikx}\}$ ($k=0, \pm 1, \dots$) is an orthogonal system in $(-\pi, \pi)$. In this complex form, we take symmetric partial sums such as $\sum_{k=-n}^n c_k e^{ikx}$ ($n=1, 2, \dots$).

Consider the power series $\frac{1}{2}a_0 + \sum_{k=1}^{\infty} (a_k - ib_k)z^k$ on the unit circle $z = e^{ix}$ in the complex plane. Its real part is the trigonometric series (2), and the imaginary part (with vanishing constant term) is

$$\sum_{k=1}^n (a_k \sin kx - b_k \cos kx), \quad (3)$$

which is called the **conjugate series** (or **allied series**) of f and is denoted by $\tilde{\Xi}(f)$. In complex form, the conjugate series is $-i \sum_{k=-\infty}^{\infty} (\operatorname{sgn} k) c_k e^{ikx}$.

If f and g belong to $L_1(-\pi, \pi)$ and

$$f(x) \sim \sum_{k=-\infty}^{\infty} c_k e^{ikx}, \quad g(x) \sim \sum_{k=-\infty}^{\infty} d_k e^{ikx},$$

then

$$\frac{1}{2\pi} \int_0^{2\pi} f(x-t)g(t) \, dt \sim \sum_{k=-\infty}^{\infty} c_k d_k e^{ikx}.$$

The function

$$f * g(x) = \frac{1}{2\pi} \int_0^{2\pi} f(x-t)g(t) \, dt$$

is called the **convolution** of f and g .

If f is †absolutely continuous, then the derivative $f'(x)$ satisfies

$$f'(x) \sim i \sum_{k=-\infty}^{\infty} k c_k e^{ikx} \\ = \sum_{k=1}^{\infty} k (b_k \cos kx - a_k \sin kx).$$

If $F(x)$ is an indefinite integral of f , then

$$F(x) - c_0 x \sim C + \sum_{k=-\infty}^{\infty} \frac{c_k}{ik} e^{ikx} \\ = C + \sum_{k=1}^{\infty} \frac{a_k \sin kx - b_k \cos kx}{k},$$

where C is a constant of integration and the symbol ' indicates that the term $k=0$ is omitted from the sum.

If $f \in L_1(-\pi, \pi)$, then the Fourier coefficients

c_n converge to 0 as $n \rightarrow \infty$ (**Riemann-Lebesgue theorem**). If f satisfies the † Lipschitz condition of order α ($0 < \alpha \leq 1$), then $c_n = O(n^{-\alpha})$, and if f is of † bounded variation, then $c_n = O(n^{-1})$.

When $f \in L_2(-\pi, \pi)$,

$$\begin{aligned} \frac{1}{\pi} \int_0^{2\pi} |f(x)|^2 dx &= 2 \sum_{k=-\infty}^{\infty} |c_k|^2 \\ &= \frac{1}{2} a_0^2 + \sum_{k=1}^{\infty} (a_k^2 + b_k^2), \end{aligned}$$

which is called the **Parseval identity**. If $\sum |c_k|^2 < \infty$, then there exists a function $f \in L_2(-\pi, \pi)$ which has the c_k as its Fourier coefficients.

This converse is implied by the † Riesz-Fischer theorem (\rightarrow Appendix A, Table 11.I).

B. Convergence Tests

The n th partial sums $s_n(x) = s_n(x; f)$ of the Fourier series $\mathfrak{S}(f)$ can be written in the form

$$s_n(x) = \frac{1}{\pi} \int_{-\pi}^{\pi} f(x+t) D_n(t) dt,$$

where

$$D_n(t) = \{\sin(n+1/2)t\} / 2 \sin(t/2).$$

The function $D_n(t)$ is called the **Dirichlet kernel**.

For a fixed point x we set $\varphi_x(t) = f(x+t) + f(x-t) - 2f(x)$; then

$$s_n(x) - f(x) = \frac{1}{\pi} \int_0^{\pi} \varphi_x(t) D_n(t) dt.$$

Hence if the integral on the right-hand side tends to zero as $n \rightarrow \infty$, $\lim_{n \rightarrow \infty} s_n(x) = f(x)$. If f vanishes in an interval $I = (a, b)$, then $\mathfrak{S}(f)$ converges uniformly in any interval $I' = (a + \varepsilon, b - \varepsilon)$ interior to I , and the sum of $\mathfrak{S}(f)$ is 0. This is called the **principle of localization**.

Here we give four convergence tests. (1) If f is of bounded variation, $\mathfrak{S}(f)$ converges at every point x to the value $\{f(x+0) + f(x-0)\}/2$. In addition, if f is continuous at every point of a closed interval I , $\mathfrak{S}(f)$ is uniformly convergent in I (**Jordan's test**). As a special case of this test, bounded functions having a finite number of maxima and minima and no more than a finite number of points of discontinuity have convergent Fourier series (**Dirichlet's test**). (2) If the integral $\int_0^{\pi} |\varphi_x(t)|/t dt$ is finite, then $\mathfrak{S}(f)$ converges at x to $f(x)$ (**Dini's test**). (3) If

$$\int_0^h |\varphi_x(t)| dt = o(h)$$

and

$$\lim_{\eta \rightarrow 0} \int_{\eta}^{\pi} \frac{|\varphi_x(t) - \varphi_x(t+\eta)|}{t} dt = 0,$$

then $\mathfrak{S}(f)$ converges at x to $f(x)$ (**Lebesgue's test**). Jordan's and Dini's tests are mutually independent, and both are included in Lebesgue's test, which, although not as convenient in certain cases, is quite powerful. (4) If $f(x)$ is continuous in (a, b) and its modulus of continuity satisfies the condition $\omega(\delta) \cdot \log(1/\delta) \rightarrow 0$ as $\delta \rightarrow 0$ in this interval, then $\mathfrak{S}(f)$ converges uniformly in $(a + \varepsilon, b - \varepsilon)$ (**Dini-Lipschitz test**).

C. Summability

Let $s_n(x)$ be the n th partial sum of the Fourier series $\mathfrak{S}(f)$, and $\sigma_n(x) = \sigma_n(x; f)$ be the first arithmetic mean ((C, 1)-mean) of $s_n(x)$ (i.e., $\sigma_n(x) = (s_0(x) + s_1(x) + \dots + s_n(x))/(n+1)$). Then we have

$$\sigma_n(x) - f(x) = \frac{1}{\pi} \int_0^{\pi} \varphi_x(t) K_n(t) dt,$$

where

$$K_n(t) = \frac{1}{2(n+1)} \left(\frac{\sin((n+1)t/2)}{\sin(t/2)} \right)^2.$$

The expression $K_n(t)$ is called the **Fejér kernel**, and the $\sigma_n(x)$ are often called **Fejér means**. If the right and left limits $f(x \pm 0)$ exist, $\mathfrak{S}(f)$ is † (C, 1)-summable at the point x to the value $(f(x+0) + f(x-0))/2$. If f is continuous at every point of a closed interval I , $\mathfrak{S}(f)$ is uniformly (C, 1)-summable in I (**Fejér theorem**, 1904). As we explain in Section H, there exist continuous functions whose Fourier series are divergent at some points. Thus the summability of $\mathfrak{S}(f)$ is more important than its convergence. Fejér's theorem remains true if we replace (C, 1)-summability by (C, α)-summability ($\alpha > 0$). More generally, if $f \in L_1(-\pi, \pi)$, then $\mathfrak{S}(f)$ is (C, α)-summable for $\alpha > 0$ to the value $f(x)$ almost everywhere (H. Lebesgue). Since (C, α)-summability ($\alpha > 0$) implies † summability by Abel's method, the result of Fejér's theorem is valid for † A-summability. However, the direct study of A-summability is also important. Let $f(r, x)$ be Abel's mean of $\mathfrak{S}(f)$; that is,

$$\begin{aligned} f(r, x) &= \frac{1}{2} a_0 + \sum_{k=1}^{\infty} (a_k \cos kx + b_k \sin kx) r^k \\ &= \frac{1}{\pi} \int_{-\pi}^{\pi} f(x+t) P(r, t) dt, \end{aligned}$$

where $P(r, t) = (1 - r^2)/2(1 - 2r \cos t + r^2)$, $0 \leq r < 1$. We call $P(r, t)$ the **Poisson kernel**. The function $f(r, x)$ is † harmonic inside the unit circle and tends to $f(x)$ as $r \rightarrow 1$ almost everywhere. Hence $f(r, x)$ gives the solution of the † Dirichlet problem for the case of the unit circle.

D. The Gibbs Phenomenon

Let $f(x)$ be of bounded variation and not continuous at 0: $f(0)=0$, $f(+0)=l>0$, $f(-0)=-l$. Then the partial sum $s_n(x)$ converges to $f(x)$ in the neighborhood of 0, but not uniformly. Moreover,

$$\lim_{n \rightarrow \infty} s_n\left(\frac{\pi}{n}\right) = lG,$$

$$G = \frac{2}{\pi} \int_0^\pi \frac{\sin t}{t} dt = 1.1789 \dots$$

Hence as x tends to 0 from above and n tends to ∞ , the values $y = s_n(x)$ accumulate in the interval $[0, lG]$, while $s_n(-x) = -s_n(x)$ in the neighborhood of 0. This phenomenon is called the **Gibbs phenomenon**. If f is of bounded variation, then $\mathfrak{S}(f)$ exhibits the Gibbs phenomenon at every point of simple discontinuity of f . However, the $(C, 1)$ -means of $\mathfrak{S}(f)$ do not exhibit this phenomenon.

E. Conjugate Functions

For any integrable $f \in L_1(-\pi, \pi)$, the integral

$$\tilde{f}(x) =$$

$$\lim_{h \rightarrow 0} -\frac{1}{\pi} \int_h^\pi \left((f(x+t) - f(x-t)) / 2 \tan \frac{t}{2} \right) dt$$

exists almost everywhere. The function $\tilde{f}(x)$ is called the **conjugate function** of $f(x)$. The conjugate series $\mathfrak{S}(f)$ is (C, α) -summable ($\alpha > 0$) to the value $\tilde{f}(x)$ at almost every point, and a fortiori summable by Abel's method. Even if $f \in L_1(-\pi, \pi)$, \tilde{f} does not always belong to the class $L_1(-\pi, \pi)$. For example, $\sum_{n=2}^\infty \cos nx / \log n$ is the Fourier series of a function $f \in L_1(-\pi, \pi)$, but its conjugate series $\sum_{n=2}^\infty \sin nx / \log n$ is not the Fourier series of a function in $L_1(-\pi, \pi)$. However, if both f and \tilde{f} are integrable, $\mathfrak{S}(f) = \mathfrak{S}(\tilde{f})$. If $f \in L_p$ ($p > 1$), then $\tilde{f} \in L_p$ and $\|\tilde{f}\|_p \leq A_p \|f\|_p$; also, $\mathfrak{S}(f) = \mathfrak{S}(\tilde{f})$. If $|f| \log^+ |f|$ is integrable (such a function is said to belong to the **Zygmund class**), then \tilde{f} is integrable and $\mathfrak{S}(f) = \mathfrak{S}(\tilde{f})$. Moreover, in this case there exist constants A and B such that

$$\int_0^{2\pi} |\tilde{f}| dx \leq A \int_0^{2\pi} |f| \log^+ |f| dx + B.$$

If f is merely integrable, so is $|\tilde{f}|^p$ for any $0 < p < 1$, and $\|\tilde{f}\|_p \leq B_p \|f\|$ ($0 < p < 1$). If $f \in \text{Lip } \alpha$ ($0 < \alpha < 1$), then $\tilde{f} \in \text{Lip } \alpha$, but the theorem fails for $\alpha = 0$ and $\alpha = 1$. The conjugate function is important for convergence of partial sums of Fourier series.

F. Mean Convergence

The theorems on conjugate functions enable us to obtain some results for the mean convergence of the partial sums s_n of $\mathfrak{S}(f)$. If $f \in L_p$ ($p > 1$), then $\|f - s_n\|_p \rightarrow 0$; if $f \in L_1$, then $\|f - s_n\|_p \rightarrow 0$, $\|\tilde{f} - \tilde{s}_n\|_p \rightarrow 0$ for every $0 < p < 1$. Also, if $|f| \log^+ |f| \in L_1$, then $\|f - s_n\| \rightarrow 0$, $\|\tilde{f} - \tilde{s}_n\| \rightarrow 0$. As a corollary of this result, we obtain the following theorem, which is a generalization of the Parseval identity: If the Fourier coefficients of functions $f \in L_p$ and $g \in L_q$ ($1/p + 1/q = 1$) are a_n, b_n and a'_n, b'_n , respectively, we have the Parseval formula

$$\frac{1}{\pi} \int_0^{2\pi} fg dx = \frac{1}{2} a_0 a'_0 + \sum_{n=1}^\infty (a_n a'_n + b_n b'_n),$$

where this series is convergent.

G. Analytic Functions of the Class H_p

Let $p > 0$. A complex function $\varphi(z)$ holomorphic for $|z| < 1$ is said to belong to the class H_p (**Hardy class**) if there exists a constant M such that

$$\lim_{r \rightarrow 1} \frac{1}{2\pi} \int_0^{2\pi} |\varphi(re^{i\theta})|^p d\theta \leq M.$$

When $\varphi(z) \in H_p$, the nontangential limit $\varphi(e^{i\theta}) = \lim_{z \rightarrow e^{i\theta}} \varphi(z)$ exists for almost all θ . We write this as $\varphi(e^{i\theta}) = f(\theta) + i\tilde{f}(\theta)$, where $f(\theta), \tilde{f}(\theta)$ belong to the class L_p . Also, $\tilde{f}(\theta)$ coincides with the conjugate function of $f(\theta)$ for $p \geq 1$. For $1 < p < \infty$, H_p is isomorphic to L_p , but for $p = 1$ and $p = \infty$, H_p and L_p are different classes. Using the theory of functions of H_p , we can discuss some properties of Fourier series. If $\varphi(e^{i\theta}) = f(\theta) + i\tilde{f}(\theta)$ is of bounded variation, then $\varphi(e^{i\theta})$ is absolutely continuous and its Fourier series converges absolutely. We set

$$g(\theta) = \left(\int_0^1 (1-r) |\varphi'(re^{i\theta})|^2 dr \right)^{1/2},$$

$$g^*(\theta) =$$

$$\left(\int_0^1 (1-r) dr \int_0^{2\pi} |\varphi'(re^{i(\theta-t)})|^2 P(r, t) dt \right)^{1/2},$$

where $P(r, t)$ is the Poisson kernel. Then $g(\theta) \leq 2g^*(\theta)$, and there exist constants A_p, B, C , and A_μ such that

$$\int_0^{2\pi} |g(\theta)|^p d\theta \leq A_p \int_0^{2\pi} |\varphi(e^{i\theta})|^p d\theta, \quad p > 0,$$

$$\int_0^{2\pi} |g^*(\theta)|^p d\theta \leq A_p \int_0^{2\pi} |\varphi(e^{i\theta})|^p d\theta, \quad p > 1,$$

$$\int_0^{2\pi} |g^*(\theta)| d\theta \leq B \int_0^{2\pi} |\varphi| \log^+ |\varphi| d\theta + C,$$

$$\int_0^{2\pi} |g^*(\theta)|^\mu d\theta \leq A_\mu \left(\int_0^{2\pi} |\varphi(e^{i\theta})| d\theta \right)^\mu, \\ 0 < \mu < 1.$$

Denote by $s_n(\theta)$ and $\sigma_n(\theta)$, respectively, the partial sums and arithmetic means of the Fourier series of $\varphi(e^{i\theta})$, and set

$$\gamma(\theta) = \left(\sum_{n=1}^{\infty} \frac{|s_n(\theta) - \sigma_n(\theta)|^2}{n} \right)^{1/2}$$

Then $0 \neq A_1 \leq g^*(\theta)/\gamma(\theta) \leq A_2 \neq \infty$. From these relations, we can prove that if the indices n_k satisfy the conditions $\beta > n_{k+1}/n_k > \alpha > 1$, $s_{n_k}(\theta)$ converges almost everywhere to $\varphi(e^{i\theta})$ for $\varphi(e^{i\theta}) \in H_p$ ($1 \leq p$). If we set $\Delta_k(\theta) = \sum_{v=n_{k-1}+1}^{n_k} c_v e^{iv\theta}$, $\delta(\theta) = (\sum_{k=0}^{\infty} |\Delta_k(\theta)|^2)^{1/2}$, where $\varphi(e^{i\theta}) \sim \sum_{v=0}^{\infty} c_v e^{iv\theta}$, then $\|\delta(\theta)\|_p \leq A_p \|\varphi\|_p$ ($p > 1$). If $\varphi(z) \in H_p$ ($0 < p < 1$), then $\sum c_n e^{in\theta}$ is $(C, p^{-1} - 1)$ -summable to $\varphi(e^{i\theta})$ almost everywhere. These functions and relations were introduced mainly by J. E. Littlewood and R. E. A. C. Paley and were later generalized by A. Zygmund. There are more precise results by E. Stein [7], G. Sunouchi [8], S. Yano [9], and others.

H. Almost Everywhere Convergence and Divergence

P. du Bois Reymond (1876) first showed that there exists a continuous function whose Fourier series diverges at a point, but the problem of whether Fourier series of continuous functions converge almost everywhere (the so-called **du Bois Reymond problem**) remained unsolved for many years. At last in 1966, L. Carleson [10] proved that the Fourier series of a function belonging to L_2 converges almost everywhere; hence the du Bois Reymond problem was solved affirmatively. Using Carleson's method, R. A. Hunt [12] proved that

$$\int_0^{2\pi} \left(\sup_n |s_n(x)| \right)^p dx \leq A_p \int_0^{2\pi} |f(x)|^p dx, \\ 1 < p < \infty,$$

which implies that the Fourier series of $f \in L_p$ ($1 < p < \infty$) converges almost everywhere. Hunt also proved that

$$\int_0^{2\pi} \left(\sup_n |s_n(x)| \right) dx \\ \leq A \int_0^{2\pi} |f(x)| (\log^+ |f(x)|)^2 dx + A.$$

Moreover, P. Sjölín proved that if

$$\int_0^{2\pi} |f| \cdot \log^+ |f| \cdot \log^+ \log^+ |f| dx < \infty,$$

then the Fourier series of $f(x)$ converges almost everywhere.

On the other hand, A. N. Kolmogorov gave an integrable function with Fourier series diverging everywhere (more precisely, $\limsup_{n \rightarrow \infty} |s_{2^n}(x)| = \infty$ almost everywhere). Using this example, J. Marcinkiewicz showed that there is an $f \in L_1$ such that $s_n(x; f)$ oscillates boundedly almost everywhere. Moreover, there exists an integrable function with integrable conjugate and almost everywhere diverging Fourier series [3]. For any given null set E , we can construct a continuous function whose Fourier series diverges on every $x \in E$.

I. Absolute Convergence

The convergence of the series (1) $\sum(|a_n| + |b_n|)$ implies the absolute convergence of the trigonometric series (2) $a_0/2 + \sum(a_n \cos nx + b_n \sin nx)$. Conversely, if the series (2) converges absolutely in a set of positive measure, the series (1) converges (**Denjoy-Luzin theorem**). For the absolute convergence of Fourier series, we have the following tests: If $f \in \text{Lip } \alpha$ ($\alpha > 1/2$), then $\mathfrak{S}(f)$ converges absolutely, but for $\alpha = 1/2$, this is no longer true. If $f(x)$ is of bounded variation and belongs to $\text{Lip } \alpha$ ($\alpha > 0$), $\mathfrak{S}(f)$ converges absolutely.

Suppose that the Fourier series of a function $f(x)$ is absolutely convergent and the value of $f(x)$ belongs to an interval (a, b) . If $\varphi(z)$ is a function of a complex variable holomorphic at every point of the interval (a, b) , the Fourier series of $\varphi\{f(x)\}$ converges absolutely (**Wiener-Lévy theorem**). As a corollary we obtain that if $\mathfrak{S}(f)$ converges absolutely and $f(x) \neq 0$, then $\mathfrak{S}(1/f)$ converges absolutely. The converse of the Wiener-Lévy theorem was proved by Y. Katznelson [6]. For a given $\varphi(x)$ defined in $[-1, 1]$, if the Fourier series of $\varphi\{f(x)\}$ converges absolutely for every $f(x)$ with absolutely convergent Fourier series ($|f(x)| \leq 1$), then $\varphi(z)$ is holomorphic at every point of the interval $[-1, 1]$.

Many problems concerning this topic still remain unsolved. In particular, the determination of the structure of the functions with absolutely convergent Fourier series has not been completed.

J. Sets of Uniqueness

If $a_n \cos nx + b_n \sin nx$ converges to 0 on a set of positive measure, then $a_n, b_n \rightarrow 0$ (**Cantor-Lebesgue theorem**). A point set $E \subset (0, 2\pi)$ is called a **set of uniqueness** (or **U-set**) if every trigonometric series converging to 0 outside E vanishes identically. A set that is not a U-set is

called a **set of multiplicity** (or **M-set**). G. Cantor showed that every finite set is a U-set, and W. H. Young showed that every denumerable set is a U-set. It is clear that any set E of positive measure is an M-set, but D. E. Men'shov showed that there are \dagger perfect M-sets of measure 0. Moreover, N. K. Bari showed that there exist perfect sets of type U. However, the structure problem of sets of uniqueness has not yet been solved completely.

A set E is said to be of type H (or an H-set) if there exists a sequence of positive integers $n_1 < n_2 < \dots$ and an interval I such that for each $x \in E$, no point of $\{n_k x\}_{k=1}^\infty$ is in $I \pmod{2\pi}$. H-sets are sets of uniqueness, a fact given by A. Rajchman. I. I. Pyatetskii-Shapiro generalized H-sets to $H^{(m)}$ -sets [3].

Lacunary trigonometric series are series in which very few terms differ from zero. Such series can be written in the form

$$\sum_{k=1}^{\infty} (a_k \cos n_k x + b_k \sin n_k x) = \sum_{k=1}^{\infty} A_{n_k}(x).$$

S. Sidon established some of the characteristic properties of such series; he generalized them further and obtained the notion of Sidon sets (\rightarrow 192 Harmonic Analysis). We often define a lacunary series more specifically as a series for which the n_k satisfy Hadamard's gaps; that is, $n_{k+1}/n_k > q > 1$. Then if $\sum_{k=1}^{\infty} (a_k^2 + b_k^2)$ is finite, the series $\sum_{k=1}^{\infty} A_{n_k}(x)$ converges almost everywhere. Conversely, if $\sum_{k=1}^{\infty} A_{n_k}(x)$ is convergent in a set of positive measure, then $\sum_{k=1}^{\infty} (a_k^2 + b_k^2)$ converges. This theorem is related to the Rademacher series and random Fourier series [4].

K. Multiple Fourier Series

Routine extensions to multiple Fourier series from the case of a single variable are easy, but significant results are difficult to obtain. Recently, however, there have been several important contributions in this field.

160 (X.23) Fourier Transform

A. Fourier Integrals

In this article we assume that $f(x)$ is a complex-valued function defined on $\mathbf{R} = (-\infty, \infty)$ and \dagger (Lebesgue) integrable on any finite interval. If the integral

$$\int_{-\infty}^{\infty} f(x) e^{-ixt} dx = \lim_{\substack{A \rightarrow -\infty \\ B \rightarrow \infty}} \int_A^B f(x) e^{-ixt} dx$$

exists, it is called the **trigonometric integral** or **Fourier integral**. We have a general result: If $f(x) \in L_1(-\infty, \infty)$, $K(x)$ is bounded on $(-\infty, \infty)$, and $\int_0^T K(x) dx = o(T)$ ($T \rightarrow \pm\infty$), then $\int_{-\infty}^{\infty} f(x) K(xt) dx$ exists and

$$\lim_{t \rightarrow \pm\infty} \int_{-\infty}^{\infty} f(x) K(xt) dx = 0.$$

In particular, it follows that if $f(x) \in L_1(-\infty, \infty)$, then $\int_{-\infty}^{\infty} f(x) e^{itx} dx$ exists and

$$\lim_{t \rightarrow \pm\infty} \int_{-\infty}^{\infty} f(x) e^{-itx} dx = 0$$

(Riemann-Lebesgue theorem).

B. Fourier's Integral Theorems

Suppose that $f(x)$ is of †bounded variation in an interval including x , or more generally satisfies the assumption for any one of the convergence tests for Fourier series (→ 159 Fourier Series B). Then **Fourier's single integral theorem**

$$\frac{1}{2}(f(x+0)+f(x-0)) = \lim_{A \rightarrow \infty} \frac{1}{\pi} \int_{-\infty}^{\infty} f(t) \frac{\sin A(t-x)}{t-x} dt \quad (1)$$

holds if one of the following three conditions is satisfied: (1) $f(x)/(1+|x|)$ belongs to $L_1(-\infty, \infty)$; (2) $f(x)/x$ tends to zero monotonically as $x \rightarrow \pm\infty$; (3) $f(x)/x = g(x)\sin(px+q)$, where $g(x)$ tends to zero monotonically as $x \rightarrow \pm\infty$ (S. Izumi, 1934). The right-hand side of (1) is called **Dirichlet's integral**.

Let $f(x)$ be of bounded variation in an interval including x (or satisfy some other convergence test for Fourier series). Then **Fourier's double integral theorem**

$$\frac{1}{2}(f(x+0)+f(x-0)) = \frac{1}{\pi} \lim_{T \rightarrow \infty} \int_0^T dt \int_{-\infty}^{\infty} f(u) \cos t(u-x) du \quad (2)$$

holds if one of the following three conditions is satisfied: (4) $f(x) \in L_1(-\infty, \infty)$; (5) $f(x)/(1+|x|) \in L_1(-\infty, \infty)$, and $f(x)$ tends to zero monotonically as $x \rightarrow \pm\infty$; (6) $f(x)/(1+|x|) \in L_1(-\infty, \infty)$ and $f(x) = g(x)\sin(px+q)$, where $g(x)$ tends to zero monotonically as $x \rightarrow \pm\infty$. If $f(x) \in L_1(-\infty, \infty)$, the formula

$$f(x) = \lim_{A \rightarrow \infty} \frac{1}{\pi A} \int_{-\infty}^{\infty} f(t) \frac{\sin^2 A(t-x)}{A(t-x)^2} dt$$

holds almost everywhere, and in particular at any x where $f(x)$ is continuous. More generally, the formula

$$f(x) = \lim_{A \rightarrow \infty} A \int_{-\infty}^{\infty} f(t) K(A(t-x)) dt = \lim_{A \rightarrow \infty} \int_{-\infty}^{\infty} f\left(x - \frac{t}{A}\right) K(t) dt \quad (3)$$

holds at any point x where $f(x+0)$ and $f(x-0)$ exist, if $K(t) \in L_1(-\infty, \infty)$, $\int_{-\infty}^{\infty} K(t) dt = 1$, $|K(t)| < M$, $K(t) = o(t^{-1})$ as $|t| \rightarrow \infty$, and $f(x) \in L_1(-\infty, \infty)$, or if $K(t) \in L_1(-\infty, \infty)$, $\int_{-\infty}^{\infty} K(t) dt = 1$, and $f(x)$ is bounded. Similarly, the formula

$$\lim_{A \rightarrow 0} \int_0^{\infty} f\left(\frac{x}{A}\right) K(x) dx = \mathfrak{M}\{f\} \int_0^{\infty} K(x) dx$$

holds if $\mathfrak{M}\{f\} = \lim_{t \rightarrow \infty} T^{-1} \int_0^T f(t) dt$ exists, $K(x)$ is differentiable, $|x^2 K(x)| \leq C$ ($1 \leq x$), and

$x^{-1} \int_0^x |f(t)| dt \leq D$, where C, D are constants (**Wiener's formula**).

C. Fourier Transforms (→ Appendix A, Table 11.II)

Let $f(x) \in L_1(0, \infty)$. Then

$$F(t) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} f(u) \cos ut du$$

is called the **(Fourier) cosine transform** of $f(x)$. Under the same condition as for the validity of (2), the **inversion formula** of the cosine transform $f(x) = \sqrt{2/\pi} \int_0^{\infty} F(t) \cos xt dt$ holds where we suppose that $f(x) = \frac{1}{2}(f(x+0) + f(x-0))$. If we define $f(-x) = f(x)$, then this is equivalent to the formula (2). Analogously,

$$G(t) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} f(u) \sin ut du$$

is called the **(Fourier) sine transform** of $f(x)$. Under the same condition as for the validity of (2), we get the inversion formula $f(x) = \sqrt{2/\pi} \int_0^{\infty} G(t) \sin xt dt$. More generally, for any $f(x) \in L_1(-\infty, \infty)$,

$$F(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(x) e^{-ixt} dx$$

is called the **Fourier transform** of $f(x)$. Under the same condition as for the validity of (2), the **Fourier inversion formula**

$$f(x) = \frac{1}{\sqrt{2\pi}} \lim_{T \rightarrow \infty} \int_{-T}^T F(t) e^{ixt} dt$$

holds. The cosine transform and the sine transform coincide with the Fourier transform when $f(x) = f(-x)$ and $-f(x) = f(-x)$, respectively.

If for any $f(x)$, $F(t) \in L_q(-\infty, \infty)$ ($1 \leq q < \infty$) exists, for which

$$\int_{-\infty}^{\infty} \left| \frac{1}{\sqrt{2\pi}} \int_{-T}^T f(x) e^{-ixt} dx - F(t) \right|^q dt \rightarrow 0 \quad (T \rightarrow \infty)$$

is valid (i.e., $(1/\sqrt{2\pi}) \int_{-T}^T f(t) e^{-ixt} dt$ converges to $F(x)$ as $T \rightarrow \infty$ in the mean of order q), then we say that $f(x)$ has the **Fourier transform** $F(t)$ in $L_q(-\infty, \infty)$. If $f(x) \in L_p(-\infty, \infty)$ ($1 < p \leq 2$), then $f(x)$ has the Fourier transform $F(t)$ in L_q ($1/p + 1/q = 1$), and $F(t)$ has the Fourier transform $f(-x)$ in L_p (E. C. Titchmarsh). Moreover,

$$\int_{-\infty}^{\infty} |F(t)|^q dx \leq \frac{1}{(2\pi)^{(q/2)-1}} \left(\int_{-\infty}^{\infty} |f(x)|^p dx \right)^{1/(p-1)}.$$

If $f(x), G(x) \in L_p(-\infty, \infty)$ ($1 < p \leq 2$) and their Fourier transforms in L_q are $F(t), g(t)$, respectively, then the **Parseval identity**

$$\int_{-\infty}^{\infty} F(t)G(t)dt = \int_{-\infty}^{\infty} f(x)g(-x)dx$$

holds. The Fourier inversion formula holds, in the sense that

$$\int_0^x F(u)du = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(t) \frac{e^{-ixt} - 1}{-it} dt,$$

$$\int_0^x f(t)dt = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} F(u) \frac{e^{ixu} - 1}{iu} du.$$

The theory of Fourier transforms is valid for cosine and sine transforms. Specifically for $p = 2$, if $f \in L_2(0, \infty)$, then $\sqrt{2/\pi} \int_0^T f(x) \cdot \cos xt dt$ converges in the mean in $L_2(0, \infty)$ to the cosine transform $F(t)$ as $T \rightarrow \infty$, and conversely, the cosine transform of $F(t)$ in L_2 is $f(x)$. The transforms $f(x), F(x)$ are connected by the formulas

$$\int_0^x F(u)du = \sqrt{\frac{2}{\pi}} \int_0^{\infty} f(t) \frac{\sin xt}{t} dt,$$

$$\int_0^x f(t)dt = \sqrt{\frac{2}{\pi}} \int_0^{\infty} F(u) \frac{\sin xu}{u} du,$$

$$\int_0^{\infty} |f(x)|^2 dx = \int_0^{\infty} |F(t)|^2 dt.$$

The theory of Fourier transforms was generalized as follows by G. N. Watson (*Proc. London Math. Soc.*, 35 (1933)). We suppose that $\chi(x)/x \in L_2(0, \infty)$ and

$$\int_0^{\infty} \frac{\chi(xu)\chi(yu)}{u^2} du = \min(x, y). \quad (4)$$

If $f(x) \in L_2(0, \infty)$, then there exists an $F(t) \in L_2(0, \infty)$ such that

$$\int_0^x F(t)dt = \int_0^{\infty} \frac{\chi(xu)f(u)}{u} du,$$

and the inversion formula

$$\int_0^x f(u)du = \int_0^{\infty} \frac{\chi(xt)F(t)}{t} dt$$

and the Parseval identity

$$\int_0^{\infty} |f(x)|^2 dx = \int_0^{\infty} |F(t)|^2 dt$$

hold. $F(t)$ is called the **Watson transform** of $f(x)$. For any $f \in L_2$, equality (4) is necessary for the existence of the Watson transform $F(t)$ for which the inversion formula holds. S. Bochner (1934) generalized this theory further to unitary transformations in L_2 (\rightarrow 192 Harmonic Analysis).

D. Conjugate Functions

Corresponding to Fourier's double integral theorem (2), the integral

$$\lim_{\lambda \rightarrow \infty} \frac{1}{\pi} \int_0^{\lambda} dt \int_{-\infty}^{\infty} \sin t(u-x)f(u)du$$

is called the **conjugate Fourier integral** of the integral in the right-hand side of (2). Formally, this is written $\lim_{x \rightarrow \infty} t^{-1} \int_0^{\infty} (1 - \cos \lambda t) t^{-1} (f(x+t) - f(x-t)) dt$. If $f(x)$ is a sufficiently regular function, the part involving $\cos \lambda t$ tends to 0 as $\lambda \rightarrow \infty$. Now let

$$g(x) = \frac{1}{\pi} \lim_{\substack{A \rightarrow \infty \\ \varepsilon \rightarrow 0}} \int_{\varepsilon}^A \frac{f(x+t) - f(x-t)}{t} dt.$$

For any $f \in L_1(0, \infty)$, the integral exists almost everywhere, and $g(x)$ is called the **conjugate function** or **Hilbert transform** of $f(x)$. If $f \in L_p$ ($p > 1$), then $g(x) \in L_p$ also and we have

$$f(x) = -\frac{1}{\pi} \lim_{\substack{A \rightarrow \infty \\ \varepsilon \rightarrow 0}} \int_{\varepsilon}^A \frac{g(x+t) - g(x-t)}{t} dt$$

and $\int_{-\infty}^{\infty} |g(x)|^p dx \leq M_p \int_{-\infty}^{\infty} |f(x)|^p dx$, where M_p is a constant depending only on p . In particular,

$$\int_{-\infty}^{\infty} |f(x)|^2 dx = \int_{-\infty}^{\infty} |g(x)|^2 dx \quad \text{for } p=2.$$

E. Boundary Functions of Analytic Functions

Suppose that a complex-valued function $f(z)$ ($z = x + iy$) is holomorphic for $y > 0$, $f(x + iy)$ converges as $y \rightarrow 0$ for almost all x to $f(x)$ (which is called the **boundary function**), and $f(x) \in L_p(-\infty, \infty)$ ($p \geq 1$). Moreover, suppose that $f(z)$ is represented by Cauchy's integral formula or Poisson's integral of $f(x)$ on the real line. If either $f(x) \in L_p$ ($p \geq 1$) and has $F(t)$ as its Fourier transform or $f(x)$ is an L_p -Fourier transform of $F(t) \in L_q$ ($q \geq 1$), then a necessary and sufficient condition for the function $f(x)$ to be the boundary function of an analytic function is that $F(t)$ be 0 almost everywhere for $t > 0$ (N. Wiener, R. E. A. C. Paley, E. Hille, J. D. Tamarkin).

F. Generalized Fourier Integrals

Let $|f(x)|/(1 + |x|^k) \in L_1(-\infty, \infty)$ for a positive integer k and

$$L_k = L_k(t, x) = \begin{cases} \sum_{v=0}^{k-1} \frac{(-itx)^v}{v!}, & |x| \leq 1, \\ 0, & |x| > 1, \end{cases}$$

$$E_k(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f(x) \frac{e^{-itx} - L_k}{(-ix)^k} dx.$$

The function $E_k(t)$ or one that differs from $E_k(t)$ by a polynomial of degree at most k is called the k th transform of $f(x)$. We write formally $f(x) = \int_{-\infty}^{\infty} e^{ixt} d^k E_k(t)$. Actually, if we give an appropriate meaning to the integral, this formula itself is valid (H. Hahn, *Wiener Berichte*, 134 (1925); S. Izumi, *Tôhoku Science Rep.*, 23 (1935)). (For the theory and applications of k th transforms \rightarrow [2, ch. 6].)

G. Applications of Fourier Transforms

Suppose that $f(x) \in L_1(-\infty, \infty)$, $F(t)$ is its Fourier transform, and $f(x) = o(e^{-\theta(x)})$, where $\theta(x)$ is positive and increasing. If $\int_1^\infty \theta(x)x^{-2} dx = \infty$ and $F(t)$ vanishes identically in an interval, then $F(t) \equiv 0$ over $(-\infty, \infty)$. If $\int_1^\infty \theta(x)x^{-2} dx < \infty$, then there exists a function $f(x)$ such that $F(t)$ vanishes identically in an interval, but $F(t)$ does not vanish identically in $(-\infty, \infty)$ (Wiener, Paley, N. Levinson). These results are applicable to the theory of † quasi-analytic functions.

Let $f(x) \in L_1(-\infty, \infty)$. Then a necessary and sufficient condition for any function in $L_1(-\infty, \infty)$ to be approximated as closely as we wish by linear combinations of the translations $\sum_{k=1}^N a_k f(x+h_k)$ of $f(x)$ with respect to the L_1 -norm is that the Fourier transform of $f(x)$ does not vanish at any real number. When $f(x) \in L_2(-\infty, \infty)$, a necessary and sufficient condition that an arbitrary function in $L^2(-\infty, \infty)$ can be approximated as closely as we wish by $\sum_{k=1}^N a_k f(x+h_k)$ with respect to the L_2 -norm is that the zeros of the Fourier transform of $f(x)$ have measure zero (Wiener). This result was used by Wiener to prove the **generalized Tauberian theorem**: Suppose that $g_1(x) \in L_1(-\infty, \infty)$ and its Fourier transform never vanishes. Moreover, let $g_2(x) \in L_1(-\infty, \infty)$ and $p(x)$ be bounded over $(-\infty, \infty)$. Then $\lim_{x \rightarrow \infty} \int_{-\infty}^x g_1(x-t)p(t) dt = A \int_{-\infty}^{\infty} g_1(t) dt$ implies that $\lim_{x \rightarrow \infty} \int_{-\infty}^x g_2(x-t)p(t) dt = A \int_{-\infty}^{\infty} g_2(t) dt$. Another type of Wiener theorem is concerned with † Stieltjes integrals. Suppose that

$$\sum_{n=-\infty}^{\infty} \sup_{n \leq x < n+1} |g_1(x)| < \infty$$

(hence $g_1(x) \in L_1$) and that the Fourier transform of $g_1(x)$ never vanishes. Moreover, let

$$\sum_{n=-\infty}^{\infty} \sup_{n \leq x < n+1} |g_2(x)| < \infty$$

and let $\int_x^{x+1} |d\alpha(t)|$ be bounded. Then

$$\lim_{x \rightarrow \infty} \int_{-\infty}^x g_1(x-t) d\alpha(t) = A \int_{-\infty}^{\infty} g_1(t) dt$$

implies

$$\lim_{x \rightarrow \infty} \int_{-\infty}^x g_2(x-t) d\alpha(t) = A \int_{-\infty}^{\infty} g_2(t) dt.$$

From these general theorems, we can prove various † Tauberian theorems about the summation of series. Also, these results were applied to the proof of the † prime number theorem by S. Ikehara and E. Landau (Wiener [1]). In the general Tauberian theorem, the boundedness of $p(t)$ can be replaced by one-sided boundedness (H. R. Pitt, 1938). In fact, the first form of the theorem still holds if we replace the condition by the following one: g_1 and g_2 are continuous, $g_1(x) \geq 0$, the Fourier transform of $g_1(x)$ does not vanish, $g_2(x)$ satisfies the conditions of the second theorem, and $p(x) \geq C$. (Concerning Fourier transforms on the topological groups \rightarrow 192 Harmonic Analysis; and concerning Fourier transforms of the distributions \rightarrow 125 Distributions and Hyperfunctions).

H. Fourier Transforms of Distributions

The Fourier transform is defined in higher-dimension \mathbf{R}^n by

$$\mathcal{F}(f) = (\sqrt{2\pi})^{-n} \int e^{-ix\xi} f(x) dx, \quad f \in L_1,$$

$$x\xi = x_1\xi_1 + x_2\xi_2 + \dots + x_n\xi_n.$$

One denotes it by $\hat{f}(\xi)$. The inverse transform is defined by

$$\overline{\mathcal{F}}(g) = (\sqrt{2\pi})^{-n} \int e^{ix\xi} g(\xi) d\xi.$$

Differentiation under the integral sign gives

$$D^\alpha \hat{f}(\xi) = (\sqrt{2\pi})^{-n} \int e^{-ix\xi} (-ix)^\alpha f(x) dx,$$

$$D^\alpha = (\partial/\partial x_1)^{\alpha_1} \dots (\partial/\partial x_n)^{\alpha_n},$$

under the assumption $(1+|x|)^{|\alpha|} f(x) \in L_1$ ($|\alpha| = \alpha_1 + \dots + \alpha_n$). Roughly speaking, the decreasing order of $f(x)$ when $|x| \rightarrow \infty$ is reflected in the differentiability of $\hat{f}(\xi)$. In the same way,

$$(i\xi)^\alpha \hat{f}(\xi) = (\sqrt{2\pi})^{-n} \int e^{-ix\xi} D^\alpha f(x) dx,$$

which shows that the differentiability of $f(x)$ is reflected in the decreasing order of $\hat{f}(\xi)$.

The same statements can evidently be made for the relation between $g(\xi)$ and its inverse Fourier transform.

Let \mathcal{S} be the space of rapidly decreasing functions $\varphi(x)$, i.e., such that for all positive integers k and $\alpha \geq 0$, $(1+|x|)^k D^\alpha \varphi(x)$ remains bounded (\rightarrow 125 Distributions and Hyperfunctions). From the facts above, it follows that the

linear mapping $f(x) \mapsto \mathcal{F}(f)$ is a topological isomorphism from \mathcal{S}_x onto \mathcal{S}_ξ . Let \mathcal{S}' be the dual space of \mathcal{S} . Usual function spaces in classical analysis are contained in \mathcal{S}' , for instance, the L_p -space and that of functions increasing at most of polynomial order at infinity.

Let $T \in \mathcal{S}'_x$. Then the mapping $\varphi \in \mathcal{S}_\xi \mapsto T(\mathcal{F}\varphi)$ is continuous, and $\mathcal{F}T \in \mathcal{S}'_\xi$ is defined by $\mathcal{F}T(\varphi) = T(\mathcal{F}\varphi)$. \mathcal{F} is also a topological isomorphism from \mathcal{S}'_x onto \mathcal{S}'_ξ . Take as an example the distribution p.v. $1/x$. This is no longer a function; however, its Fourier transform can be calculated as follows:

$$\lim_{\substack{\varepsilon \rightarrow 0 \\ A \rightarrow \infty}} (\sqrt{2\pi})^{-1} \int_{\varepsilon \leq |x| \leq A} e^{-ix\xi} \frac{dx}{x} = \frac{2i}{\sqrt{2\pi}} \\ \times \lim_{A \rightarrow \infty} \int_0^A \frac{\sin(x\xi)}{x} dx = \begin{cases} \sqrt{\frac{\pi}{2}} i, & \xi > 0, \\ -\sqrt{\frac{\pi}{2}} i, & \xi < 0, \end{cases}$$

where the limit is taken with respect to the topology of \mathcal{S}' .

Using the definition above, classical results can be extended to \mathcal{S}' almost automatically. For example, $\mathcal{F}(D^\alpha T) = (i\xi)^\alpha \mathcal{F}(T)$, $\mathcal{F}((-ix)^\alpha T) = D^\alpha \mathcal{F}(T)$. Moreover, if $T \in \mathcal{S}'$, then $\mathcal{F}T = \sqrt{2\pi}^{-n} T(e^{-ix\xi})$. In particular, $\mathcal{F}\delta = (2\pi)^{-n/2}$.

The **Plancherel theorem** says that if for $f(x) \in L_2$ one defines its Fourier transform by

$$\hat{f}(\xi) = \text{l.i.m.}_{A \rightarrow \infty} \sqrt{2\pi}^{-n} \int_{|x| \leq A} e^{-ix\xi} f(x) dx,$$

then the correspondence $f(x) \mapsto \hat{f}(\xi)$ is a unitary mapping from L_2 onto L_2 , i.e.,

$$\int |f(x)|^2 dx = \int |\hat{f}(\xi)|^2 d\xi.$$

This result can be extended. For any non-negative integer m , the element of H^m (\rightarrow 168 Function Spaces) is characterized by its Fourier transform: $f(x) \in H^m$ if and only if $(1 + |\xi|)^m \hat{f}(\xi) \in L_2$. Furthermore, for arbitrary real s , the space H^s can be defined as the set of all elements of \mathcal{S}' whose Fourier transform $\hat{f}(\xi)$ satisfies $(1 + |\xi|)^s \hat{f}(\xi) \in L_2$. H^s and H^{-s} are dual to each other.

For $f \in L_1$, $g \in L_2$, or $f, g \in L_2$, the convolution makes sense as a function, and it holds that $\mathcal{F}(f * g) = \mathcal{F}(f)\mathcal{F}(g)$. This relation can be extended to distributions, to state

$$\mathcal{F}(S * T) = (\mathcal{F}S)(\mathcal{F}T).$$

This holds for $(S, T) \in \mathcal{S}' \times \mathcal{S}'$, $\mathcal{D}'_{L_2} \times \mathcal{D}'_{L_2}$ is the dual of \mathcal{D}_{L_2} , etc.

Fourier transforms are also often defined by

$$\hat{f}(\xi) = \int e^{-ix\xi} f(x) dx \quad \text{or} \quad = \int e^{-2\pi i x \xi} f(x) dx.$$

In the former case, the inversion formula takes the form

$$f(x) = (2\pi)^{-n} \int e^{ix\xi} \hat{f}(\xi) d\xi,$$

and the Parseval identity becomes

$$\int |f(x)|^2 dx = (2\pi)^{-n} \int |\hat{f}(\xi)|^2 d\xi.$$

161 (IV.3) Free Groups

A. General Remarks

A group F is called a **free group** if it is the *free product (\rightarrow 190 Groups M) of *infinite cyclic groups G_1, \dots, G_n generated by a_1, \dots, a_n , respectively. Then n is called the **rank** of F . A

free product of \dagger semigroups is defined similarly to that of groups, and the free product of infinite cyclic semigroups $G_i = \{1, a_i, a_i^2, \dots\}$ ($i = 1, \dots, n$) is called a **free semigroup** generated by n elements a_i ($i = 1, \dots, n$).

If a group G is generated by subgroups H_i ($i = 1, \dots, n$) isomorphic to G_i , then G is a homomorphic image of the free product of the groups G_i . A subgroup $\neq \{e\}$ of the free product F of groups G_i is itself the free product of a free group and several subgroups, each of which is conjugate in F to a subgroup of some G_j (A. G. Kurosh, 1934). Notably, a subgroup $\neq \{e\}$ of a free group is itself a free group (O. Schreier, *Abh. Math. Sem. Univ. Hamburg*, 5 (1927)). A subgroup of index j of a free group of rank n is a free group of rank $1 + j(n-1)$ (Schreier).

Let F be the free group generated by n elements a_1, \dots, a_n , and let G be a group generated by n elements b_1, \dots, b_n . Then there is a homomorphism of F onto G . Let N be its kernel. If the class of a \dagger word $w(a_1, \dots, a_n)$ belongs to N , then we have $w(b_1, \dots, b_n) = 1$. We call $w(b_1, \dots, b_n) = 1$ a **relation** among the generators b_1, \dots, b_n . If N is the minimal normal subgroup of F containing the classes of words $w_1(a_1, \dots, a_n), \dots, w_m(a_1, \dots, a_n)$, then the relations $w_1(b_1, \dots, b_n) = 1, \dots, w_m(b_1, \dots, b_n) = 1$ are called **defining relations** (or **fundamental relations**). If generators a_1, \dots, a_n and words $w_1(a_1, \dots, a_n), \dots, w_m(a_1, \dots, a_n)$ are given, then there is a group generated by a_1, \dots, a_n with defining relations $w_1(a_1, \dots, a_n) = 1, \dots, w_m(a_1, \dots, a_n) = 1$. In fact, let F be the free group generated by a_1, \dots, a_n and N the minimal normal subgroup containing the classes of words $w_1(a_1, \dots, a_n), \dots, w_m(a_1, \dots, a_n)$. Then the factor group F/N is such a group. A free group is a group with an empty set of defining relations. In the preceding discussion, n and m are not necessarily finite. If both n and m are finite, then G is called **finitely presented**.

B. The Word Problem

If a finitely presented group G is given, then a general procedure has to be determined by which it can be decided, in a finite number of computational steps, whether a given word equals the identity element as an element of G . This is called the **word problem** (\rightarrow 190 Groups M). A solution to the word problem does not always exist (P. S. Novikov [8], 1955); in fact, there is a group with two generators and 32 defining relations for which the word problem cannot be solved (W. Boone [7]). However, it was shown by V. A. Tartakovskii that the problem can be solved for a large class of

groups. W. Magnus (1931) showed that it is solvable for any group with a single defining relation. The word problem is an example of decision problems (\rightarrow 97 Decision Problem). The word problem for groups is closely related to that for semigroups (A. M. Turing, 1937; E. L. Post, 1947; A. A. Markov, 1947). Similar problems for other algebraic systems can also be considered. The problem of determining a general procedure by which it can be decided, in a finite number of steps, whether two given words interpreted as elements of G can be transformed into each other by an (inner) automorphism of G is called the **transformation problem**.

Let F be a free group of rank n and $F = F_1 \supset \dots \supset F_r \supset F_{r+1} \supset \dots$ be the \dagger lower central series of F . Then F_r/F_{r+1} is a \dagger free Abelian group of rank $\mu_n(r) = (1/r) \sum_{d|r} \mu(r/d) n^d$, where μ is the \dagger Möbius function (E. Witt). The intersection of all subgroups of F of finite index is the identity element.

C. The Burnside Problem

The original problem of Burnside is: If every element of a group G is of finite order (but not necessarily of bounded order) and G is finitely generated, is G a finite group? E. S. Golod [6] (1964) showed that this problem for p -groups has a negative solution. The following is the more usual form of the **Burnside problem**: If a group G is finitely generated and the orders of elements of G divide a given integer r , is G finite? Let F be a free group of rank n , N be the normal subgroup of F generated by all the r th powers x^r of elements of F , and $B(r, n) = F/N$. Then the problem is the same as the question of whether $B(r, n)$ is finite. For $r = 2, 3, 4, 6$ the group is certainly finite (I. N. Sanov, M. Hall). The **restricted Burnside problem** is the question whether the orders of finite factor groups of $B(r, n)$ are bounded. It was solved affirmatively for r a prime (A. I. Kostrikin [5], 1959).

A group generated by two generators x, y and satisfying the relations $x^u = y^v = (xy)^w = 1$ (where u, v, w are integers) is infinite if $1/u + 1/v + 1/w - 1 \leq 0$, and is of order g if $0 < 1/u + 1/v + 1/w - 1 = 2/g$.

There is also a finitely presented group which is isomorphic to its proper factor group (B. H. Neumann).

162 (XII.1) Functional Analysis

The origin of **functional analysis** can be traced to the 1887 work of V. Volterra. He stressed the important notion of operations or **operators**, that is, generalized functions of which the domains as well as the ranges are sets of functions. A typical example is the operator assigning to a function f its derivative f' . An operator is called a **functional** if its values are numbers, as in the case of the operator assigning to a function f the value $f'(a)$ or the value $\int_a^b f(t) dt$. In 1896, Volterra considered the operator mapping a continuous function f to a continuous solution φ of the integral equation $f(x) = \varphi(x) - \int_a^x K(x, y) \varphi(y) dy$, where $K(x, y)$ is a continuous function. Defining $I\varphi = \varphi$ and $(K\varphi)(x) = \int_a^x K(x, y) \varphi(y) dy$, he showed that φ is given by $\varphi = (I - K)^{-1}f = f + Kf + K^2f + \dots$, where $K^n f = K(K^{n-1}f)$. Following this lead, I. Fredholm studied in 1900 the integral equation $f(x) = \varphi(x) - \lambda \int_a^b K(x, y) \varphi(y) dy$ containing a parameter λ . He proved the so-called **†alternative theorem**: For a given λ_0 , the operator equation $(I - \lambda_0 K)\varphi = f$, $(K\varphi)(x) = \int_a^b K(x, y) \varphi(y) dy$, either admits a uniquely determined continuous solution φ for every continuous function f or else $(I - \lambda_0 K)\varphi_0 = 0$ admits a nontrivial continuous solution $\varphi_0 \neq 0$. D. Hilbert discussed (1904–1910) a **†continuous linear operator** K defined on the **†Hilbert space** L_2 with values in L_2 , and he called a complex number λ_0 a **†spectrum** of K if $(I - \lambda_0 K)$ does not have a continuous linear inverse. He proved that if K is **†Hermitian**, then K admits a **†spectral resolution** with real spectra only. One of his

outstanding contributions was the discovery of the **†continuous spectrum**. In 1918, F. Riesz proved that Fredholm's alternative theorem holds for a **†completely continuous linear operator** in the space of continuous functions, and later the result was extended to Banach spaces.

In 1932, three important books by S. Banach [1], J. von Neumann [2], and M. H. Stone [3] were published. These books treated **†closed linear operators** that are not necessarily continuous. The notion of **†Banach space** was introduced: a **†normed linear space** complete with respect to the distance $\text{dis}(x, y) = \|x - y\|$. By making use of the **†Baire-Hausdorff theorem** and the **†Hahn-Banach theorem**, Banach proved, for closed linear operators in Banach spaces, the fundamental principle consisting of the **†open mapping theorem**, the **†closed graph theorem**, the **†uniform boundedness theorem**, the **†resonance theorem**, and the **†closed range theorem**. These theorems were modified to be applicable in locally convex topological linear spaces by the Bourbaki group beginning in the late 1940s.

In 1929, von Neumann proved, as a mathematical foundation of quantum mechanics, that a closed linear operator T in a Hilbert space admits spectral resolution with real spectra if and only if T is a **†self-adjoint operator** (→ also Stone [3]). The condition that a closed linear operator is a **†function of a self-adjoint operator** was given by von Neumann, F. Riesz, and Y. Mimura (1934–1936). K. Friedrichs (1934) proved that a **†semibounded linear operator** admits a self-adjoint extension. T. Kato [4] (1950) proved that a Schrödinger-type Hermitian operator is **†essentially self-adjoint**.

Von Neumann's **†mean ergodic theorem** in the Hilbert space (1932) was extended to Banach spaces by K. Yosida, S. Kakutani, and Riesz in 1936. G. D. Birkhoff's **†pointwise ergodic theorem** (1931) was extended by N. Wiener (1939), Yosida (1940), E. Hopf (1954), N. Dunford (1955), R. V. Chacon and D. S. Ornstein (1960), and others in various ways. The **†Abelian ergodic theorems** were discussed by E. Hille and R. S. Phillips [5] and Yosida [6].

The notion of **†Banach algebra** was introduced by M. Nagumo in 1936. I. M. Gel'fand proved that a commutative Banach algebra with multiplicative unit e satisfying $\|e\| = 1$ (= the normed ring) admits a representation by an algebra of complex-valued continuous functions (1941).

The **†reflexivity** as well as the **†duality** of Banach spaces were studied by S. Kakutani (1939), V. L. Shmul'yan (1940), and W. T. Eberlein (1941).

The notion of \dagger vector lattice ($=\dagger$ Riesz space) was introduced in analysis by Riesz (1930). This was followed by the work of L. V. Kantorovich (1935) and H. Freudenthal (1936). Kakutani gave two standard types of \dagger Banach lattice: the \dagger abstract (M) space (1940) and the \dagger abstract (L) space (1941). M. Krein and S. Krein (1940) and Yosida and M. Fukamiya (1940) discussed the (M)-type vector lattices, and Yosida (1941), the (L)-type vector lattices. H. Nakano (1940–1941) and T. Ogasawara and F. Maeda (1942) studied the spectral resolution of the Banach lattice.

The connection between \dagger Brownian motion and \dagger potential theory was clarified by Kakutani (1942), and extended by J. L. Doob (1956) and G. A. Hunt (1957–1958).

The \dagger one-parameter semigroup of continuous linear operators in Banach spaces was studied by Hille and Yosida, and they gave in 1948 a characterization of the \dagger infinitesimal generator of such semigroups. Its dual was given by Phillips (1955). The one-parameter semigroup of nonlinear \dagger contractive operators in Hilbert spaces was studied by Y. Kōmura (1967), who obtained a nonlinear version of the Hille-Yosida theorem. This has been extended considerably in Banach spaces by many scholars, e.g., Kato (1967), M. G. Crandall and A. Pazy (1969), Crandall and T. Liggett (1971), I. Miyadera and S. Oharu (1970), H. Brezis (1973), P. Bénéilan (1973), and others.

In 1936, S. Sobolev gave a generalization of the notion of functions and their derivatives through integration by parts. This generalization has been extended by L. Schwartz (1945–) [9] to the notion of \dagger distributions, which are continuous linear functionals defined on the function spaces $\mathcal{D}(\mathbf{R}^n)$ and $\mathcal{S}(\mathbf{R}^n)$, and this extension gives, e.g., a reasonable interpretation of Dirac's δ -function. Since 1959, Gel'fand [10] has been publishing, with his collaborators, books on the distribution theory pertaining to function spaces other than $\mathcal{D}(\mathbf{R}^n)$ and $\mathcal{S}(\mathbf{R}^n)$. M. Sato introduced (1959–1960) [11] the theory of \dagger hyperfunctions, as a generalization of distribution theory. In the case of one independent variable, a hyperfunction f may be defined as a generalized boundary value on the real axis R of a holomorphic function F defined in $\mathbf{C}^1 - \mathbf{R}^1$. Hyperfunction theory has been refined to \dagger microlocal analysis and studied extensively by Sato, A. Martineau, H. Komatsu, P. Schapira, T. Kawai, M. Kashiwara, M. Morimoto, A. Kaneko, and others (\rightarrow [12]).

163 (XIII.16) Functional-Differential Equations

A. General Remarks

In many models, it is assumed that the future behavior of a system under consideration is governed only by its present state and not by past states. However, for various systems arising in practical problems we cannot ignore the effect of the past on the future. Such a phenomenon is often observed in population problems, epidemiology, chemical reactions, system engineering, and so on.

The description of such phenomena may involve **difference-differential equations**

$$\dot{x}(t) = f(t, x(t), x(t-h_1), \dots, x(t-h_m)), \quad (1)$$

or **integro-differential equations**

$$\dot{x}(t) = g(t, x(t)) + \int_0^t f(t, s, x(t), x(s)) ds. \quad (2)$$

An enormous variety of equations is discussed in the literature, but most of them can be

expressed in the form

$$\dot{x}(t) = f(t, x(s)), \quad (3)$$

which is usually called the **functional differential equation**; here s varies in an interval I_t and f depends on the function x of I_t . If t is the right or left endpoint of the interval I_t , then (3) is said to be of **retarded** or **advanced type**, respectively. Most of the results obtained have been from work on equations of retarded type. In this case, the maximal length of the interval I_t is called the **retardation (delay, lag, deviation, etc.)**, and (3) is often called the **retarded differential equation, delay differential equation, or differential equation with lag (retardation, deviating argument)**.

B. Historical Remarks

Functional differential equations of a sort were studied by Johann Bernoulli in the 18th century in connection with the string problem. Since then, a good deal of work has been done in this field by many people; some of this work was done before the beginning of this century. Among the investigators, Volterra [1, 2] is noteworthy for his systematic study on rather general equations related to problems of predator-prey populations and viscoelasticity, though his results were ignored by his contemporaries. In the early 1940s, Minorsky [3], in his famous study of ship stabilization, pointed out the importance of delay effects in control theory, with many of the modern issues first appearing in his work [4]. Mishkis [5] studied linear systems extensively, and Driver [6] gave a unified representation for functional differential equations. Important achievements were given by Krasovskii [7] and Bellman and Cooke [8]. They laid the foundation for the qualitative theory of functional differential equations. Inspired by these works, many books (such as [9–14]) were published. Owing to these books together with many articles on this field, the theory of functional differential equations has become an important branch in the theory of differential equations.

Equations of advanced type are treated in, e.g., [5, 8], but qualitative theory for them has hardly been established. The equation

$$\dot{x}(t) = ax(t) + bx(\lambda t) \quad \text{on} \quad 0 \leq t < \infty \quad (4)$$

is of advanced type if $\lambda > 1$, and its analytic solution has been studied in detail. Equation (3), whose right-hand side involves differential operators, e.g., $\dot{x}(t) = f(t, x(t), x(t-h), \dot{x}(t-h))$, is said to be of **neutral type** [5, 8, 14], and is generally considered to be of neither retarded nor advanced type because of its distinctive

features. However, Hale [14] originated the study of a class of equations of neutral type for which the general qualitative theory can be developed in the same manner as for equations of retarded type.

For the case of infinite retardation, proper choice of the space of functions x contained in the right-hand side of (3) is of great significance. A general treatment of the phase space for equations with infinite retardation in an axiomatic setting is given in [15].

C. Phase Space

For simplicity, let I_t always be the interval $[t-h, t]$ with a finite retardation $h > 0$. A **solution** of (3) starting at $t = \tau$ is a function defined on $[\tau-h, a)$ for $a > \tau$ such that the solution coincides with a preassigned function (the **initial function**) on $[\tau-h, \tau]$ and is continuously differentiable and satisfies (3) on $[\tau, a)$. Since a solution starting at $t = \tau$ must be continuous for $t \geq \tau$, it is quite natural, as is done in much of the literature in order to develop a qualitative theory, to choose the space $C([t-h, t], \mathbf{R}^n)$ of continuous \mathbf{R}^n -valued functions on $[t-h, t]$ as a space of functions x involved in the right-hand side of (3). Introducing a symbol x_t which represents an element of $C = C([-h, 0], \mathbf{R}^n)$ defined by $x_t(s) = x(t+s)$ ($s \in [-h, 0]$), we can rewrite (3) in a more convenient form:

$$\dot{x}(t) = f(t, x_t), \quad (E) \quad (5)$$

where the function $f(t, \varphi)$ is defined on $\mathbf{R} \times C$ (or on its subspace). Here C is considered to be a Banach space with the norm $\|\varphi\| = \max_{s \in [-h, 0]} |\varphi(s)|$, $|\cdot|$ being a norm in \mathbf{R}^n . The space C is said to be the **phase space** of (E), and the initial condition can be written as

$$x_\tau = \xi, \quad (\tau, \xi) \in \mathbf{R} \times C. \quad (5)$$

D. Initial Value Problem

Let $f(t, \varphi)$ be a continuous functions defined on an open domain $D \subset \mathbf{R} \times C$. The **initial value problem** is to find a solution of (E)–(5) for a given $(\tau, \xi) \in D$. Many fundamental results hold as for ordinary differential equations: (a) There always exists a solution of (E)–(5) under the continuity of f on D . Here, the solution means the one to the right. No general existence theorem is given for the solution to the left. (b) The solution of (E)–(5) is unique, if f satisfies the **Lipschitz condition**: $|f(t, \varphi) - f(t, \psi)| \leq L \|\varphi - \psi\|$ in a neighborhood of each point of D , where L is a constant depending on the neighborhood. (c) If f varies in the space $C(D, \mathbf{R}^n)$

equipped with the compact open topology and if the solution of (E)–(5) is unique for every $(\tau, \xi) \in D$, then the solution is continuous as a function of (τ, ξ, f) . (d) If f is completely continuous on D , that is, f is a continuous mapping of bounded subsets of D into bounded sets in \mathbf{R}^n , then every solution can be continuable to the right as long as it remains bounded or stays away from the boundary of D . This assertion is no longer true in the absence of complete continuity.

To prove the existence theorem, Schauder's fixed point theorem is utilized; the Picard successive method is also effective under the Lipschitz condition. Consider the case when $f(t, \varphi)$ can be written as $f(t, \varphi) = g(t, \varphi(0), \varphi)$, where $g(t, x, \varphi)$ is defined for $(t, x, \varphi) \in \mathbf{R} \times \mathbf{R}^n \times C$, and $g(t, x, \varphi) = g(t, x, \psi)$ if $\varphi(s) = \psi(s)$ on $[-h, -\delta]$, $\delta > 0$. Equation (1) is one such case, where $h = \max h_k$, $\delta = \min h_x$. Then, $g(t, x, x_t)$ is a function of (t, x) alone on $[\tau, \tau + \delta]$ under the given condition (5), that is, (E) is reduced to an ordinary differential equation. This makes it possible to find a solution of (E)–(5) by matching successively the solutions of ordinary differential equations on $[\tau, \tau + \delta]$, $[\tau + \delta, \tau + 2\delta]$, This is the **step-by-step method**, which is effective even for equations of neutral type with the same property.

Under uniqueness, the solution $x(t)$ of (E) induces a mapping $T(t, \tau): G(t, \tau) \rightarrow C$, $t \geq \tau$, which maps $x_t \in G(t, \tau)$ to $x_t \in C$, where $G(t, \tau) \subset C$ is the set of ξ for which the solution of (E)–(5) is continuable up to t . Then

$$T(t, s)T(s, \tau) = T(t, \tau) \quad \text{for} \quad t \geq s \geq \tau, \tag{6}$$

and $T(t, \tau)$ is strongly continuous in t . If (E) is **autonomous**, that is, $f(t, \varphi)$ is independent of t , then there exists a mapping $T(t)$, $t \geq 0$, satisfying $T(t - \tau) = T(t, \tau)$, and $\{T(t)\}_{t \geq 0}$ becomes a one-parameter semigroup.

E. Linear System

When $f(t, \varphi)$ is continuous on $I \times C$ for an interval I and is linear in φ , equation (E) is said to be a **linear system** (denoted by (L)). In this case, $f(t, \varphi)$ satisfies the Lipschitz condition with $L = L(t)$ on $I \times C$ for a continuous function $L(t)$ of I , which also implies that f is completely continuous. Thus the solution of (L)–(5) uniquely exists over $[\tau, \infty) \cap I$ for any $(\tau, \xi) \in I \times C$, and the mapping (the **fundamental** or **solution operator**) $T(t, \tau)$ is a \dagger bounded linear operator on C for any $t, \tau \in I$, $t \geq \tau$, and \dagger compact if $t \geq \tau + h$. $T(t, \tau)$ corresponds to the fundamental matrix for ordinary linear differential equations, but it is not invertible in general.

A continuous function $f(t, \varphi)$ linear in φ

may be expressed in the form

$$f(t, \varphi) = \int_{-h}^0 [d_s \eta(t, s)] \varphi(s), \tag{7}$$

where $\eta(t, s)$ is an $n \times n$ matrix defined on $I \times [-h, 0]$, which is measurable in (t, s) and of \dagger bounded variation in s with a \dagger total variation less than $L(t)$, and the integration is that of Stieltjes with respect to s . From this fact it follows that the range of the initial functions can be extended to the space of \dagger piecewise-continuous functions, and the solution $x(t)$ of the nonhomogeneous linear system $\dot{x}(t) = f(t, x_t) + p(t)$ through $(\tau, \xi) \in I \times C$ can be represented by the **constant variational formula**

$$x(t) = [T(t, \tau)\xi](0) + \int_{\tau}^t [T(t, s)\Gamma](0)p(s)ds, \quad t \geq \tau,$$

where $\Gamma(s) = E$ (the unit matrix) for $s = 0$, and $\Gamma(s) = O$ (the zero matrix) for $s < 0$.

F. Autonomous Linear System

Let (L) be an autonomous linear system

$$\dot{x}(t) = f(x_t). \tag{AL}$$

In this case, (7) is not different from the Riesz representation theorem $f(\varphi) = \int_{-h}^0 [d\eta(s)] \varphi(s)$. For (AL) the fundamental operator $T(t)$ plays an extremely important role. As was seen, $\{T(t)\}_{t \geq 0}$ is a one-parameter semigroup of bounded linear operators $T(t)$ which is strongly continuous in $t \geq 0$ and compact for $t \geq h$. Thus the asymptotic behavior of the solutions of (AL) are determined by the distribution of the spectra $\sigma(A)$ of the infinitesimal generator A of $T(t)$, which is given by $A\varphi = \dot{\varphi}$ with the domain $D(A) = \{\varphi \in C \mid \dot{\varphi} \in C \text{ and } \varphi(0) = f(\varphi)\}$. The properties of $T(t)$ assert that: (a) $\sigma(A)$ consists of point spectra alone. (b) The number of $\Lambda_\alpha = \{\lambda \in \sigma(A) \mid \operatorname{Re} \lambda \geq \alpha\}$ is at most finite for any $\alpha \in \mathbf{R}$. (c) For every $\lambda \in \sigma(A)$ the dimension of the generalized eigenspace of λ is finite. (d) The spectra of A coincide with the roots (**characteristic roots**) of the **characteristic equation** of (AL),

$$\det \left[\lambda E - \int_{-h}^0 e^{\lambda s} d\eta(s) \right] = 0,$$

together with their multiplicities. (e) $e^{\lambda t} \in \sigma(T(t))$, $t \geq 0$, if and only if $\lambda \in \sigma(A)$.

Let P_α , $\alpha \in \mathbf{R}$, be the linear space spanned by the generalized eigenfunctions corresponding to a $\lambda \in \Lambda_\alpha$. Then, (a) P_α is invariant under $T(t)$, that is, $T(t)P_\alpha \subset P_\alpha$ for $t \geq 0$; (b) the restriction of $T(t)$ to P_α is invertible and hence extendable over $t \in \mathbf{R}$; (c) if $\xi \in P_\alpha$, then $[T(t)\xi](0) = \sum_{\lambda \in \Lambda_\alpha} p_{\lambda}(t, \xi)e^{\lambda t}$, where $p_{\lambda}(t, \xi)$ are polynomials

in t and linear in ξ ; (d) there is a direct-sum decomposition $C = P_\alpha + Q_\alpha$ such that Q_α is invariant under $T(t)$, the projection along $Q_\alpha \pi_\alpha: C \rightarrow P_\alpha$ is bounded, and there exist positive constants K, ε for which $\|T(t)\xi\| \leq K e^{(\alpha - \varepsilon)t} \|\xi\|$, $t \geq 0$ if $\xi \in Q_\alpha$. Hence for any $\xi \in C$ the solution $x(t)$ of (AL) through ξ at $t=0$ satisfies

$$\left| x(t) - \sum_{\lambda \in \Lambda_\alpha} p_\lambda(t, \pi_\alpha \xi) e^{\lambda t} \right| \leq K(1 + \|\pi_\alpha\|) e^{(\alpha - \varepsilon)t} \|\xi\|, \quad t \geq 0, \quad (8)$$

where $\|\pi_\alpha\|$ denotes the operator norm of π_α . The set $Q = \bigcap_{\alpha \in R} Q_\alpha$ may contain an element ξ other than the zero element, but $T(t)\xi$ must be identically zero for $t \geq h$.

For a linear system (L) with $f(t, \varphi)$ ω -periodic in t , similar conclusions result, with $T(\omega, 0)$ in place of A ; and relation (8) holds, where Λ_α is defined similarly by replacing $\sigma(A)$ by $\{(1/\omega) \log \mu \mid \mu \in \sigma(T(\omega, 0))\}$ and $p_\lambda(t, \xi)$ are polynomials with ω -periodic coefficients. This corresponds to Floquet's theorem for ordinary periodic linear systems. $\mu \in \sigma(T(\omega, 0))$ and $(1/\omega) \log \mu$ are said to be the **characteristic multiplier** and the **characteristic exponent**, respectively.

G. Stability Problem

The concept of stability can be defined and studied in the same spirit as for ordinary differential equations, and the Lyapunov second method also turns out to be effective. For instance, the zero solution of (E) with f defined on $D_H = [0, \infty) \times \{\varphi \in C \mid \|\varphi\| < H\}$ for $H > 0$ is said to be **uniformly asymptotically stable** if there are a constant $\alpha > 0$ and positive functions $\delta(\varepsilon)$ and $\sigma(\varepsilon)$ of $\varepsilon > 0$ such that any solution $x(t)$ of (E) satisfies

$$|x(t)| < \varepsilon \text{ as long as } x(t) \text{ exists,} \quad (9)$$

whenever $\|x_\tau\| < \delta(\varepsilon)$ and $t \geq \tau$ or $\|x_\tau\| \leq \alpha$ and $t \geq \tau + \sigma(\varepsilon)$ for $\tau \geq 0$. In the above definition, if f is completely continuous on D_H and if $0 < \varepsilon < H$, then the phrase "as long as $x(t)$ exists" is redundant, and (9) is equivalent to the claim that $x(t)$ exists for all $t \geq \tau$ and $|x(t)| < \varepsilon$. Under the Lipschitz condition and the complete continuity on f in (E), the zero solution of (E) is uniformly asymptotically stable if and only if there exists a continuous \mathbf{R} -valued function (**Lyapunov function**) $V(t, \varphi)$ defined on D_{H_1} for $0 < H_1 \leq H$ such that

$$(i) \quad a(\|\varphi(0)\|) \leq V(t, \varphi) \leq b(\|\varphi\|),$$

$$(ii) \quad D^+ V(t, x_t) \leq -cV(t, x_t)$$

as long as $(t, x_t) \in D_{H_1}$ for a solution $x(t)$ of (E), where $a(r), b(r)$ are continuous functions with $a(r) > 0$ for $r > 0$, $b(0) = 0$, $c > 0$ is a constant,

and D^+ denotes the upper-right Dini derivative. Furthermore, the Lyapunov function can be endowed with a Lipschitz condition $|V(t, \varphi) - V(t, \psi)| \leq L_1 \|\varphi - \psi\|$ for some constant L_1 if f in (E) is uniformly Lipschitzian, that is, the coefficient L is constant over the domain. The Lipschitz condition together with (ii) makes it possible for a solution $y(t)$ of the perturbed equation

$$\dot{y}(t) = f(t, y_t) + P(t, y_t) \quad (10)$$

to satisfy

$$D^+ V(t, y_t) \leq -cV(t, y_t) + L_1 |P(t, y_t)|.$$

By using this fact, the stability of (10) can be discussed.

However, for functional differential equations it is quite a difficult problem to construct a suitable Lyapunov function for a given (E).

Many of the attempts to improve the sufficiency condition that have been made up to now are such that a stability property can be verified by means of a simple Lyapunov function. The main effort has been devoted to replacing condition (ii) by another type of condition. One of them is

$$(ii^*) \quad D^+ V(t, x_t) \leq -c(|x(t)|)$$

under the uniform boundedness of $f(t, \varphi)$, where $c(r)$ is a continuous function with $c(r) > 0$ for $r > 0$. Another one is for the case when $V(t, \varphi) = W(t, \varphi(0))$, where $W(t, x)$ is defined for $(t, x) \in \mathbf{R} \times \mathbf{R}^n$. In this case, (ii) can be replaced by

$$(ii^{**}) \quad D^+ V(t, x_t) \leq -cV(t, x_t)$$

whenever $V(t + s, x_{t+s}) \leq F(V(t, x_t))$ for $s \in [-h, 0]$, where $c > 0$ is a constant and $F(r)$ is a continuous function satisfying $F(r) > r$ for $r > 0$. The condition (ii**) was given by B. S. Razumikhin and provides an easier way to construct a Lyapunov function.

For a linear system, uniform asymptotic stability implies $\|T(t, \tau)\| \leq 1/\delta(1)$ for $t \geq \tau$ and $\|T(t, \tau)\| \leq 1/2$ for $t \geq \tau + \sigma(\alpha/2) + h$. These facts together with (6) show that the zero solution is **exponentially stable**, that is, $|x(t)| \leq K e^{-\nu(t-\tau)} \|x_\tau\|$ for $t \geq \tau$, where $\nu = (\log 2)/(\sigma(\alpha/2) + h)$, $K = 2/\delta(1)$. From (8) it follows that the zero solution of (AL) is uniformly asymptotically stable if and only if

$$\{\lambda \in \sigma(A) \mid \operatorname{Re} \lambda \geq 0\} = \emptyset. \quad (11)$$

H. Equations of Neutral Type

To deal with an equation of neutral type, such as

$$\dot{x}(t) = f(t, x_t, \dot{x}_t), \quad (12)$$

a phase space such as $C^1 = C^1([-h, 0], \mathbf{R}^n)$ of continuously differentiable functions should be chosen. The solution of (E) will become smooth as time elapses if f in (E) is sufficiently smooth. However, this property cannot be expected for (12), and the solution of (12)–(5) need not belong to C^1 even if $\xi \in C^1$ without a specific condition on ξ such as $\dot{\xi}(0) = f(\tau, \xi, \dot{\xi})$. Such a restriction on initial functions is an obstruction to the development of the general theory. Equations of the form

$$\frac{d}{dt}D(t, x_t) = f(t, x_t) \quad (\text{N})$$

cover a fairly general class of equations of neutral type, where $D(t, \varphi)$ and $f(t, \varphi)$ are defined on an open set $D \subset \mathbf{R} \times C$ and a **solution** of (N)–(5) means a continuous function $x(t)$ defined on $[\tau - h, a]$, $a > \tau$, which satisfies (5) and

$$D(t, x_t) = D(\tau, \xi) + \int_{\tau}^t f(s, x_s) ds \quad \text{on } [\tau, a].$$

(E) corresponds to the case where $D(t, \varphi) = \varphi(0)$, while $\dot{x}(t) = G(t, \dot{x}_t) + g(t, x_t)$ is reduced to the form (N) if $G(t, \varphi)$ is linear in φ and continuously differentiable with respect to t by setting $D(t, \varphi) = \varphi(0) - G(t, \varphi)$ and $f(t, \varphi) = g(t, \varphi) - (\partial/\partial t)G(t, \varphi)$.

A continuous function $D(t, \varphi)$ linear in φ is said to be **atomic at 0** if in the representation

$$D(t, \varphi) = \int_{-h}^0 [d_s \mu(t, s)] \varphi(s)$$

(see equation (7)) $P(t) = \mu(t, 0) - \mu(t, -0)$ exists and is nonsingular, which is equivalent to

$$D(t, \varphi) = P(t)\varphi(0) + \int_{-h}^0 [d_s \mu_0(t, s)] \varphi(s) \quad (13)$$

with a nonsingular matrix $P(t)$ and a matrix $\mu_0(t, s)$ whose total variation with respect to s on $[-\sigma, 0]$ tends to 0 as $\sigma \rightarrow 0$ locally uniformly in t . A nonlinear function $D(t, \varphi)$ is said to be **atomic at 0** if $D(t, \varphi)$ has a continuous † Fréchet derivative $D_{\varphi}(t, \varphi)$ with respect to φ and $D_{\varphi}(t, \varphi)$ is atomic at 0. In equation (N), $D(t, \varphi)$ is always assumed to be atomic at 0, and many of the fundamental theorems for (E) are also valid for (N). Let $T(t)$ be the operator solution of the autonomous linear equation

$$\frac{d}{dt}D(x_t) = f(x_t). \quad (14)$$

Then $\{T(t)\}_{t \geq 0}$ is a strongly continuous semi-group of bounded linear operators, and the corresponding † infinitesimal generator A has the domain $D(A) = \{\varphi \in C \mid \dot{\varphi} \in C \text{ and } D(\dot{\varphi}) = f(\varphi)\}$. The properties of the spectra $\sigma(A)$ are the same as for (AL), except that the character-

istic equation is now given by

$$\det \left[\lambda \left(P + \int_{-h}^0 e^{\lambda s} d\mu_0(s) \right) - \int_{-h}^0 e^{\lambda s} d\eta(s) \right] = 0$$

and the property (b) is true if $\alpha > a_D$, where $D(\varphi)$, $f(\varphi)$ are assumed to be of the forms (13) and (7), respectively, without the argument t , and where a_D is given by

$$a_D = \max \left\{ \operatorname{Re} \lambda \mid \det \left[P + \int_{-h}^0 e^{\lambda s} d\mu_0(s) \right] = 0 \right\}.$$

Similarly, the decomposition $C = P_{\alpha} + Q_{\alpha}$ is possible if $\alpha > a_D$. Hence, to obtain the uniform asymptotic stability of the zero solution of (14), the condition $a_D < 0$ should be assumed in addition to (11). The linear function $D(\varphi)$ is said to be **stable** if $a_D < 0$. If $D(\varphi)$ is stable, then the Lyapunov method is also applicable, as a sufficient condition, to the stability problem of (N) with linear $D(\varphi)$ instead of general $D(t, \varphi)$, but in this case condition (i) for $V(t, \varphi)$ should be replaced by

$$a(|D(\varphi)|) \leq V(t, \varphi) \leq b(\|\varphi\|).$$

I. Infinite Retardation

There are some basic differences between cases of finite retardation and of infinite retardation. For example, in the definition of stability, the inequality $|x(t)| < \varepsilon$ in (9) can be replaced by $\|x_t\| < \varepsilon$ with no difference in the case of finite retardation, but this replacement yields a different concept deeply connected with the choice of the phase space in case of infinite retardation.

There are several ways to define a phase space for a functional differential equation with infinite retardation. One of those phase spaces generally used is a linear space X of functions: $(-\infty, 0] \rightarrow \mathbf{R}^n$ with a seminorm $\|\cdot\|_X$ such that if a function $x: (-\infty, a) \rightarrow \mathbf{R}^n$ satisfies $x_t \in X$ and it is continuous on $[\tau, a]$, then

- (i) $x_t \in X$ for all $t \in [\tau, a]$,
- (ii) x_t is continuous as a function $[\tau, a) \rightarrow X$,
- (iii) $m|x(t)| \leq \|x_t\|_X \leq K \max_{s \in [\tau, t]} |x(s)| + M(t - \tau)\|x_t\|_X$,

where m and K are positive constants and $M(t)$ is a continuous function.

If X satisfies the foregoing conditions and if $f(t, \varphi)$ is continuous on an open domain $D \subset \mathbf{R} \times X$, then the local properties (a)–(c) in Section D hold, and so does (d) when $D = \mathbf{R} \times X$. On the other hand, if X has a **fading memory**, namely,

- (iv) $M(t) \leq M e^{-\mu t}$ in (iii) for positive constants M, μ ,

then the procedure in Section F is applicable by restricting $\sigma(A)$ to $\sigma_\mu(A) = \{\lambda \in \sigma(A) \mid \operatorname{Re} \lambda > -\mu\}$ and, hence the zero solution of (AL) with infinite retardation is uniformly asymptotically stable under (11).

For $0 \leq h \leq \infty$ and $0 \leq \gamma < \infty$, both the space $C_{h,\gamma}$ of continuous functions $\varphi: (-h, 0] \rightarrow \mathbf{R}^n$ with a finite limit $\lim_{s \rightarrow -h} e^{\gamma s} \varphi(s)$ and the space $M_{h,\gamma}$ of measurable functions $\varphi: (-h, 0] \rightarrow \mathbf{R}^n$ with $\int_{-h}^0 e^{\gamma s} |\varphi(s)| ds < \infty$ satisfy the foregoing conditions, where the norms are given by $\|\varphi\|_{C_{h,\gamma}} = \sup_{(-h, 0]} e^{\gamma s} |\varphi(s)|$ and $\|\varphi\|_{M_{h,\gamma}} = |\varphi(0)| + \int_{-h}^0 e^{\gamma s} |\varphi(s)| ds$. These spaces have a fading memory if $h < \infty$ or $\gamma > 0$.

In much of the literature in which the equation of infinite retardation has a form like (2) or (4), the space CB of bounded continuous functions or the space C_0 of continuous functions with compact supports are sufficient as a phase space under the norm $\|\varphi\| = \sup_{s \leq 0} |\varphi(s)|$. However, it is to be noted that C_0 is not complete when CB does not satisfy condition (ii). When CB is chosen as the phase space, in order to show the existence theorem, $f(t, x_t)$ should be continuous for any bounded continuous function x in addition to the continuity in (t, φ) . This condition is satisfied if $I_t = [g(t), t]$ in (3) for a continuous function $g(t) \leq t$. Equation (2) or (4) with $0 \leq \lambda < 1$ give rise to such a case, but $g(t)$ must be equal to 0 in (2) and (4) with $\lambda = 0$. If $g(t) \rightarrow \infty$ as $t \rightarrow \infty$, the Razumikhin condition (ii**) $D^+ V(t, x_t) \leq -cV(t, x_t)$ whenever $V(s, x_s) \leq F(V(t, x_t))$ ($s \in [g(t), t]$) for a Lyapunov function is effective, but one can conclude only that $x(t) \rightarrow 0$ as $t \rightarrow \infty$ without uniformity.

164 (XII.18) Function Algebras

A. Definition [1–3]

Let $C(X)$ be the \dagger Banach algebra of all continuous complex-valued functions on a compact Hausdorff space X with pointwise operations and \dagger uniform norm. A **function algebra** (or **uniform algebra**) on X is a closed subalgebra A of $C(X)$ containing the constant functions and separating the points of X , i.e., for any $x, y \in X$, $x \neq y$, there exists $f \in A$ with $f(x) \neq f(y)$. If $\varphi_x, x \in X$, denotes the evaluation mapping $f \rightarrow f(x)$ of A , the correspondence $x \rightarrow \varphi_x$ is a homeomorphism of X into the \dagger maximal ideal space $\mathfrak{M}(A)$ of A . Since $\hat{f}(\varphi_x) = f(x)$ for any $x \in X$ and $f \in A$, the \dagger Gel'fand representation of A is an isometric isomorphism. By identifying x with φ_x , we regard X as a closed subset of $\mathfrak{M}(A)$ and the Gel'fand transform $\hat{f}, f \in A$, as a continuous extension of f to $\mathfrak{M}(A)$.

B. Examples [1, 3, 4]

For a compact plane set K let $P(K)$ ($R(K)$) be the subalgebra of all functions in $C(K)$ that can be approximated uniformly on K by polynomials (rational functions with poles off K). $A(K)$ denotes the subalgebra of all functions in $C(K)$ that are analytic in the interior of K . These are function algebras on K and $P(K) \subseteq R(K) \subseteq A(K)$. When K is the unit circle $\mathbf{T} =$

$\{|z|=1\}$, $P(\mathbf{T})$ is called the **disk algebra**, the most typical concrete example.

The theory of function algebras emerged from attempts to solve, by means of functional analysis, certain problems in complex analysis, especially problems of uniform approximation, e.g., when does $A(K)=P(K)$ or $A(K)=R(K)$ hold?

Another important example is given by the algebra $H_\infty(U)$ of all bounded analytic functions on a bounded plane domain U with the supremum norm $\|f\|_\infty = \sup\{|f(z)| \mid z \in U\}$ [5]. Since the Gelfand representation is an isometric isomorphism of $H_\infty(U)$ into the algebra $C(\mathfrak{M}(H_\infty(U)))$, $H_\infty(U)$ is viewed as a function algebra on the space $\mathfrak{M}(H_\infty(U))$. Further examples result if we take K or U in a Riemann surface or in the complex n -space.

We list a few abstract function algebras that reflect certain relevant properties possessed by concrete examples. A is called a **Dirichlet** (resp. **logmodular**) **algebra** if the set $\text{Re } A = \{\text{Re } f \mid f \in A\}$ (resp. $\log |A^{-1}| = \{\log |f| \mid f, f^{-1} \in A\}$) is dense in $C_{\mathbf{R}}(X)$, the space of all continuous real-valued functions on X . It is called **hypo-Dirichlet** if the closure of $\text{Re } A$ has finite codimension in $C_{\mathbf{R}}(X)$, and the linear span of $\log |A^{-1}|$ is dense in $C_{\mathbf{R}}(X)$.

In the following, A denotes a function algebra on X unless otherwise specified.

C. Boundary and Representing Measure [1–4]

A subset E of X is a **boundary** for A if for any $f \in A$ there exists $x \in E$ such that $|f(x)| = \|f\|$.

A **closed boundary** is a boundary closed in X . G. E. Shilov proved that there is a smallest closed boundary, ∂A , which is called the **Shilov boundary** for A . A positive Borel measure μ on X is a **representing measure** for $\varphi \in \mathfrak{M}(A)$ if $f(\varphi) = \int f(x) d\mu(x)$ for all $f \in A$. Each $\varphi \in \mathfrak{M}(A)$ has a representing measure supported by ∂A . The **Choquet boundary**, $c(A)$, consists of all $x \in X$ such that the evaluation φ_x at x has a unique representing measure. Then $c(A)$ is a boundary, whose closure is ∂A . If X is metrizable, $c(A)$ is a G_δ set in X and supports a representing measure for every member of $\mathfrak{M}(A)$.

For $\varphi \in \mathfrak{M}(A)$, M_φ denotes the set of representing measures for φ . It is a * weak* compact convex subset of the space of measures on X . M_φ is a singleton if A is Dirichlet or logmodular. It is finite-dimensional if A is hypo-Dirichlet. The case $\dim M_\varphi < +\infty$ has been studied in detail. Extensive studies for the case $\dim M_\varphi = +\infty$ have been done only for concrete examples related to polydisks, infinitely connected domains, etc.

The notion of boundary reflects the * maxi-

mum modulus principle for analytic functions, and representing measures come from * Poisson's integral formula. The most relevant maximum principle is H. Rossi's **local maximum modulus principle**: For any closed set K in $\mathfrak{M}(A)$, we have $\|\hat{f}\|_K = \|\hat{f}\|_{\text{bd } K \cap (K \cap \partial A)}$ for all $f \in A$, where $\text{bd } K$ is the topological boundary of K and $\|\hat{f}\|_S = \sup\{|\hat{f}(s)| \mid s \in S\}$. A corresponding result for function spaces was considered by Y. Hirashita and J. Wada. Closely related to representing measures are the **orthogonal measures** for A , i.e., complex Borel measures μ on X such that $\int f d\mu = 0$ for all $f \in A$; they are often useful in studying function algebras by means of the duality technique. The set of orthogonal measures is denoted by A^\perp .

D. Peak Sets [1–3]

A subset K of X is a **peak set** for A if there exists $f \in A$ such that $f(x) = 1$ for $x \in K$ and $|f(y)| < 1$ for $y \in X - K$. K is a **generalized peak set** if it is the intersection of peak sets. A point $x \in X$ is a **(generalized) peak point** if the set $\{x\}$ is a (generalized) peak set. The set of generalized peak points equals the Choquet boundary for A . If X is metrizable, the peak sets and generalized peak sets coincide. There exist X and A such that X is metrizable: $X = \mathfrak{M}(A) = c(A)$, but $A \neq C(X)$ (B. Cole). A subset E of X is **interpolating** for A if for any bounded continuous function u on E there exists $f \in A$ with $f|_E = u$. Then a closed G_δ set K in X is an interpolating peak set if and only if $\mu \in A^\perp$ implies $|\mu|(K) = 0$ (E. Bishop).

E. Antisymmetric Decomposition [1–3]

A subset F of X is a **set of antisymmetry** for A if every function in A which is real-valued on F is constant on F . Bishop's antisymmetric decomposition then appears as an extension of the * Weierstrass-Stone theorem on uniform approximation. It is a refinement of Shilov's decomposition and reads as follows: If $\{E_\alpha\}$ is the family of maximal sets of antisymmetry for A , it is a partition of X into generalized peak sets such that $f \in C(X)$ with $f|_{E_\alpha} \in A|_{E_\alpha}$ for all α belongs to A . An interesting connection was found by J. Tomiyama between the maximal antisymmetric decomposition of X relative to A and that of $\mathfrak{M}(A)$ relative to \hat{A} .

F. Parts and Analytic Structure [1–4]

A. M. Gleason defined an equivalence relation \sim in $\mathfrak{M}(A)$ by setting $\varphi \sim \psi$ if $\sup\{|\hat{f}(\varphi) - \hat{f}(\psi)| \mid f \in A, \|f\| < 1\} < 2$. Each equivalence class for this relation is a **part** (or a **Gleason**

part) for A . Two points φ, ψ belong to the same part if and only if there exist mutually absolutely continuous representing measures μ for φ and ν for ψ such that $c^{-1} < d\mu/d\nu < c$ for some constant $c > 0$ (Bishop). An **analytic structure** in $\mathfrak{M}(A)$ is a pair (V, τ) , with an \dagger analytic set V in some open subset of \mathbb{C}^n and a nonconstant continuous mapping $\tau: V \rightarrow \mathfrak{M}(A)$ such that $\hat{f} \circ \tau$ is analytic on V for all $f \in A$. For such a structure, $\tau(V)$ is always within a part. But there can be a nontrivial part with no analytic structure, as was shown by G. Stolzenberg. A topological characterization of parts was obtained by J. Garnett. Sample results in the positive direction are: (1) If the ideal $A_\varphi = \{f \in A \mid \hat{f}(\varphi) = 0\}$ is finitely generated, there is an analytic structure (V, τ) such that τ is a homeomorphism of V onto an open neighborhood of φ (Gleason); (2) if φ has a unique representing measure and if the part P of φ is not a singleton, there is a bijective continuous mapping τ of the open unit disk onto P such that $\hat{f} \circ \tau$ is analytic for $f \in A$ (J. Wermer, K. Hoffman and G. Lumer); (3) if A is hypo-Dirichlet and if a part P is not a singleton, P can be made into a 1-dimensional \dagger analytic space so that each $f \in A$ is analytic on P (J. Wermer and B. V. O'Neill). Analytic structures in \dagger polynomially convex hulls of curves in \mathbb{C}^n have also been studied [3, 4].

G. Abstract Function Theory [1, 6–9]

Let $\varphi \in \mathfrak{M}(A)$, and choose $m \in M_\varphi$, which is fixed. The **generalized Hardy class** $H_p(m)$, $0 < p \leq \infty$, associated with A is the closure (weak* closure, if $p = \infty$) of A in the $\dagger L_p$ space $L_p(m)$ on the measure space (X, m) . Under suitable restrictions on A , φ , or m , we can recapture some of the important classical facts, most of which have their origins in the works of A. Beurling, R. Nevanlinna, F. and M. Riesz, and G. Szegő. In this area, H. Helson and D. Lowdenslager came up with a powerful method using orthogonal projections in Hilbert space and gave together with S. Bochner's remark, a strong influence for subsequent development. The modification argument was then devised by Hoffman and Wermer, inspired by F. Forelli. After Hoffman's detailed study of logmodular algebras, Lumer observed that most results remain valid when φ has a unique representing measure. T. P. Srinivasan and J.-K. Wang (\rightarrow [8]) introduced the notion of weak* Dirichlet algebra and showed that some major theorems are mutually equivalent and are in fact measure-theoretic. With the Hoffman-Rossi complement, their result now states that for fixed $m \in M_\varphi$ the following are equivalent: (i) $A + \bar{A}$ is weak* dense in

$L_\infty(m)$, i.e., A is a **weak* Dirichlet algebra** on (X, m) ; (ii) if $\mu \in M_\varphi$ is absolutely continuous with respect to m , then $\mu = m$; (iii) if a closed subspace M of $L_2(m)$ is simply invariant in the sense that $A_\varphi M \subseteq M$ and $A_\varphi M$ is not dense in M , then $M = qH_2(m)$ with $q \in L_\infty(m)$, $|q| = 1$ a.e.; (iv) the set $\log|H_\infty(m)^{-1}|$ coincides with $L_\infty(m; \mathbb{R})$, the set of real-valued elements in $L_\infty(m)$; (v) for every $w \in L_1(m)$, $w \geq 0$, we have $\inf\{\int |1 - f|^2 w dm \mid f \in A_\varphi\} = \exp(\int \log w dm)$; (vi) the linear functional $h \rightarrow \int h dm$ on $H_\infty(m)$ has a unique positive extension to $L_\infty(m)$. Further extensions were subsequently made by use of the conjugation operator (\rightarrow Section K) by T. Gamelin, H. König, Lumer, K. Yabuta, and others. Some more properties of weak* Dirichlet algebras have been obtained by T. Nakazi.

H. Generalized Analytic Functions [1, 10]

Let Γ be a dense subgroup of the additive group \mathbb{R} of the reals with discrete topology, and let G be the \dagger character group of Γ . Each $a \in \Gamma$, as a character of G , defines a continuous function χ_a on G . Let A be the closed subalgebra of $C(G)$ generated by $\{\chi_a \mid a \in \Gamma, a \geq 0\}$. A is a Dirichlet algebra but is far more difficult to describe than the disk algebra. The study of this algebra, especially that of invariant subspaces, has evolved from papers by Helson and D. Lowdenslager. Let σ be the \dagger Haar measure of G and $H_2(\sigma)$ the closure of A in $L_2(\sigma)$. A closed subspace M of $L_2(\sigma)$ is called **invariant** if $\chi_a M \subseteq M$ for all $a \in \Gamma$, $a \geq 0$. M is called **doubly invariant** if $\chi_a M \subseteq M$ for all $a \in \Gamma$. Otherwise, it is called **simply invariant**. In fact, only the latter is interesting. Let $e_t \in G$ with $t \in \mathbb{R}$ be the character of Γ defined by $e_t(a) = e^{ita}$. Then the mapping $t \rightarrow e_t$ is a faithful representation of \mathbb{R} into G . A **cocycle** on G is defined to be a Borel function B on $G \times \mathbb{R}$ such that (i) $|B(x, t)| = 1$, (ii) $B(x + e_t, t) = \bar{B}(x, s)B(x, s + t)$ for $x \in G$ and $s, t \in \mathbb{R}$. Two cocycles are identified if they differ only on a null set in $G \times \mathbb{R}$. For a cocycle B , let M_B be the set of $f \in L_2(\sigma)$ such that $\overline{B(x, t)f(x + e_t)} \in H_2(dt/(1 + t^2))$ for almost all $x \in G$, where $H_2(dt/(1 + t^2))$ is the closure, in the space $L_2(dt/(1 + t^2))$ on \mathbb{R} , of the set of boundary value functions on \mathbb{R} of bounded analytic functions on the upper half-plane. Then the mapping $B \rightarrow M_B$ is a bijection from the set of cocycles onto the set of simply invariant subspaces M of $L_2(\sigma)$ such that $M = \bigcap \{\chi_a M \mid a \in \Gamma, a < 0\}$. Moreover, $M_B = qH_2(\sigma)$ for some $q \in L_\infty(\sigma)$, $|q| = 1$ a.e. if and only if $B(x, t) = \overline{q(x)}q(x + e_t)$, i.e., B is a **coboundary**. When $\Gamma \neq \mathbb{R}$, there is a cocycle that is not a coboundary. Further studies have been done by Helson,

Gamelin, J. Tanaka, and others. On the other hand, F. Forelli observed that flows in compact spaces give rise to a kind of analyticity. In the above case, the algebra A consists of all $f \in C(G)$ that are analytic with respect to the flow $T_t(x) = x + e_t$ for $x \in G$ and $t \in \mathbb{R}$. Generalized analytic functions induced by flows in general have been studied by Forelli and P. S. Muhly.

I. The Unit Disk [1, 6, 7, 11, 12]

Let A be the disk algebra $P(\mathbb{D})$, \mathbb{D} the open unit disk $\{|z| < 1\}$, and m the normalized Lebesgue measure on \mathbb{T} . The algebra A has been the most important model in the theory of function algebras, and we find here the origin of many abstract results. Some typical results: (i) every orthogonal measure for A is absolutely continuous with respect to m (F. and M. Riesz); (ii) a closed set E in \mathbb{T} is an interpolating peak set for the Gel'fand transform \hat{A} of A if and only if $m(E) = 0$ (W. Rudin and L. Carleson); (iii) A is maximal among the closed subalgebras of $C(\mathbb{T})$ (Wermer); (iv) a function $f \in C(\text{Cl } \mathbb{D})$ belongs to \hat{A} if f is analytic at every $z \in \mathbb{D}$ with $f(z) \neq 0$ (T. Radó).

The generalized Hardy class $H_p(m)$, $0 < p \leq \infty$, associated with A is viewed as the set of nontangential boundary value functions of elements in the classical Hardy class $H_p(\mathbb{D})$. Here we find the origin of invariant subspace theorems: A closed subspace $M (\neq \{0\})$ of $H_2(m)$ is invariant, i.e., $AM \subseteq M$, if and only if $M = qH_2(m)$ with $q \in H_\infty(m)$, $|q| = 1$ a.e. (Beurling).

The algebra $H_\infty = H_\infty(m)$ is a weak* Dirichlet algebra, whose Shilov boundary is identified with the maximal ideal space X of $L_\infty(m)$. We have $L_\infty(m; \mathbb{R}) = \log |(H^\infty)^{-1}|$, and a fortiori H_∞ is logmodular on X . The mapping $z \rightarrow \varphi_z$ embeds the disk \mathbb{D} in $\mathfrak{M}(H_\infty)$ as an open set. The structure of $\mathfrak{M}(H_\infty)$ was studied in detail by I. J. Schark, Hoffman, and others. We finish with three remarkable results: (i) \mathbb{D} is dense in $\mathfrak{M}(H_\infty)$ (Carleson). This is the **corona theorem** and was proved in the following equivalent form: For any $f_1, \dots, f_n \in H_\infty(\mathbb{D})$ with $|f_1| + \dots + |f_n| \geq \varepsilon > 0$ on \mathbb{D} , there exist $g_1, \dots, g_n \in H_\infty(\mathbb{D})$ with $f_1 g_1 + \dots + f_n g_n = 1$. A simple proof was discovered by T. Wolff [12]. (ii) The convex combinations of Blaschke products are uniformly dense in the unit ball of $H_\infty(\mathbb{D})$ (D. Marshall) [12]. (iii) Every closed subalgebra B between H_∞ and $L_\infty(m)$ is a **Douglas algebra**, i.e., B is generated by H_∞ and the complex conjugates of a family of inner functions (S.-Y. Chang and Marshall) [11]. The proof of (iii) is an interesting application of the theory of bounded mean oscillation.

J. Rational Approximation [1, 2]

The problem of rational (polynomial) approximation on a compact plane set K asks when $A(K) = R(K)$ ($A(K) = P(K)$) holds. An important tool for such problems is **Cauchy's transform** of measure μ : $\hat{\mu}(\zeta) = \int (z - \zeta)^{-1} d\mu(z)$. Using this, one can show, for instance, the following: (1) $A(K) = P(K)$ if and only if K has a connected complement (S. N. Mergelyan); (2) $f \in C(K)$ belongs to $R(K)$ if each point $z \in K$ has a closed neighborhood V with $f|_{K \cap V} \in R(K \cap V)$ (Bishop); (3) $A(K) = R(K)$ if the diameters of the components of $\mathbb{C} - K$ are bounded away from zero (Mergelyan); (4) $C(K) = R(K)$ if and only if almost all points of K are peak points for $R(K)$ (Bishop). The last result cannot be extended much because there is a set K such that $A(K) \neq R(K)$, while $A(K)$ and $R(K)$ have the same peak points (A. M. Davie).

A complete characterization for $A(K) = R(K)$ was obtained by A. G. Vitushkin: (5) The following are equivalent: (i) $A(K) = R(K)$; (ii) for any bounded open set D in \mathbb{C} , $\alpha(D - K) = \alpha(D - K^0)$; (iii) for any $z \in \text{bd } K$, there exists $r \geq 1$ such that $\limsup_{\delta \rightarrow 0} \alpha(\Delta(z; \delta) - K^0) / \alpha(\Delta(z; r\delta) - K) < +\infty$, where $\Delta(z; \delta)$ is the disk $\{w \in \mathbb{C} \mid |w - z| \leq \delta\}$ and $\alpha(E)$, for any bounded set E in \mathbb{C} , is the **continuous analytic capacity** of E , which is the supremum of $|f'(\infty)|$ for all continuous functions f on the Riemann sphere $\mathbb{C} \cup \{\infty\}$ such that $|f| \leq 1$, $f(\infty) = 0$, and f is analytic off a compact subset of E . As for uniform or asymptotic approximation on noncompact closed subsets in \mathbb{C} , Carleman's classical study has recently been extended by N. U. Arakelyan, A. A. Nersesyan, A. Stray, and others in an interesting way.

In connection with rational approximation, we should note detailed studies on pointwise bounded approximation in $H_\infty(U)$, U being a bounded open set in \mathbb{C} , by O. J. Farrell, L. Rubel and A. Shields, Gamelin and J. Garnett, and Davie.

K. Further Topics

(1) **Conjugation operator** [9, 13]. Take any $m \in M_\varphi$, $\varphi \in \mathfrak{M}(A)$. The **conjugation operator** then associates with each $u \in \text{Re } A$ the unique element $*u$ in $C_R(X)$ such that $u + i*u \in A$ and $\int *u dm = 0$. After the classical inequalities of Kolmogorov and M. Riesz, we consider the following conditions with constants c_p and d_p : (K) $(\int |*u|^p dm)^{1/p} \leq c_p \int |u| dm$ for $0 < p < 1$; (M) $(\int |*u|^p dm)^{1/p} \leq d_p (\int |u|^p dm)^{1/p}$ for $1 < p < \infty$. Let m be arbitrary. Then the inequality (K) is valid for $u \in \text{Re } A$, $u > 0$. The inequality (M) is valid for all $u \in \text{Re } A$ if p is an even integer ≥ 2 ; it is

valid for all $u \in \operatorname{Re} A$, $u > 0$, if p is not an odd integer. All remaining cases have counterexamples. On the other hand, M_φ always contains an m such that $\log|f(\varphi)| \leq \int \log|f| dm$ for $f \in A$ (Bishop). Such a representing measure is called a **Jensen measure** for φ . If m is Jensen, (K) is valid for all $u \in \operatorname{Re} A$ and all $0 < p < 1$, and (M) is valid for all $u \in \operatorname{Re} A$ and all $1 < p < \infty$.

(2) **Riemann surfaces.** For a compact bordered Riemann surface R , let $A(R)$ be the algebra of functions, continuous on $\operatorname{Cl} R$ and analytic on R . Then $A(R)$ is hypo-Dirichlet on the border $\operatorname{bd} R$ of R , and many results for the disk algebra are extended to $A(R)$. Most of the basic results are described in [14]. The maximality of $A(R)$ in $C(\operatorname{bd} R)$ was obtained by H. Royden; extreme points of related Hardy classes were discussed by Gamelin and M. Voichick; and invariant subspaces were determined by Forelli, M. Hasumi, D. Sarason, and Voichick. A further extension to infinitely connected surfaces has been obtained by C. W. Neville, Hasumi, and M. Hayashi in the case of open Riemann surfaces R of Parreau-Widom type, which is defined as follows: Let $G(a, z)$ be \dagger Green's function for R , and let $B(a, \alpha)$, $\alpha > 0$, be the first \dagger Betti number of the domain $\{z \in R \mid G(a, z) > \alpha\}$; then R is of **Parreau-Widom type** if $\int B(a, \alpha) d\alpha < +\infty$. For such surfaces the situation looks favorable: For instance, the Cauchy-Read theorem is valid, and the Brelot-Choquet problem concerning Green's lines is solved affirmatively.

As for the generalization of approximation theorems of Mergelyan and Arakelyan, we refer to the work of Bishop and L. K. Kodama for compact sets and to that of S. Scheinberg for noncompact closed sets.

(3) **Higher-dimensional sets.** Much attention has been paid to algebras of analytic functions on domains in \mathbb{C}^n , $n \geq 2$, e.g., polydisks, unit balls, and general pseudoconvex domains. Polydisk algebras and ball algebras have been studied extensively by W. Rudin, P. Ahern, Forelli, and many others [15, 16]. Approximation theorems of Mergelyan type were obtained by G. M. Henkin, N. Kerzman, and I. Lieb for strictly pseudoconvex domains with smooth boundary and by L. Hörmander and Wermer and L. Nirenberg and R. O. Wells, Jr., in the case of totally real manifolds. Further improvements have been obtained by R. M. Range, A. Sakai, and others.

165 (II.4) Functions

A. History

Leibniz used the term *function* (Lat. *functio*) in the 1670s to refer to certain line segments whose lengths depend on lines related to curves. Soon the term was used to refer to dependent quantities or expressions. In 1718, Johann Bernoulli used the notation φx , and by 1734 the modern functional notation $f(x)$ had been used by Clairaut and by Euler, who defined functions as analytic formulas constructed from variables and constants (1728) [1]. \dagger Cauchy stated (1821) [2]: "When there is a relation among many variables, which determines along with values of one of them the values of the others, we usually consider the others as expressed by the one. We then call

the one an 'independent variable,' and the others 'dependent variables.'" †Dirichlet considered a function of $x \in [a, b]$ in his paper (1837) [3] concerning representations of "completely arbitrary functions" and stated that there was no need for the relation between y and x to be given by the same law throughout an interval, nor was it necessary that the relation be given by mathematical formulas. A function was simply a correspondence in which values of one variable determined values of another.

B. Functions

Today, the word "function" is used generally in mathematics in the same sense as a †mapping (\rightarrow 381 Sets C) or, which is the same thing, a †univalent correspondence (\rightarrow 358 Relations B). But this word is sometimes used in a wider sense, to mean a general (not necessarily univalent) correspondence, called a **many-valued** (or **multivalued**) **function**; in that case a univalent correspondence is called a **single-valued function**.

Specialists in each branch of mathematics have their respective ways of using the word. In analysis, values of a function are often considered real or complex numbers; such functions are called **real-valued functions** or **complex-valued functions**, respectively. Furthermore, if the domain of the function is also a set of real or complex numbers, then it is called a **real function** or a **complex function**, respectively (\rightarrow 131 Elementary Functions; 84 Continuous Functions; 198 Holomorphic Functions). If the domain of a real- or complex-valued function is contained in a †function space, the function is often called a **functional**; the †distribution is an example. In algebra we often fix a †field, †ring, etc., and consider functions whose domains and ranges are in such algebraic systems. Special names are given to functions having special properties, which can be defined according to the structures of the domain and the range. For example, when both domain and range of a function f are sets of real numbers, f is called an **even function** if $f(t) = f(-t)$, and an **odd function** if $f(t) = -f(-t)$. A function f that preserves the order relation between real numbers, i.e., such that $t_1 < t_2$ implies $f(t_1) \leq f(t_2)$, is called a †monotone increasing function.

A mapping from a set I to a set F of functions, $\varphi: I \rightarrow F$, is called a **family of functions indexed by I** (or simple **family of functions**), and is denoted, using the form f_λ instead of $\varphi(\lambda)$, by $\{f_\lambda\}_{\lambda \in I}$ or $\{f_\lambda\}_{\lambda \in I}$. In particular, if I is the set of natural numbers, the family is called a **sequence of functions**.

C. Variables

A letter x , for which we can substitute a name of an element of a set X , is called a **variable**, and X is called the **domain** of the variable. An element of the domain of a variable x is called a **value** of x . In particular, if the domain is a set of real numbers or complex numbers, the variable is called a **real variable** or a **complex variable**, respectively. On the other hand, a letter that stands for a particular element is called a **constant**.

When the domain and range of a function f are X and Y , respectively, a variable x whose domain is X is called the **independent variable**, and a variable y whose domain is Y is called the **dependent variable**. Then we say y is a function of x , and write $y = f(x)$. When a concrete method is given by which we make a value of y correspond to each value of x , we say that y is an **explicit function** of x . When a function is determined only by a †binary relation such as $R(x, y) = 0$, we say that y is an **implicit function** of x (\rightarrow 208 Implicit Functions).

Given functions f, g with an independent variable t , suppose that y is regarded as a function of x defined by relations $x = f(t)$, $y = g(t)$. Then we say that y is a function of x with the variable t as a **parameter**. A function whose range is a given set C with variable t as its independent variable is often called a **parametric representation** of C by t .

If the domain of a function f is contained in a Cartesian product set $X_1 \times X_2 \times \dots \times X_n$, the independent variable is denoted by (x_1, x_2, \dots, x_n) , and f is often called a **function of n variables** or a **function of many variables** (when $n \geq 2$).

D. Families and Sequences

A function whose domain is a set I , $\varphi: I \rightarrow X$, is called a **family indexed by I** (or simply **family**), and I is called the **index set**. In the case $\varphi(\lambda) = x_\lambda (\lambda \in I)$, the family is denoted by $\{x_\lambda\}_{\lambda \in I}$ or $\{x_\lambda\}_{\lambda \in I}$. If the range X of a function φ is a set of points, a set of functions, a set of mappings, or a set of sets, then the family $\{x_\lambda\}_{\lambda \in I}$ is called a **family of points**, a **family of functions**, a **family of mappings**, or a **family of sets**, respectively. If the set I is a †directed set, the family is called a **directed family**. Generally, if J is a subset of I , the family $\{x_\lambda\}_{\lambda \in J}$ is called a **subfamily** of $\{x_\lambda\}_{\lambda \in I}$. In particular, if I is a finite or infinite set of natural numbers, the family indexed by I is called a **finite sequence** or **infinite sequence**, respectively. **Sequence** is a generic name for both, but in many cases it means an infinite sequence, and usually we

have $I = \mathbf{N}$. Then the value corresponding to $n \in \mathbf{N}$ is called the **n th term** or, generally, a **term**. For convenience, the 0th term is often used as well. If each term of a sequence is a number, a point, a function, or a set, the sequence is called a **sequence of numbers**, a **sequence of points**, a **sequence of functions**, or a **sequence of sets**, respectively. A sequence is usually denoted by $\{a_n\}$. If it is necessary to show the domain of n explicitly, the sequence is denoted by $\{a_n\}_{n \in I}$. If J is a subset of I , a sequence $\{a_n\}_{n \in J}$ is called a **subsequence** of the sequence $\{a_n\}_{n \in I}$. And if $I = \mathbf{N}$, the composite $\{a_{k_n}\}$ of $\{a_n\}$ and a sequence $\{k_n\}$ of natural numbers with $k_1 < k_2 < k_3 \dots$ is usually called a subsequence of $\{a_n\}$.

166 (X.5) Functions of Bounded Variation

A. Monotone Functions

A function (or mapping) f from an \dagger ordered set X to another ordered set Y is called a **monotone increasing (monotone decreasing) function** if

$$\begin{aligned} x_1 < x_2 & \text{ implies } f(x_1) \leq f(x_2) \\ (x_1 < x_2 & \text{ implies } f(x_1) \geq f(x_2)). \end{aligned} \quad (1)$$

A monotone increasing (decreasing) function is also called a **nondecreasing (nonincreasing) function**. In either case, the function f is called simply a **monotone function**. If X and Y are \dagger totally ordered sets and the inequality $< (>)$ holds in (1) instead of $\leq (\geq)$, then f is called a **strictly (monotone) increasing (strictly (monotone) decreasing) function**. In either case, f is called simply a **strictly monotone function**.

In particular, when X and Y are subsets of the real line \mathbf{R} , a monotone function is contin-

uous except for at most a countable number of points. Hence it is \dagger Riemann integrable in a finite interval provided that it is bounded. A continuous real function $f(x)$ defined on an interval in \mathbf{R} is \dagger injective if and only if it is strictly monotone. In such a case, the range of the function $f(x)$ is also an interval, and the inverse function is also strictly monotone. Furthermore, a differentiable real function f defined on an interval is monotone if and only if its derivative f' is always ≥ 0 (monotone increasing) or always ≤ 0 (monotone decreasing). If $f' > 0$ (< 0), f is strictly monotone increasing (decreasing).

B. Functions of Bounded Variation

Let $f(x)$ be a real function defined on a closed interval $[a, b]$ in \mathbf{R} . Given a subdivision of the interval $a = x_0 < x_1 < x_2 < \dots < x_n = b$, we denote the sum of positive differences $f(x_i) - f(x_{i-1})$ by P and the sum of negative differences $f(x_i) - f(x_{i-1})$ by $-N$. Then we easily obtain

$$P - N = f(b) - f(a),$$

$$P + N = \sum_i |f(x_i) - f(x_{i-1})|.$$

The suprema of P , N , and $P + N$ for all possible subdivisions of $[a, b]$ are called the **positive variation**, the **negative variation**, and the **total variation** of the function $f(x)$ in the interval $[a, b]$, respectively. If any of these three values is finite, then all three values are finite. In such a case, the function $f(x)$ is called a **function of bounded variation**. Every function of bounded variation is bounded, but the converse is not true. The positive and negative variations $\pi(t)$, $v(t)$ of the function $f(x)$ in the interval $[a, t]$ are monotone increasing functions with respect to t , and we have

$$f(x) - f(a) = \pi(x) - v(x) \quad (2)$$

if $f(x)$ is a function of bounded variation. Hence every function of bounded variation has both left and right limits at every point. A monotone function is a function of bounded variation, and the sum, the difference, or the product of two functions of bounded variation is also a function of bounded variation. Hence $f(x)$ is a function of bounded variation if and only if it is the difference of two monotone functions. The representation (2) (representing a function of bounded variation as the difference of two monotone increasing functions) is called the **Jordan decomposition** of the function $f(x)$. A function of bounded variation is Riemann integrable, continuous except for at

most a countable number of points, and differentiable †almost everywhere.

A continuous function defined on a closed interval is bounded but not necessarily of bounded variation (e.g., $f(x) = x \sin(1/x)$ ($x \in (0, 1]$, 0 ($x = 0$)). A discontinuous function may be a function of bounded variation on a closed interval (e.g., $\text{sgn}(x)$). However, an †absolutely continuous function, a differentiable function with bounded derivative, or a function satisfying the †Lipschitz condition is a function of bounded variation on a closed interval.

The notion of functions of bounded variation was introduced by C. Jordan in connection with the notion of the length of curves (\rightarrow 246 Length and Area).

C. Lebesgue-Stieltjes Integral

Let $f(x)$ be a right continuous function of bounded variation on a closed interval $[a, b]$, and $f(x) = \pi(x) - v(x)$ the Jordan decomposition of $f(x)$. Then $\pi(x)$ and $v(x)$ are monotone increasing right continuous functions and hence define bounded measures $d\pi(x)$ and $dv(x)$ on $[a, b]$, respectively (\rightarrow 270 Measure Theory L (v)). The difference $d\pi - dv$ of these two measures is a †completely additive set function on $[a, b]$ which is often called the (**signed**) **Lebesgue-Stieltjes measure** induced by f , written df . For every function g integrable with respect to the measure $d\mu = d\pi + dv$, we define $\int_E g df$ to be equal to $\int_E g d\pi - \int_E g dv$ and call it the **Lebesgue-Stieltjes integral**. In this case, $h(x) = \int_{[a, b]} g df$ is of bounded variation on $[a, b]$ and the Lebesgue-Stieltjes measure $dh(x)$ is denoted by $g(x)df(x)$. If f_1 and f_2 are of bounded variation on $[a, b]$, then so is the product $f = f_1 f_2$, and we have

$$df(x) = f_1(x \pm 0)df_2(x) + f_2(x \mp 0)df_1(x). \quad (3)$$

The Lebesgue-Stieltjes integral for a continuous integrand is often called the **Riemann-Stieltjes integral**, because it can be defined in an elementary way similar to the definition of the Riemann integral.

The notion of bounded variation can also be defined for interval functions on \mathbf{R}^n and set functions on an abstract space (\rightarrow 380 Set Functions).

Functions of Confluent Type

A. Confluent Hypergeometric Functions

If some singularities of an ordinary differential equation of †Fuchsian type are confluent to each other, we obtain a **confluent differential equation** whose solutions are called **functions of confluent type**. The equations that appear frequently in practical problems are the **confluent hypergeometric differential equations**

$$z \frac{d^2 w}{dz^2} + (\gamma - z) \frac{dw}{dz} - \alpha w = 0 \quad (1)$$

and related equations. Equation (1) corresponds to the †hypergeometric differential equation for which a †regular singular point coincides with the point at infinity and is an †irregular singular point of class 1. For (1), $z = 0$ is a regular singular point, and a series solution (radius of convergence ∞) is given by

$$F(\alpha, \gamma; z) = {}_1F_1(\alpha, \gamma; z) = \sum_{n=0}^{\infty} \frac{\alpha(\alpha+1)\dots(\alpha+n-1)}{n!\gamma(\gamma+1)\dots(\gamma+n-1)} z^n \quad (|z| < \infty), \quad (2)$$

where γ is not a nonpositive integer. The function ${}_1F_1$ in (2) is a †generalized hypergeometric function due to Barnes and is called a **hypergeometric function of confluent type** or **Kummer function**. If γ is not equal to a positive integer, the other solution of (1) independent of (2) is given by $z^{1-\gamma} F(1+\alpha-\gamma, 2-\gamma; z)$ (\rightarrow Appendix A, Table 19.I).

B. Whittaker Functions

Equation (1) with $w = e^{z/2} z^{-\gamma/2} W$, $\gamma - 2\alpha = 2k$, $\gamma^2 - 2\gamma = 4m^2 - 1$ reduces to **Whittaker's differential equation**

$$\frac{d^2 W}{dz^2} + \left(-\frac{1}{4} + \frac{k}{z} + \frac{\frac{1}{4} - m^2}{z^2} \right) W = 0. \quad (3)$$

If $2m$ is not equal to an integer, (3) has two series solutions for any finite z :

$$M_{k,m}(z) = z^{(1/2)+m} e^{-z/2} F\left(\frac{1}{2} + m - k, 1 + 2m; z\right),$$

$$M_{k,-m}(z) = z^{(1/2)-m} e^{-z/2} F\left(\frac{1}{2} - m - k, 1 - 2m; z\right).$$

If $2m$ is an integer, since the functions $M_{k,m}$ and $M_{k,-m}$ are linearly dependent, E. T. Whittaker considered a solution of the form

$$W_{k,m}(z) = -\frac{1}{2\pi i} \Gamma(k + \frac{1}{2} - m) z^k e^{-z/2} \times \int_{\infty}^{(0+)} (-t)^{-k-(1/2)+m} \left(1 + \frac{t}{z}\right)^{k-(1/2)+m} e^{-t} dt.$$

If $k - \frac{1}{2} - m$ is equal to a negative integer, this integral does not exist. The function

$$W_{k,m}(z) = \frac{z^k e^{-z/2}}{\Gamma(\frac{1}{2} - k + m)} \int_0^\infty t^{-k-(1/2)+m} \times \left(1 + \frac{t}{z}\right)^{k-(1/2)+m} e^{-t} dt$$

for $\text{Re}(k - \frac{1}{2} - m) \leq 0$ is defined for any m, k , and for any z except when z is a negative real number. We call $M_{k,m}$ and $W_{k,m}$ the **Whittaker functions**. †Bessel functions are particular cases of these functions, and the relation

$$J_n(z) = \frac{z^{-1/2}}{2^{2n+(1/2)} \Gamma(n+(1/2)) \Gamma(n+1)} M_{0,n}(2iz)$$

is satisfied. In Whittaker's differential equation, since $W_{-k,m}(-z)$ is also a solution and $W_{k,m}(z)/W_{-k,m}(-z)$ is not equal to a constant, $W_{k,m}(z)$ and $W_{-k,m}(-z)$ can be considered a pair of fundamental solutions (\rightarrow Appendix A, Table 19.II).

C. Parabolic Cylinder Functions

Putting $x = (\xi^2 - \eta^2)/2$ and $y = \xi\eta$, the curves corresponding to $\xi = \text{constant}$ and to $\eta = \text{constant}$, respectively, constitute families of orthogonal parabolas. The curvilinear coordinates (ξ, η, z) in three dimensions are called **parabolic cylindrical coordinates**. By using parabolic coordinates, separating variables in Laplace's equation into the form $f(\xi)g(\eta)e^{iz}$, and making a simple transformation, we find that f and g satisfy a differential equation of the form

$$\frac{d^2 F}{dz^2} + (n + \frac{1}{2} - \frac{1}{4}z^2)F = 0. \quad (4)$$

By means of the Whittaker function $W_{k,m}(z)$, a solution $D_n(z)$ of (4) is represented by

$$D_n(z) = 2^{n/2+(1/4)} z^{-1/2} W_{n/2+(1/4), -1/4}(\frac{1}{2}z^2).$$

Equation (4) is called **Weber's differential equation** or the **Weber-Hermite differential equation**, and $D_n(z)$ the **Weber function**. Another solution of (4) is $D_{-n-1}(iz)$ or $D_{-n-1}(-iz)$. The solutions of (4) are called **parabolic cylinder functions**. In particular, if n is equal to a nonnegative integer, then

$$H_n(z) = 2^{-n/2} \exp(\frac{1}{2}z^2) D_n(\sqrt{2}z)$$

is the †Hermite polynomial of degree n . Solutions of differential equations for harmonic oscillators in quantum mechanics are of this form.

In general, suppose that three regular singular points are confluent to the point at infinity, and that they are reduced to an irregular singular point of class 2. Suppose further that

there are no other singularities. Then differential equations of order 2 with these conditions are transformed into the form (4), whose solutions are represented by parabolic cylinder functions. Differential equations of the form (4) are reduced to confluent hypergeometric differential equations if z^2 is chosen as an independent variable (\rightarrow Appendix A, Table 20.III).

D. Indefinite Integrals of Elementary Functions

Since exponential and trigonometric functions can be represented by particular types of Kummer functions, their indefinite integrals that cannot be represented by elementary functions, e.g., †incomplete Γ -functions and the **error function** $\text{Erf } z = \int_0^z \exp(-t^2) dt$, can be represented by Kummer or Whittaker functions. They are included in a family of †special functions of confluent type. The functions defined by

$$C(z) = \frac{1}{\sqrt{2\pi}} \int_0^z \frac{\cos t}{\sqrt{t}} dt,$$

$$S(z) = \frac{1}{\sqrt{2\pi}} \int_0^z \frac{\sin t}{\sqrt{t}} dt$$

are called **Fresnel integrals**, which are also represented in terms of the Whittaker function as

$$C(z) - iS(z) = \frac{1-i}{2} \left(1 - \frac{e^{-\pi i/8}}{\sqrt{\pi}} z^{1/4} e^{-z^2/2} W_{-1/4, 1/4}(iz) \right).$$

Fresnel integrals first appeared in the theory of the diffraction of waves. More recently they have been applied to designing highways for high-speed automobiles. Furthermore, the functions

$$C(u) = \int_0^u \cos\left(\frac{\pi}{2}s^2\right) ds,$$

$$S(u) = \int_0^u \sin\left(\frac{\pi}{2}s^2\right) ds$$

(obtained by a change of variables $z = \pi u^2/2$) are also called Fresnel integrals. Numerical tables are available for them. The curves $x = C$ and $y = S$ with a parameter z or u are called **Cornu's spiral** (Fig. 1). The functions

$$\text{Li } x = \int_0^x \frac{dt}{\log t}, \quad \text{Ei } x = \int_{-\infty}^x \frac{e^t}{t} dt,$$

where a †principal value must be taken at $t = 0$ if $x > 0$,

$$\text{Si } x = \int_0^x \frac{\sin t}{t} dt, \quad \text{and} \quad \text{Ci } x = - \int_x^\infty \frac{\cos t}{t} dt$$

Fig. 1

are called the **logarithmic integral**, **exponential integral**, **sine integral**, and **cosine integral**, or **integral logarithm**, **integral exponent**, **integral sine**, and **integral cosine**, respectively. They satisfy the relations

$Ei\,x = Li\,e^x, \quad Ei\,ix = Ci\,x + i\,Si\,x + (\pi/2)i.$

They have important applications: $Ei\,x$ in quantum mechanics, $Si\,x$ and $Ci\,x$ in electrical engineering, and $Li\,x$ in estimating the number of †primes less than x (→ 123 Distribution of Prime Numbers). $Li\,x$ is also denoted by $li\,x$ (→ Appendix A, Table 19.II).

E. Stokes's Equation

Consider a linear differential equation of the second order with five regular singular points including the point at infinity such that the difference of the characteristic indices at every singularity is equal to 1/2. Such equations are called **generalized Lamé's differential equations**. F. Klein and M. Bôcher have shown that every linear differential equation that is commonly treated in mathematical physics is represented by a confluent type of generalized Lamé's equation. Among these equations, if all five singularities are confluent to the point at infinity, the resulting equation is called **Stokes's differential equation**, which is applied to the investigation of diffraction. This is reduced to †Bessel's differential equation of order 1/3 by suitable transformations of the independent and dependent variables.

Function Spaces

A. General Remarks

It is a general method in modern analysis to consider a set X of mappings of a space Ω into another space A as a space (→ 381 Sets) and its elements (namely, mappings of Ω into A) as points of the space X , and to investigate them as geometric objects. In particular, it is important to consider the case where Ω is a †topological space, a †measure space, or a †differentiable manifold and X is a set of real- or complex-valued functions defined on Ω and satisfying certain conditions, such as continuity, measurability, and differentiability. Such spaces are generally called **function spaces**; they usually form †topological linear spaces (→ 37 Banach Spaces; 197 Hilbert Spaces; 424 Topological Linear Spaces).

B. Examples of Function Spaces

The following are important examples of function spaces. Throughout this section, all functions are real- or complex-valued, and two functions on a measure space are identified whenever they are equal to each other †almost everywhere.

(1) **The Function Spaces $C(\Omega)$, $C_\infty(\Omega)$, and $C_0(\Omega)$.** The totality of continuous functions $f(x)$ defined on a compact †Hausdorff space Ω is denoted by $C(\Omega)$. Let $f + g$ and αf (α a real or complex number) be the functions $f(x) + g(x)$ and $\alpha f(x)$, respectively. Then $C(\Omega)$ forms a †linear space. Furthermore, define the norm of f by $\|f\| = \sup_{x \in \Omega} |f(x)|$. Then $C(\Omega)$ becomes a †Banach space since it is complete in (the

metric defined by) the norm. The norm is called the **supremum norm** or **uniform norm** because $\lim_{n \rightarrow \infty} \|f_n - f\| = 0$ means that $f_n(x)$ converges to $f(x)$ uniformly on Ω as $n \rightarrow \infty$. Define $f \cdot g$ to be the function $f(x)g(x)$. Then clearly $\|f \cdot g\| \leq \|f\| \|g\|$. Hence $C(\Omega)$ is also a \dagger Banach algebra.

Suppose that a subset R of $C(\Omega)$ satisfies the following three conditions: (i) R is a \dagger algebra over the complex number field with respect to the addition and multiplication defined above and contains the function identically equal to one. (ii) For any two distinct points x and y of Ω , there exists a function $f \in R$ satisfying $f(x) \neq f(y)$. (iii) For any $f \in R$, there exists an $f^* \in R$ such that $f^*(x) = \overline{f(x)}$ on Ω . Then R is dense in $C(\Omega)$ with respect to the supremum norm (namely, in the sense of uniform convergence). This fact is known as the **Weierstrass-Stone theorem** (or **Stone-Gel'fand theorem**). A subset E of $C(\Omega)$ is \dagger precompact (i.e., any sequence of functions in E contains a subsequence that converges uniformly on Ω) if and only if E is \dagger uniformly bounded and \dagger equicontinuous (**Ascoli-Arzelà theorem**). Since $C(\Omega)$ is not a \dagger reflexive Banach space except for trivial cases (\rightarrow Section C), precompact sets and relatively compact sets are different in the \dagger weak topology. For important characterizations of the latter sets \rightarrow [2, 5].

When Ω is a topological space that is not necessarily compact, the totality of bounded continuous functions on Ω (denoted by $BC(\Omega)$) is also a Banach space with respect to the supremum norm $\|f\| = \sup_{x \in \Omega} |f(x)|$. Let Ω be a locally compact Hausdorff space. Then the space $C(\Omega)$ of all continuous functions on Ω is endowed with the topology of uniform convergence on the compact sets, i.e., the \dagger locally convex topology defined by the \dagger seminorms $\sup_{x \in K} |f(x)|$ as K ranges over the compact sets in Ω . $C(\Omega)$ is always a complete locally convex space. It is a \dagger Fréchet space if Ω is σ -compact (i.e., Ω is the union of a countable family of compact sets). We denote by $C_\infty(\Omega)$ the subspace of all functions $f(x) \in C(\Omega)$ that converge to zero as x tends to infinity (i.e., given an $\varepsilon > 0$, there is a compact set K such that $|f(x)| < \varepsilon$ for $x \notin K$). $C_\infty(\Omega)$ is a Banach space with the norm $\sup_{x \in \Omega} |f(x)|$. It can be regarded as a closed linear subspace of $BC(\Omega)$.

The totality of continuous functions with compact support is denoted by $C_0(\Omega)$ or $\mathcal{K}(\Omega)$, where the **support** (or **carrier**) of a function f is the \dagger closure of the set $\{x | f(x) \neq 0\}$ in Ω and is usually denoted by $\text{supp } f$. If Ω is not compact, $C_0(\Omega)$ is not complete with respect to the supremum norm, but when Ω is σ -compact $C_0(\Omega)$ is complete with respect to the strongest locally convex topology with the property that for each compact set K in Ω the embed-

ding in $C_0(\Omega)$ of the linear subspace \mathcal{K}_K of all functions with support in K equipped with the supremum norm is continuous. Usually $\mathcal{K}(\Omega)$ denotes the space $C_0(\Omega)$ equipped with this topology.

(2) **The Lebesgue Spaces $L_p(\Omega)$** ($0 < p < \infty$). Let (Ω, μ) be a \dagger measure space. We denote by $L_p(\Omega)$ the totality of \dagger measurable functions $f(x)$ on Ω such that $|f(x)|^p$ is integrable. A function f defined on (Ω, μ) is called **square integrable** if $f \in L_2(\Omega, \mu)$. If Ω is the interval (a, b) equipped with the Lebesgue measure, it is sometimes denoted by $L_p(a, b)$. We define the norm $\|f\|_p$ by

$$\|f\| = \|f\|_p = \left(\int_{\Omega} |f(x)|^p d\mu(x) \right)^{1/p}.$$

If $1 \leq p < \infty$, then $L_p(\Omega)$ is a Banach space. The triangle inequality for this norm is precisely the \dagger Minkowski inequality. If $0 < p < 1$, the norm no longer satisfies the triangle inequality but does satisfy the quasinorm inequality $\|f + g\|_p \leq 2^{1/p-1}(\|f\|_p + \|g\|_p)$, and if $\sum \|f_n\|_p < \infty$, then $\sum f_n$ converges unconditionally in $L_p(\Omega)$. Hence $L_p(\Omega)$, $0 < p < 1$, is a \dagger quasi-Banach space. If $\lim_{n \rightarrow \infty} \|f_n - f\|_p = 0$, we say that the sequence $\{f_n\}$ **converges to f in the mean of order p** (or **in the mean of power p**), and write $\text{l.i.m.}_{n \rightarrow \infty} f_n = f$. If $\{f_n\}$ converges to f in the mean of order 2, we simply say that $\{f_n\}$ converges to f in the mean. (The notation l.i.m. means the **limit in the mean** and is used mostly when $p = 2$.) For any $f, g \in L_2(\Omega)$, $(f, g) = \int_{\Omega} f(x) \overline{g(x)} d\mu(x)$ is well defined, by the \dagger Schwarz inequality, and has the properties of the \dagger inner product. Hence, $L_2(\Omega)$ is a \dagger Hilbert space. If $1 < p < \infty$, then $L_p(\Omega)$ is a \dagger uniformly convex Banach space and is in particular \dagger reflexive. Deepest results on $L_p(\mathbb{R}^n)$, $1 < p < \infty$, are often derived from the **Littlewood-Paley theory** due to J. E. Littlewood and R. E. A. C. Paley, A. Zygmund [6], and E. M. Stein [7]. Its starting point is the inequality

$$A_p \|f\|_p \leq \|g(f)\|_p \leq A'_p \|f\|_p,$$

where $g(f)$ is the function

$$g(f)(x) = \left(\int_0^\infty |\text{grad}_x u(x, t)|^2 t dt \right)^{1/2}$$

obtained from the **Poisson integral**

$$u(x, t)$$

$$= \frac{\Gamma((n+1)/2)}{\pi^{(n+1)/2}} \int_{\mathbb{R}^n} t(t^2 + |x - y|^2)^{-(n+1)/2} f(y) dy,$$

where $|x| = (x_1^2 + \dots + x_n^2)^{1/2}$.

The L_p spaces, $1 < p < \infty$, are generalized in the following way. Let $\Phi(s)$ be a convex and nondecreasing function on $[0, \infty)$ satisfying $\Phi(0) = 0$ and $\Phi(s)/s \rightarrow \infty$ as $s \rightarrow \infty$. Denote

by $L_\Phi(\Omega)$ ($L_\Phi^*(\Omega)$) the set of all functions $f(x)$ such that $\Phi(|f(x)|)$ is integrable ($\Phi(k|f(x)|)$ is integrable for some $k > 0$). $L_\Phi(\Omega) = L_\Phi^*(\Omega)$ if $\Phi(2s) \leq C\Phi(s)$. $L_\Phi^*(\Omega)$ is a Banach space, called the **Orlicz space**, under the norm

$$\|f\| = \inf \left\{ \lambda > 0 \mid \int \Phi(\lambda^{-1}|f(x)|) d\mu(x) \leq 1 \right\}.$$

$L_p(\Omega)$, $1 < p < \infty$, is the Orlicz space for $\Phi(s) = s^p$.

(3) The Function Space $M(\Omega) = L_\infty(\Omega)$. Let Ω and μ be as in (2). A measurable function $f(x)$ on Ω is said to be **essentially bounded** if there exists a positive number α such that $|f(x)| \leq \alpha$ almost everywhere on Ω . The infimum of such α is called the **essential supremum** of f , denoted by $\text{ess sup}_{x \in \Omega} |f(x)|$. The totality of essentially bounded measurable functions on Ω (denoted by $M(\Omega)$) is a Banach space with respect to the norm $\|f\| = \|f\|_\infty = \text{ess sup}_{x \in \Omega} |f(x)|$. If $\mu(\Omega) < \infty$, then $M(\Omega) \subset L_p(\Omega)$ for any $p > 0$, and $\|f\|_\infty = \lim_{p \rightarrow \infty} \|f\|_p$ for any $f \in M(\Omega)$. From this point of view, $M(\Omega)$ is also denoted by $L_\infty(\Omega)$ even when $\mu(\Omega) = \infty$. This is also the reason why the notation $\|\cdot\|_\infty$ is used for the norm in $M(\Omega)$.

(4) The Lorentz Spaces $L_{(p,q)}(\Omega)$ ($0 < p, q \leq \infty$). The Lebesgue spaces $L_p(\Omega)$, $0 < p \leq \infty$, are **rearrangement invariant**. Namely, define for a measurable function f on a measure space (Ω, μ) the **distribution function** $\mu_f(s) = \mu\{x \in \Omega \mid |f(x)| > s\}$, $s > 0$, and the **rearrangement** $f^*(t) = \inf\{s > 0 \mid \mu_f(s) \leq t\}$, $t > 0$. Then $f \in L_p(\Omega)$ if and only if $f^* \in L_p(0, \infty)$ and $\|f\|_p = \|f^*\|_p$. Another important class of rearrangement invariant spaces are the **Lorentz spaces** $L_{(p,q)}(\Omega)$, $0 < p, q \leq \infty$ (G. G. Lorentz, 1950; R. A. Hunt [8]), which is defined to be the quasi-Banach space of all measurable functions f on Ω such that

$$\|f\|_{(p,q)} = \|t^{1/p} f^*(t)\|_{L_q^*} < \infty,$$

where L_q^* is the L_q -space on $(0, \infty)$ relative to the measure dt/t . $L_{(p,p)}(\Omega) = L_p(\Omega)$ with equal norms. If $1 < p < \infty$ and $1 \leq q \leq \infty$, then $L_{(p,q)}(\Omega)$ is a Banach space under the equivalent norm $\|t^{1/p-1} \int_0^t f^*(s) ds\|_{L_q^*}$. Except for these cases, $L_{(p,q)}(\Omega)$ is not equivalent to a normed space in general [8]. If $q_0 < q_1$, then $L_{(p,q_0)}(\Omega) \subset L_{(p,q_1)}(\Omega)$ with continuous embedding. In case $\mu(\Omega) < \infty$, $L_{(p_0,q_0)}(\Omega) \subset L_{(p_1,q_1)}(\Omega)$ for $p_0 > p_1$ and any q_0, q_1 . The Lorentz spaces play an important role in interpolation and approximation theory (\rightarrow 224 Interpolation of Operators).

(5) The Function Space $S(\Omega)$. Let (Ω, μ) be a measure space with $\mu(\Omega) < \infty$. Denote by $S(\Omega)$

the totality of measurable functions on Ω that take finite value almost everywhere. Then $\|f\| = \int_\Omega (|f(x)|/(1+|f(x)|)) d\mu(x)$ for $f \in S(\Omega)$ has the properties of the \dagger pseudonorm and $S(\Omega)$ is a \dagger Fréchet space (in the sense of Banach) that is not locally convex in general. We have $\lim_{n \rightarrow \infty} \|f_n - f\| = 0$ if and only if

$$\lim_{n \rightarrow \infty} \mu(\{x \mid |f_n(x) - f(x)| > \varepsilon\}) = 0$$

for any positive number ε . Convergence of this type is called **convergence in measure** (or **asymptotic convergence**) and is the same notion as \dagger convergence in probability of a sequence of \dagger random variables (\rightarrow 342 Probability Theory). If $\{f_n\} \in L_p(\Omega)$ converges to $f \in L_p(\Omega)$ in the mean of order p , then $\{f_n\}$ converges to f asymptotically, but the converse is not true in general. If a sequence $\{f_n\} \in S(\Omega)$ converges to $f \in S(\Omega)$ almost everywhere, then $\{f_n\}$ converges to f asymptotically. Any sequence $\{f_n\}$ that converges to f asymptotically contains a subsequence $\{f_{n_k}\}$ that converges to f almost everywhere.

(6) The Sequence Spaces c, c_0, l_p ($0 < p < \infty$), $m = l_\infty$, and s . The totality c (resp. c_0) of sequences $x = \{\xi_n\}$ that converges (resp. converges to zero) as $n \rightarrow \infty$ forms a Banach space with respect to the norm $\|x\| = \sup |\xi_n|$. c_0 (resp. c) is the space $C_\infty(\Omega)$ (resp. $C(\Omega)$) when Ω is (resp. the one-point compactification of) the discrete locally compact space $\{1, 2, 3, \dots\}$. The sequence space l_p , $0 < p < \infty$ (resp. $m = l_\infty$), is defined to be the spaces $L_p(\Omega)$ (resp. $M(\Omega)$), where Ω is the space $\{1, 2, 3, \dots, n, \dots\}$, of which each point has unit mass, while s denotes the space $S(\Omega)$, where $\Omega = \{1, 2, \dots, n, \dots\}$, provided with the measure assigning mass $1/2^n$ to the point n . s is the set of all sequences equipped with the topology of pointwise convergence (s is also used to denote the space of rapidly decreasing sequences; \rightarrow Section (16)).

Assume that the space $L_2(\Omega)$ mentioned in (2) is \dagger separable and that $\{\varphi_n\}$ is a \dagger complete orthonormal set in $L_2(\Omega)$. Then putting

$$\xi_n = \int_\Omega f(x) \overline{\varphi_n(x)} d\mu(x)$$

(\dagger Fourier coefficients) for any $f \in L_2(\Omega)$, we have $\{\xi_n\} \in l_2$ and $\sum_{n=1}^\infty |\xi_n|^2 = \|f\|^2$. Conversely, for any $\{\xi_n\} \in l_2$ there exists an $f = \sum_{n=1}^\infty \xi_n \varphi_n \in L_2(\Omega)$ whose Fourier coefficients are the given ξ_n (**Riesz-Fischer theorem**). By means of this correspondence, separable spaces $L_2(\Omega)$ and l_2 are mutually isomorphic as Hilbert spaces. Sometimes we denote by $l_p(\Omega)$ the function space $L_p(\Omega)$, where Ω is an arbitrary set endowed with the measure assigning mass 1 to each point.

(7) **The John-Nirenberg Space BMO .** A locally integrable function $f(x)$ on \mathbf{R}^n is said to be of **bounded mean oscillation** if

$$\|f\|_{BMO} = \sup |S|^{-1} \int_S |f(x) - f_S| dx < \infty, \quad (1)$$

where the supremum is taken over all (solid) spheres S in \mathbf{R}^n , f_S is the mean $|S|^{-1} \int_S f(x) dx$, and $|S|$ denotes the measure of S (F. John and L. Nirenberg, 1961). The set $BMO(\mathbf{R}^n)$ of all functions on \mathbf{R}^n of bounded mean oscillation forms a Banach space under the norm mentioned above if two functions f and g are identified whenever $f - g$ is equal to a constant almost everywhere. Condition (1) is equivalent to

$$\sup \left(|S|^{-1} \int_S |f(x) - f_S|^p dx \right)^{1/p} < \infty$$

for any $1 \leq p < \infty$. There are constants B and $K > 0$ such that

$$\begin{aligned} |\{x \in S \mid |f(x) - f_S| > \lambda\}| \\ \leq B|S| \exp(-K\lambda/\|f\|_{BMO}) \end{aligned}$$

for any sphere S and $\lambda > 0$. BMO is a slightly larger space than L_∞ (e.g. $\log|x| \in BMO$) and has better properties. For example, the \dagger Calderón-Zygmund operators are bounded in $BMO(\mathbf{R}^n)$. We have

$$BMO(\mathbf{R}^n) = L_\infty(\mathbf{R}^n) + \sum_{j=1}^n R_j L_\infty(\mathbf{R}^n),$$

where R_j are the \dagger Riesz transforms [9]. This is called the **Fefferman-Stein decomposition**. The Riesz transforms can be replaced by more general families of singular integral operators (A. Uchiyama, *Acta Math.* (1982)).

(8) **The Hardy Spaces H_p** ($0 < p < \infty$). The classical theory of Hardy classes (\rightarrow 159 Fourier Series G) has been reconstructed by the real-analysis method and extended to higher-dimensional cases by E. M. Stein, G. Weiss, C. Fefferman, and others. According to their terminology the elements of the Hardy space H_p are (the complex linear combinations of) the real parts of the boundary values of holomorphic functions of the Hardy class.

Let $f \in \mathcal{S}'(\mathbf{R}^n)$ be a \dagger tempered distribution. For a $\varphi \in \mathcal{S}(\mathbf{R}^n)$ define the radial maximal function $M_\varphi^+ f$ and the nontangential maximal function $M_\varphi^* f$ relative to φ by

$$M_\varphi^+ f(x) = \sup_{t>0} |\varphi_t * f(x)|,$$

$$M_\varphi^* f(x) = \sup_{|x-y| \leq t} |\varphi_t * f(y)|,$$

where $\varphi_t(x) = t^{-n} \varphi(x/t)$ and $*$ denotes convolution. Then the **Hardy space $H_p(\mathbf{R}^n)$** , $0 < p < \infty$, is defined to be the space of all tempered distributions f which satisfy the following

equivalent conditions: (i) $M_\varphi^+ f \in L_p$ for a φ with $\int \varphi(x) dx \neq 0$; (ii) $M_\varphi^* f \in L_p$ for a φ with $\int \varphi dx \neq 0$; (iii) $M_\varphi^+ f \in L_p$ for any φ ; (iv) $M_\varphi^* f \in L_p$ for any φ . If a distribution f satisfies (one of) these conditions, then its Poisson integral $u(x, t) = \varphi_t * f(x)$ is a function, where $\varphi(x) = \text{const}(1 + |x|^2)^{-(n+1)/2}$, and its **radial maximal function** $u^+(x) = \sup_{t>0} |u(x, t)|$ and **nontangential maximal function** $u^*(x) = \sup_{|x-y| < t} |u(y, t)|$ both belong to L_p . Conversely if $u(x, t)$ is a harmonic function on the upper half-space $t > 0$ and if either u^+ or u^* belongs to L_p , then its boundary value $f = u(\cdot, 0)$ exists in the sense of tempered distribution and f satisfies the above conditions. Define the norm of an $f \in H_p(\mathbf{R}^n)$ by $\|u^*\|_p$. Then $H_p(\mathbf{R}^n)$ becomes a quasi-Banach space. If $1 < p < \infty$, then $H_p(\mathbf{R}^n) = L_p(\mathbf{R}^n)$ with equivalent norms. $H_1(\mathbf{R}^n)$ is a Banach space strictly smaller than $L_1(\mathbf{R}^n)$. An $f \in L_1(\mathbf{R}^n)$ belongs to $H_1(\mathbf{R}^n)$ if and only if all the Riesz transforms $R_j f$ are in $L_1(\mathbf{R}^n)$, and $\|f\|_{H_1}$ is equivalent to $\|f\|_1 + \sum \|R_j f\|_1$. Similar characterizations of $H_p(\mathbf{R}^n)$ are also known for $p > 0$ (Fefferman and Stein [9]).

Let $\Gamma_j, j = 1, \dots, m$, be \dagger proper convex open cones in \mathbf{R}^n such that the \dagger polars Γ_j° cover \mathbf{R}^n . Then an $f \in \mathcal{S}'(\mathbf{R}^n)$ belongs to $H_p(\mathbf{R}^n)$ if and only if there are holomorphic functions $F_j(x + iy)$ on $\mathbf{R}^n + i\Gamma_j$ such that $\sup \{\|F_j(\cdot + iy)\|_p \mid y \in \Gamma_j\} < \infty$ and $f = \sum F_j(\cdot + i\Gamma_j 0)$ (D. L. Burkholder, R. F. Gundy, and M. L. Silverstein for $n = 1$ and L. Carleson for $n > 1$). Let $0 < p \leq 1$. A measurable function a on \mathbf{R}^n is said to be a **p -atom** if there is a sphere S such that $\text{supp } a \subset S$ and $\|a\|_\infty \leq |S|^{-1/p}$ and if $\int a(x) x^\alpha dx = 0$ for all multi-indices α with $|\alpha| \leq n(p^{-1} - 1)$. Here a **multi-index** α is an n -tuple $(\alpha_1, \dots, \alpha_n)$ of nonnegative integers, $|\alpha| = \alpha_1 + \dots + \alpha_n$ and $x^\alpha = x_1^{\alpha_1} \dots x_n^{\alpha_n}$. A distribution f belongs to $H_p(\mathbf{R}^n)$, $0 < p \leq 1$, if and only if there are a sequence of p -atoms a_j and a sequence of numbers $\lambda_j \geq 0$ in l_p such that $f = \sum \lambda_j a_j$ in the sense of distributions, and the norm $\|f\|_{H_p}$ is equivalent to the infimum of $\|\lambda_j\|_{l_p}$ (R. R. Coifman for $n = 1$ and R. H. Latter for $n > 1$). The theory of H_p and BMO has been generalized to more general situations (\rightarrow Coifman and Weiss, *Bull. Amer. Math. Soc.* (1977)).

From now on we assume that Ω is a domain in the n -dimensional Euclidean space \mathbf{R}^n (or more generally a differentiable manifold). D^α stands for $D_1^{\alpha_1} \dots D_n^{\alpha_n}$, where $D_j = \partial/\partial x_j$.

(9) **The Function Spaces $C^l(\Omega)$ and $C_0^l(\Omega)$** ($l = 0, 1, 2, \dots, \infty$). The totality of l -times continuously differentiable functions in Ω (namely, differentiable functions of \dagger class C^l in Ω) is denoted by $C^l(\Omega)$. We say that a sequence $\{f_v\}$ of functions in $C^l(\Omega)$ converges to 0 in $C^l(\Omega)$ if $|D^\alpha f_v(x)|$ converges to 0 uniformly on

every compact subset of Ω for every α satisfying $0 \leq |\alpha| \leq l$ ($0 \leq |\alpha| < \infty$ if $l = \infty$). $C^l(\Omega)$ is a Fréchet space. The totality of functions in $C^l(\Omega)$ whose supports are compact subsets of Ω is denoted by $C_0^l(\Omega)$. We say that a sequence $\{f_v\}$ of functions in $C_0^l(\Omega)$ converges to 0 in $C_0^l(\Omega)$ if $\text{supp } f_v$ ($v = 1, 2, \dots$) is contained in a compact subset of Ω independent of v and $\{f_v\}$ converges to 0 in $C^l(\Omega)$. $C_0^l(\Omega)$ is an ${}^t(\text{LF})$ -space.

When Ω is a locally closed set in \mathbf{R}^n (or a differentiable manifold with boundary), we denote by $C^l(\Omega)$ the totality of functions $f(x)$ on Ω together with their continuous formal derivatives $D^\alpha f(x)$, $|\alpha| \leq l$ ($|\alpha| < \infty$ if $l = \infty$) on Ω such that for every α and m with $|\alpha| \leq m \leq l$ ($m < \infty$ if $l = \infty$),

$$D^\alpha f(x) - \sum_{|\beta| \leq m - |\alpha|} D^{\alpha+\beta} f(y) (x-y)^\beta / \beta! \\ = o(|x-y|^{m-|\alpha|})$$

locally uniformly in Ω as $|x-y|$ tends to 0. Convergence in $C^l(\Omega)$ is defined in the same way as above.

If Ω is a closed set in \mathbf{R}^n with a finite number of connected components in each of which two points x and y are connected by an arc of length $\leq C|x-y|$ with a constant C independent of x and y , then every f in $C^l(\Omega)$ can be extended to an \tilde{f} in $C^l(\mathbf{R}^n)$ (**Whitney's extension theorem**).

(10) The Lipschitz Spaces Λ^s . Let $s > 0$, and let k be the least integer greater than s . The **Lipschitz** (or **Hölder**) **space $\Lambda^s(\mathbf{R}^n)$** is the totality of functions $f(x)$ on \mathbf{R}^n which satisfy

$$\|f\|_{\Lambda^s} = \sup_{x,y} \left| \sum_{j=0}^k \binom{k}{j} (-1)^j f(x+jy) \right| / |y|^s < \infty.$$

When $s < 1$, this is exactly the t Lipschitz (or Hölder) condition of order s . But when $s = 1$, it is strictly weaker than the t Lipschitz condition. A function $f \in \Lambda^1$ is said to be **smooth in the sense of A. Zygmund** [6]. Suppose $0 < h < s$ is an integer. Then a function f belongs to Λ^s if and only if it is h times continuously differentiable and all the derivatives $D^\alpha f$ of order h are in Λ^{s-h} . $\Lambda^s(\mathbf{R}^n)$ is a Banach space of functions modulo the polynomials of degree $\leq k-1$.

Suppose that $1 \leq q < \infty$ and f is a measurable function on \mathbf{R}^n such that

$$\sup_S \inf_P \left(|S|^{-1-(sq/n)} \int_S |f(x) - P(x)|^q dx \right)^{1/q} < \infty,$$

where the supremum is taken over all spheres in \mathbf{R}^n and the infimum over all polynomials of degree $\leq s$. Then $f(x)$ is equal to a function $\tilde{f}(x)$ in $\Lambda^s(\mathbf{R}^n)$ almost everywhere and the supremum is equivalent to the norm $\|\tilde{f}\|_{\Lambda^s}$. Conversely every $f \in \Lambda^s(\mathbf{R}^n)$ satisfies the above inequality (S. Campanato).

(11) The Sobolev Spaces $W_p^l(\Omega)$, $H^l(\Omega)$, and $H_0^l(\Omega)$ ($l = 0, 1, 2, \dots, 1 \leq p \leq \infty$ or $-\infty < l < \infty, 1 < p < \infty$). Let $l \geq 0$ be an integer and $1 \leq p \leq \infty$. The Sobolev space $W_p^l(\Omega)$ is the totality of functions $f(x)$ such that for all α satisfying $|\alpha| \leq l$, the derivatives $D^\alpha f(x)$ in the sense of distribution (\rightarrow 125 Distributions and Hyperfunctions) belong to $L_p(\Omega)$ with respect to Lebesgue measure in Ω . $W_p^l(\Omega)$ is a Banach space with the norm

$$\|f\| = \|f\|_{W_p^l} = \left(\sum_{0 \leq |\alpha| \leq l} \int_\Omega |D^\alpha f(x)|^p dx \right)^{1/p}.$$

Clearly $W_p^0(\Omega) = L_p(\Omega)$. $W_2^l(\Omega)$ is a Hilbert space with respect to the inner product

$$(f, g) = \int_\Omega \sum_{0 \leq |\alpha| \leq l} D^\alpha f(x) \cdot \overline{D^\alpha g(x)} dx.$$

Sometimes $W_2^l(\Omega)$ is denoted by $H^l(\Omega)$. Its closed linear subspace obtained as the completion of $C_0^\infty(\Omega)$ is denoted by $H_0^l(\Omega)$. We have $H_0^0(\Omega) = W_2^0(\Omega) = L_2(\Omega)$. However, if $l \geq 1$, we have $H_0^l(\Omega) \subset W_2^l(\Omega)$, and identity does not hold unless $\Omega = \mathbf{R}^n$.

The definition of Sobolev spaces has been extended to those with fractional and also negative order $-\infty < s < \infty$ in many different ways. When $1 < p < \infty$, it is natural to define $W_p^s(\mathbf{R}^n)$ to be the space of all tempered distributions f on \mathbf{R}^n such that $(1 - \Delta)^{s/2} f = \mathcal{F}^{-1}((1 + |\xi|^2)^{s/2} \mathcal{F}f) \in L_p(\mathbf{R}^n)$. If $s > 0$, then $W_p^s(\mathbf{R}^n)$ thus defined coincides with the space of all $f \in L_p(\mathbf{R}^n)$ whose Poisson integral $u(x, t)$ satisfies

$$\left\| \left(\int_0^\infty t^{4k-2s-1} |\Delta^k u(\cdot, t)|^2 dt \right)^{1/2} \right\|_p < \infty$$

for some (and any) integer $k > s/2$.

The Poisson integral can be replaced by other regularizations, and thus the definition of Sobolev spaces of fractional orders is extended to arbitrary open set Ω with the cone condition (T. Muramatsu [13]). Here Ω is said to satisfy the cone condition if there are a bounded and uniformly continuous mapping $\Psi: \mathbf{R}^n \rightarrow \mathbf{R}^n$ and an $\varepsilon > 0$ such that for any $x \in \Omega$ the convex hull of the ε -ball with center at $x + \Psi(x)$ and $\{x\}$ is included in Ω .

(12) The Besov Spaces $B_{p,q}^s$ ($-\infty < s < \infty, 1 \leq p, q \leq \infty$). The effort to make the Sobolev embedding theorem [10] more precise led S. M. Nikol'skii and O. V. Besov [11] to the other classes of "Sobolev spaces" of fractional order. Let $s > 0$ and $1 \leq p, q \leq \infty$. The **Besov space $B_{p,q}^s(\mathbf{R}^n)$** is the totality of functions $f \in L_p(\mathbf{R}^n)$ such that

$$\|f\|_{B_{p,q}^s} = \left(\int \left\| \sum_{j=0}^k \binom{k}{j} (-1)^j f(\cdot + jy) \right\|_p^q \frac{dy}{|y|^{qs+n}} \right)^{1/q} < \infty$$

for some (and any) integer $k > s$. In terms of the Poisson integral an $f \in L_p(\mathbf{R}^n)$ belongs to $B_{p,q}^s(\mathbf{R}^n)$ if and only if

$$\left(\int_0^\infty t^{(2k-s)q-1} \left\| \Delta^k u(\cdot, t) \right\|_p^q dt \right)^{1/p} < \infty$$

for some (and any) integer $k > s/2$. The first definition is obviously extended to an arbitrary domain Ω in \mathbf{R}^n . If Ω satisfies the cone condition, then the functions in $B_{p,q}^s(\Omega)$ are characterized similarly as above by using a suitable regularization $u(x, t)$ of $f(x)$ (Muramatu [13]). Let Ω be a domain with the cone condition. When $0 < h < s$ is an integer, an f belongs to $B_{p,q}^s(\Omega)$ if and only if $f \in W_p^h(\Omega)$ and all the derivatives $D^\alpha f$ of order h are in $B_{p,q}^{s-h}(\Omega)$. $B_{p,q}^s(\Omega)$ is a Banach space with the norm $\|f\|_p + |f|_{B_{p,q}^s}$. If $p=2$, then $B_{2,2}^s(\Omega)$ coincides with the Sobolev space $W_2^s(\Omega)$. But in the other cases, $B_{p,q}^s(\Omega)$ is different from $W_p^s(\Omega)$ for any q . However, $B_{p,p}^s(\Omega)$ or $B_{p,\infty}^s(\Omega)$ is often called a Sobolev space of order s and denoted by $W_p^s(\Omega)$. Clearly we have $B_{\infty,\infty}^s = L_\infty \cap \Lambda^s$.

The **Besov space** $B_{p,q}^s(\Omega)$ of order $s \leq 0$ is defined to be the totality of distributions f which can be represented as $f = \sum_{|\alpha| \leq k} D^\alpha f_\alpha$ with $f_\alpha \in B_{p,q}^{s+k}(\Omega)$ for some (and any) integer k such that $s+k > 0$. The norm is defined to be $\inf \sum_\alpha \|f_\alpha\|_{B_{p,q}^{s+k}(\Omega)}$. In terms of the Poisson integrals or other regularizations the same characterization holds as above.

If Ω is a domain in \mathbf{R}^n with the cone condition, then the restriction $B_{p,q}^s(\mathbf{R}^n) \rightarrow B_{p,q}^s(\Omega)$ (resp. $W_p^s(\mathbf{R}^n) \rightarrow W_p^s(\Omega)$ for $1 < p < \infty$) is a bounded linear surjection with a bounded right inverse [13].

From now on we denote by $B_{p,q}^s$, etc., $B_{p,q}^s(\Omega)$, etc. for a domain $\Omega \subset \mathbf{R}^n$ with the cone condition. If $q < r$, then $B_{p,q}^s \subset B_{p,r}^s$. If $1 \leq p \leq 2$, then $B_{p,p}^s \subset W_p^s \subset B_{p,2}^s$. If $2 \leq p \leq \infty$, then $B_{p,2}^s \subset W_p^s \subset B_{p,p}^s$. If $s > t$, then $B_{p,\infty}^s \subset B_{p,\infty}^t$.

Sobolev-Besov embedding theorems: (i) Let $p < p'$ and $s - n/p = s' - n/p'$. Then $B_{p,q}^s \subset B_{p',q}^{s'}$, $B_{p,p'}^s \subset W_{p'}^{s'}$, $W_p^s \subset B_{p',p}^{s'}$ and, if $p' < \infty$, then $W_{p'}^{s'} \subset W_p^{s'}$. (ii) Let $0 < s < n/p$ and $n/p' = n/p - s$. Then $B_{p,q}^s \subset L_{(p',q)}$ and $W_p^s \subset L_{(p',p)} (\subset L_{p'})$. (iii) Let $s = n/p$. Then $B_{p,1}^s \subset BC$ for any p and $B_{p,\infty}^s \subset BMO$ for $p < \infty$. (iv) Let $0 \leq n' < n$ and $0 < s' = s - (n - n')/p$. Then there is a bounded **trace operator** $Tr: B_{p,q}^s(\mathbf{R}^n) \rightarrow B_{p,q}^{s'}(\mathbf{R}^{n'})$ that extends the restriction mapping $\mathcal{S}(\mathbf{R}^n) \rightarrow \mathcal{S}(\mathbf{R}^{n'})$. Tr is surjective and has a bounded linear right inverse [11–13].

(13) The Function Spaces \mathcal{D} , \mathcal{E} , \mathcal{D}_{L_p} , \mathcal{B} , and \mathcal{S} . The spaces of infinitely differentiable functions $C_0^\infty(\Omega)$ and $C^\infty(\Omega)$ are also denoted by $\mathcal{D}(\Omega)$ and $\mathcal{E}(\Omega)$, respectively. The totality of functions $f(x)$ in $C^\infty(\Omega)$ such that, for all α , $D^\alpha f(x)$ belongs to $L_p(\Omega)$ with respect to † Lebesgue measure is denoted by $\mathcal{D}_{L_p}(\Omega)$. The neighbor-

hood $V_{l,\varepsilon}$ of 0 in $\mathcal{D}_{L_p}(\Omega)$ is defined to be the totality of functions $f(x)$ such that $\|D^\alpha f\|_p < \varepsilon$ for any α satisfying $|\alpha| \leq l$. In particular, $\mathcal{D}_{L_\infty}(\Omega)$ is also denoted by $\mathcal{B}(\Omega)$. ($\mathcal{B}(\Omega)$ is also used to denote the space of hyperfunctions.)

A function $f(x)$ is called a **rapidly decreasing C^∞ -function** if it belongs to $C^\infty(\mathbf{R}^n)$ and satisfies

$$\lim_{|x| \rightarrow \infty} |x|^k |D^\alpha f(x)| = 0$$

for any α and any integer $k > 0$. The totality of rapidly decreasing C^∞ -functions is denoted by \mathcal{S} . The neighborhood $V_{l,k,\varepsilon}$ of 0 in \mathcal{S} is defined to be the totality of functions $f(x)$ such that $(1 + |x|^2)^k |D^\alpha f(x)| < \varepsilon$ for any α satisfying $|\alpha| \leq l$.

The spaces in this section are † nuclear except for \mathcal{D}_L and \mathcal{B} , and are employed in the theory of distributions [14] (\rightarrow 125 Distributions and Hyperfunctions). When $\Omega = \mathbf{R}^n$, we usually omit (\mathbf{R}^n) ; for example, $\mathcal{D}(\mathbf{R}^n)$ and $\mathcal{D}_{L_p}(\mathbf{R}^n)$ are denoted by \mathcal{D} and \mathcal{D}_{L_p} , respectively.

(14) The Function Spaces $\mathcal{D}_{\{M_p\}}$, $\mathcal{D}_{(M_p)}$, $\mathcal{E}_{\{M_p\}}$, $\mathcal{E}_{(M_p)}$, and $\mathcal{A} = C^\omega$. Let $\{M_p\}$ be a sequence of positive numbers satisfying the logarithmic convexity $M_p^2 \leq M_{p-1} M_{p+1}$. $\mathcal{E}_{\{M_p\}}(\Omega)$ (resp. $\mathcal{E}_{(M_p)}(\Omega)$) denotes the totality of C^∞ -functions f on Ω such that for any compact set K in Ω there are constants k and C (resp. for any $k > 0$ there is a constant C) satisfying

$$|D^\alpha f(x)| \leq C k^{|\alpha|} M_{|\alpha|}, \quad x \in K, |\alpha| \geq 0.$$

$\mathcal{E}_{\{p\}}(\Omega)$ is the totality of † real analytic functions on Ω and is denoted by $\mathcal{A}(\Omega)$ or $C^\omega(\Omega)$. If $\{M_p\}$ satisfies the **Denjoy-Carleman condition** $\sum M_p/M_{p+1} < \infty$, then $\mathcal{D}_{\{M_p\}}(\Omega) = \mathcal{D}(\Omega) \cap \mathcal{E}_{\{M_p\}}(\Omega)$ and $\mathcal{D}_{(M_p)}(\Omega) = \mathcal{D}(\Omega) \cap \mathcal{E}_{(M_p)}(\Omega)$ are dense in $\mathcal{D}(\Omega)$. Conversely, if $\mathcal{D}_{\{M_p\}}(\Omega)$ is different from $\{0\}$, then $\{M_p\}$ satisfies the Denjoy-Carleman condition. In this case an $f \in \mathcal{E}_{\{M_p\}}(\Omega)$ (resp. $\mathcal{E}_{(M_p)}(\Omega)$) is sometimes called an **ultradifferentiable function** of class $\{M_p\}$ (resp. (M_p)). The most important is the case where $M_p = p!^s$ for an $s > 1$. Then an $f \in \mathcal{E}_{\{M_p\}}(\Omega)$ (resp. $\mathcal{E}_{(M_p)}(\Omega)$) is called a **function of Gevrey class $\{s\}$** (resp. (s)). The topological properties of $\mathcal{A}(\Omega)$ (resp. $\mathcal{E}_{\{M_p\}}(\Omega)$, etc.) have been discussed by A. Martineau (resp. H. Komatsu).

For function spaces of S type \rightarrow 125 Distributions and Hyperfunctions.

(15) The Function Spaces $\mathcal{O}(\Omega)$, $\mathcal{O}_p(\Omega) = A_p(\Omega)$, and $A(\Omega)$. Let Ω be an open set in \mathbf{C}^n . The totality of holomorphic functions on Ω is denoted by $\mathcal{O}(\Omega)$. $\mathcal{O}(\Omega)$ is a † nuclear Fréchet space with the topology of uniform convergence on compact sets. It is a closed linear subspace of $C(\Omega)$ and also of $C^\infty(\Omega)$.

For any $p \geq 1$, the totality of functions f

holomorphic in Ω and satisfying $\int_{\Omega} |f(z)|^p dx dy < \infty$ ($z = x + iy$; $dx dy$ is Lebesgue measure), denoted by $\mathcal{O}_p(\Omega)$ or $A_p(\Omega)$, is a Banach space with respect to the norm $\|f\|_p = (\int_{\Omega} |f(z)|^p dx dy)^{1/p}$. In particular, it is a Hilbert space when $p = 2$.

The totality of functions bounded and continuous on the closure of Ω and holomorphic in Ω (denoted by $A(\Omega)$) is a Banach space with respect to the norm $\|f\| = \sup_{z \in \Omega} |f(z)|$.

(16) The Köthe Spaces $\bigcap \lambda(x^{(k)})$ and $\sum \lambda^{\times}(x^{(k)})$. Let $\{\alpha^{(k)}\}$ be an increasing sequence of sequences $\alpha^{(k)} = (\alpha_1^{(k)}, \alpha_2^{(k)}, \dots)$ of positive numbers. The **echelon space** $\bigcap \lambda^{(\alpha^{(k)})}$ of G. Köthe [15] is the totality of sequences $x = (\xi_1, \xi_2, \dots)$ such that $p^{(k)}(x) = \sum \alpha_i^{(k)} |\xi_i| < \infty$ for any k . It is a Fréchet space with the topology determined by the seminorms $p^{(k)}$. The **co-echelon space** $\sum \lambda^{\times}(x^{(k)})$ is the totality of sequences $y = (\eta_1, \eta_2, \dots)$ such that $|\eta_i| \leq C \alpha_i^{(k)}$ for some C and k . The space s of **rapidly decreasing sequences** and the space s' of **slowly increasing sequences** are the echelon space and the co-echelon space for the sequence $\alpha_i^{(k)} = i^k$. If $\alpha_i^{(k)} = k^i$, then we obtain the space of power series with infinite radius of convergence and the space of convergent power series. More generally, let $\alpha = (\alpha_i)$ be a sequence of positive numbers. The echelon spaces for $\alpha_i^{(k)} = \exp(k\alpha_i)$ and $\exp(-k^{-1}\alpha_i)$ are called the **infinite type power series space** and the **finite type power series space** and are denoted by $\Lambda_{\infty}(\alpha)$ and $\Lambda_1(\alpha)$, respectively. Echelon spaces and co-echelon spaces have been employed to construct examples and counterexamples in the theory of †locally convex spaces by Köthe [15], Grothendieck, Y. and T. Kōmura, E. Dubinsky, D. Vogt, and others.

C. Dual Spaces

When Ω is a compact Hausdorff space, any bounded linear functional Φ on $C(\Omega)$ is expressed by the †Stieltjes integral

$$\Phi(f) = \int_{\Omega} f(x) d\varphi(x), \quad f \in C(\Omega), \tag{2}$$

with a †Radon measure φ , i.e., a (real- or complex-valued) †regular †countably additive set function defined on the Borel sets in Ω . Since φ is of bounded variation, the totality of such φ is denoted by $BV(\Omega)$. Conversely, any $\varphi \in BV(\Omega)$ gives a bounded linear functional on $C(\Omega)$ defined by (2), and $\|\Phi\|$ = the total variation of φ over Ω . Hence the dual space of $C(\Omega)$ is isomorphic to the Banach space $BV(\Omega)$ with the norm $\|\Phi\|$.

Let Ω be a locally compact Hausdorff space. Then the dual space of $C_{\infty}(\Omega)$ is again the

Banach space $BV(\Omega)$ of Radon measures of bounded variation. On the other hand, the dual space of $C_0(\Omega)$ is the space of all Radon measures on Ω . N. Bourbaki takes this fact as the definition of measure.

Any bounded linear functional Φ on $L_1(\Omega)$ is expressed as

$$\Phi(f) = \int_{\Omega} f(x) \varphi(x) d\mu(x), \quad f \in L_1(\Omega), \tag{3}$$

with a suitable $\varphi \in M(\Omega)$; and $\|\Phi\| = \|\varphi\|_{\infty}$.

Conversely, any $\varphi \in M(\Omega)$ defines a bounded linear functional on $L_1(\Omega)$ by means of (3). Accordingly, the dual space of $L_1(\Omega)$ is isomorphic to $M(\Omega)$.

The dual space of $L_p(\Omega)$ ($1 < p < \infty$) is isomorphic to $L_q(\Omega)$, where q is the real number defined by $(1/p) + (1/q) = 1$ (accordingly, $1 < q < \infty$) and is called the **conjugate exponent** of p . Any bounded linear functional on $L_p(\Omega)$ is expressible by the formula in (3) (where $f \in L_p(\Omega)$) with $\varphi \in L_q(\Omega)$, and $\|\Phi\| = \|\varphi\|_q$.

The dual space of $M(\Omega)$ is isomorphic to the normed linear space of all (real- or complex-valued) finitely additive set functions φ defined on all measurable sets in Ω , of bounded variation over Ω , and absolutely continuous with respect to the measure μ given in Ω (i.e., $\mu(N) = 0$ implies $\varphi(N) = 0$). If $1 < p < \infty$ and $1 \leq q < \infty$, then the dual space of $L_{(p,q)}(\Omega)$ is isomorphic to $L_{(p',q')}(\Omega)$, where p' and q' are conjugate exponents of p and q , respectively.

If Ω is **nonatomic** (i.e., Ω has no set of positive measure that cannot be decomposed into two subsets of positive measure), then no continuous linear functionals exist other than zero on $S(\Omega)$ and on $L_p(\Omega)$ and $L_{(p,q)}(\Omega)$ for $0 < p < 1$.

The sequence spaces c_0 , l_p ($1 \leq p < \infty$), m , and s (the space defined in Section B (6)) are special cases of $C_{\infty}(\Omega)$, $L_p(\Omega)$, $M(\Omega)$, and $S(\Omega)$, respectively. Hence their dual spaces can be described explicitly. For example, the dual space of c_0 (resp. l_1) is l_1 (resp. m), and if $1 < p < \infty$, the dual space of l_p is l_q (where $(1/p) + (1/q) = 1$). The coupling of $x = (\xi_n)$ and $y = (\eta_n)$ is given by $\sum \xi_n \eta_n$. The dual space of s is the totality of sequences (η_n) such that $\eta_n = 0$ except for a finite number of n .

Let $VMO(\mathbb{R}^n)$ denote the closure of $C_0(\mathbb{R}^n)$ in $BMO(\mathbb{R}^n)$. Then the dual space of $VMO(\mathbb{R}^n)$ is identified with $H_1(\mathbb{R}^n)$. This can be considered to be a generalization of the †F. and M. Riesz theorem. On the other hand, the dual space of $H_1(\mathbb{R}^n)$ is $BMO(\mathbb{R}^n)$ [9]. Hardy spaces $H_p(\mathbb{R}^n)$, $0 < p < 1$, are not locally convex but have sufficiently many bounded linear functionals, and their dual spaces are identified with Lipschitz spaces $\Lambda^s(\mathbb{R}^n)$, where $s = n(p^{-1} - 1)$.

Let $1 < p, q < \infty$. Then the dual space of $W_p^s(\mathbb{R}^n)$ is isomorphic to $W_p^{-s}(\mathbb{R}^n)$ and that of

$B_{p,q}^s(\mathbf{R}^n)$ to $B_{p',q'}^{-s}(\mathbf{R}^n)$, where p' and q' are conjugate exponents of p and q , respectively. The dual space \mathcal{D}' of \mathcal{D} is defined to be the space of \dagger distributions; the dual spaces of \mathcal{E} , \mathcal{D}_{L_p} , and \mathcal{S} are (algebraically) linear subspaces of \mathcal{D}' . Similarly, the dual spaces of $\mathcal{D}_{\{M_p\}}$ and $\mathcal{D}_{(M_p)}$ are called the spaces of \dagger ultradistributions of classes $\{M_p\}$ and (M_p) , respectively. The dual space of \mathcal{A} is identified with the space of \dagger hyperfunctions with compact support (\rightarrow 125 Distributions and Hyperfunctions). A continuous linear functional on $\mathcal{O}(\Omega)$ is called an **analytic functional**. For each analytic functional Φ there is a compact set $L \subset \Omega$ such that $|\Phi(f)| \leq C \sup_{z \in L} |f(z)|$. A compact set K is called a **porter** of Φ if every compact neighborhood L of K satisfies this condition. Porters are similar to supports of generalized functions, but an analytic functional does not necessarily have a smallest porter.

The dual space of an echelon space is the corresponding co-echelon space.

169 (XI.19) Function-Theoretic Null Sets

A. General Remarks

By a **function-theoretic null set** we mean an exceptional set that appears in theorem as the one asserting that a certain property holds with a “small exception.” We give below some of the more important examples of exceptional sets. For simplicity, we limit ourselves to the n -dimensional Euclidean space \mathbf{R}^n ($n \geq 2$).

B. Sets of Harmonic Measure Zero

Denote by χ_E the characteristic function of a set E on the boundary ∂D of a bounded domain D in \mathbf{R}^n . We call the \dagger hypofunction H_{χ_E} and \dagger hyperfunction \bar{H}_{χ_E} (\rightarrow 120 Dirichlet Problem) the **inner** and **outer harmonic measures** of E (with respect to D), respectively. When they coincide, the function is called the **harmonic measure** of E . A necessary and sufficient condition for E to be of inner harmonic measure zero is that $u \leq 0$ hold in D whenever a \dagger subharmonic function u bounded above in D satisfies $\limsup u(P) \leq 0$ as P tends to any point of $\partial D - E$. This theorem implies the following uniqueness theorem: If h is bounded and harmonic in D , if E is a set of inner harmonic measure zero on ∂D , and if $h(P) \rightarrow 0$ as P tends to any point of $\partial D - E$, then $h \equiv 0$. A necessary and sufficient condition for E to be of outer harmonic measure zero is that there exist a positive \dagger superharmonic function v in D such that $v(P) \rightarrow \infty$ as P tends to any point of E . (Concerning the existence of a limit for a subharmonic or \dagger harmonic function at every boundary point except those on a set of harmonic measure zero, \rightarrow 193 Harmonic Functions and Subharmonic Functions.)

C. Sets of Capacity Zero

Although there are many kinds of capacity (\rightarrow 48 Capacity), here we consider only \dagger logarithmic capacity and α -capacity ($\alpha > 0$). Let K be a nonempty compact set in \mathbf{R}^n . Set

$W(K) = \inf_{\mu} \iint \overline{PQ}^{-\alpha} d\mu(P) d\mu(Q)$, where μ runs through the class of nonnegative \dagger Radon measures of total mass 1 supported by K , and write $C_{\alpha}(K) = (W(K))^{-1/\alpha}$. Define $C_{\alpha}(\emptyset) = 0$ for an empty set \emptyset . For a general set $E \subset \mathbf{R}^n$, define the inner capacity by $\sup_{K \subset E} C_{\alpha}(K)$ and the outer capacity by the infimum of the inner capacity of an open set containing E . When the inner and outer capacities coincide, the common value is called the α -**capacity** (or **capacity of order α**) of E and is denoted by $C_{\alpha}(E)$. We denote the logarithmic capacity of E by $C_0(E)$. In order that $C_0(K) = 0$ ($n = 2$) or the \dagger Newtonian capacity $C_{n-2}(K) = 0$ ($n \geq 3$) for a compact set K , it is necessary and sufficient that the harmonic measure of K with respect to $G - K$ vanish for any bounded domain G containing K . Then K is removable for any harmonic function that is bounded or has a finite \dagger Dirichlet integral in $G - K$. In general, K is said to be **removable** for a family F of functions if for any domain G containing K and $f \in F$ defined in $G - K$, there exists $g \in F$ defined in G such that $g = f$ in $G - K$. Let K be a compact set in \mathbf{R}^2 with $C_0(K) = 0$ and G be a domain containing K . Let f be a holomorphic function defined in $G - K$ for which every point of K is an \dagger essential singularity. Then the set of \dagger exceptional values for f at every point of K is of logarithmic capacity zero. If f is \dagger meromorphic in $|z| < 1$ and

$$\iint \frac{|f'|^2}{(1+|f|^2)^2} (1-|z|)^{\alpha} dx dy < \infty \quad (0 \leq \alpha < 1),$$

then f has a finite limit in any angular domain with a vertex at every point of $|z| = 1$ except for those belonging to a set of α -capacity zero (logarithmic capacity zero if $\alpha = 0$).

D. Hausdorff Measure

Let $\alpha > 0$ and a set E be given in \mathbf{R}^n . Denote by σ a covering of E by a countable number of balls with radii d_1, d_2, \dots , all of which are smaller than ε (> 0). As $\varepsilon \rightarrow 0$, $\inf_{\sigma} \sum_k d_k^{\alpha}$ increases. The limit is called the **Hausdorff measure** of E of dimension α and is denoted by $\Lambda_{\alpha}(E)$. In order for a compact set K to be removable for the family of harmonic functions defined in a bounded domain and satisfying the \dagger Hölder condition of order α , it is necessary and sufficient that $\Lambda_{n-2+\alpha}(K) = 0$. Next, suppose that K is a compact set in a plane and the complement G of K with respect to the plane is connected. Set $\|f\|_q = (\iint_G |f|^q dx dy)^{1/q}$ for f holomorphic in G and $q, 1 \leq q < \infty$, and $\|f\|_{\infty} = \sup_G |f|$. Denote by H^q the family of $f \neq 0$ with $\|f\|_q < \infty$. If p is defined by $1/p + 1/q = 1$, then $\Lambda_{2-p}(K) < \infty$ implies $H^q = \emptyset$ for $q, 2 < q < \infty$, and $\Lambda_1(K) = 0$

Function-Theoretic Null Sets

implies $H^{\infty} = \emptyset$. Moreover, $H^2 = \emptyset$ if and only if $C_0(K) = 0$, and $H^q = \emptyset$ implies $C_{2-p}(K) = 0$ for $q, 2 < q \leq \infty$ [1].

E. Null Sets Defined with Respect to Families of Functions

Conversely, L. V. Ahlfors and A. Beurling characterized the size of sets in a plane by means of families of functions [2]. Let D be a domain, and let f represent a holomorphic function in D . Fix a point z_0 in D . Set

$$\mathfrak{B} = \{f \mid |f| \leq 1\},$$

$$\mathfrak{D} = \left\{f \mid \iint_D |f'|^2 dx dy \leq \pi\right\},$$

$$\mathfrak{E} = \{f \mid \text{the area of } R^c \geq \pi\},$$

where R^c is the complement of the \dagger range R of $(f(z) - f(z_0))^{-1}$. Denote by $\mathfrak{B}, \mathfrak{D}, \mathfrak{E}$ the families consisting of constants and \dagger univalent functions in $\mathfrak{B}, \mathfrak{D}, \mathfrak{E}$, respectively. Use the notation \mathfrak{F} to represent any one of these six families, and define $M_{\mathfrak{F}} = M_{\mathfrak{F}}(z_0; D)$ by $\sup\{|f'(z_0)| \mid f \in \mathfrak{F}\}$. Then $M_{\mathfrak{B}} = M_{\mathfrak{E}} \geq M_{\mathfrak{D}} = M_{\mathfrak{D}\mathfrak{E}} \geq M_{\mathfrak{B}\mathfrak{E}} = M_{\mathfrak{D}\mathfrak{E}}$, and $M_{\mathfrak{F}}(z_0; D) = 0$ implies $M_{\mathfrak{F}}(z; D) = 0$ for any $z \in D$.

Denote by $N_{\mathfrak{F}}$ the class of compact sets K such that the complement K^c of K is connected and $M_{\mathfrak{F}}(z; K^c) = 0$. We call $K \in N_{\mathfrak{F}}$ a **null set of class $N_{\mathfrak{F}}$** . In order for K to be removable for \mathfrak{B} or \mathfrak{D} , it is necessary and sufficient that $K \in N_{\mathfrak{B}}$ or $\in N_{\mathfrak{D}}$, respectively. We in general have

$$\{K \mid C_0(K) = 0\} \subsetneq N_{\mathfrak{B}} \subsetneq N_{\mathfrak{D}} \subsetneq N_{\mathfrak{B}\mathfrak{E}}.$$

If $\Lambda_1(K) = 0$, then $K \in N_{\mathfrak{B}}$. There exists a set $K \in N_{\mathfrak{B}}$ with $\Lambda_1(K) > 0$ (A. G. Vitushkin, *Dokl. Akad. Nauk SSSR*, 127 (1959); J. Garnett, *Proc. Amer. Math. Soc.*, 21 (1970)). When K is a subset of an analytic arc A , $K \in N_{\mathfrak{B}}$ implies $\Lambda_1(K) = 0$, $N_{\mathfrak{D}}$ is equal to $N_{\mathfrak{B}\mathfrak{E}}$, and K belongs to $N_{\mathfrak{D}}$ if and only if $C_0(A) = C_0(A - K)$. If an \dagger analytic function has an essential singularity at every point of $K \in N_{\mathfrak{B}}$, then any compact subset of the set of exceptional values at every point of K belongs to $N_{\mathfrak{B}}$. A necessary and sufficient condition for $K \in N_{\mathfrak{D}}$ is either that the complement of any one-to-one \dagger conformal image of K^c be of plane measure zero or that any \dagger univalent analytic function in K^c be reduced to a \dagger linear fractional function. If the union of at most a countable number of $N_{\mathfrak{B}}$ or $N_{\mathfrak{D}}$ sets is compact, it belongs to the same class. But it not true for $N_{\mathfrak{B}\mathfrak{E}}$ sets [3].

F. Analytic Capacity

For a compact set K , let D_K be the unbounded connected component of K^c . The quantity

Function-Theoretic Null Sets

$M_{\mathbb{B}}(\infty, D_K)$ is called the **analytic capacity** of K and is denoted by $\alpha(K)$. If $\alpha(K) > 0$, there exists an extremal function $f_0(z) = \alpha(K)z^{-1} + \dots$, called the \dagger Ahlfors function, that maps D_K onto a covering surface of the unit disk. In general, $\alpha(K)$ is not greater than the logarithmic capacity $C_0(K)$. If K is a continuum, then $\alpha(K) = C_0(K)$, and $\alpha(K)$ is attained by and only by $f_0(z)$, which maps D_K onto $|w| < 1$ conformally and $z = \infty$ to $w = 0$. For a linear set K , $\alpha(K)$ is equal to a quarter of its length (C. Pommerenke, *Arch. Math.*, 11 (1960)). The concept of analytic capacity is basic for the theory of rational approximation on compact sets.

170 (IX.2) Fundamental Groups

A \dagger continuous mapping f from the interval $I = \{t | 0 \leq t \leq 1\}$ into a topological space Y is called a **path** connecting the **initial point** $f(0)$ and the **terminal point** $f(1)$. In particular, a path satisfying $f(0) = f(1) = y_0$ is called a **loop** (or **closed path**) with y_0 as the **base point**. For a path f , the **inverse path** \bar{f} of f is defined by $\bar{f}(t) = f(1 - t)$. When the terminal point of f and the initial point of g coincide, the path F defined by $F(t) = f(2t)$ for $0 \leq t \leq 1/2$ and $F(t) = g(2t - 1)$ for $1/2 \leq t \leq 1$ is called the **product** (or **concatenation**) of f and g , and is denoted by $f \cdot g$. With $[f]$ standing for the equivalence class of a path f under the relation of \dagger homotopy relative to 0, 1 ($\in I$) (i.e., by homotopy with 0 and 1 being fixed), the inverse $[f]^{-1} = [\bar{f}]$ and the product $[f] \cdot [g] = [f \cdot g]$ are defined. In particular, in the set of homotopy

classes of loops with one common base point y_0 , the product is always defined, and the set forms a group $\pi_1(Y, y_0)$. This group is called the **fundamental group** (or **Poincaré group**) (H. Poincaré, 1985) of Y (with respect to y_0). If Y is \dagger arcwise connected, then $\pi_1(Y, y_0) \cong \pi_1(Y, y_1)$ for an arbitrary pair of points y_0, y_1 , and the structure of the group is independent of the choice of the base point. This group is denoted simply by $\pi_1(Y)$. A continuous mapping $\varphi: (Y, y_0) \rightarrow (Y', y'_0)$ induces a homomorphism $\varphi_*: \pi_1(Y, y_0) \rightarrow \pi_1(Y', y'_0)$ by sending $[f]$ to $\varphi_*[f] = [\varphi \circ f]$, and $(\varphi' \circ \varphi)_* = \varphi'_* \circ \varphi_*$ holds for the composite $\varphi' \circ \varphi$ of mappings. Thus $\pi_1(Y)$ is a \dagger topological invariant of Y . If $\pi_1(Y)$ consists of only one class (the class of the constant path), we say that Y is **simply connected**. For example, cells and spheres S^n ($n \geq 2$) are simply connected. The famous \dagger Poincaré conjecture states that a simply connected 3-dimensional compact \dagger manifold is homeomorphic to the 3-dimensional sphere. We have **van Kampen's theorem**: Let P be a connected polyhedron, P_1 and P_2 be its connected subpolyhedra such that $P_1 \cap P_2$ is connected, and $P = P_1 \cup P_2$. Then $\pi_1(P)$ is isomorphic to the group (\dagger amalgamated product) obtained from the \dagger free product of $\pi_1(P_1)$ and $\pi_1(P_2)$ by giving the relations that the images of each element of $\pi_1(P_1 \cap P_2)$ in $\pi_1(P_1)$ and in $\pi_1(P_2)$ are equivalent. Also, the fundamental group of the \dagger product spaces is the direct product of the fundamental groups of the spaces involved. Any group is the fundamental group of some \dagger CW complex. The Abelianization $\pi_1/[\pi_1, \pi_1]$ of the fundamental group $\pi_1 = \pi_1(Y)$ (Y arcwise connected) is isomorphic to the 1-dimensional integral \dagger homology group $H_1(Y)$. For example, the fundamental groups of a circle S^1 and a \dagger torus T^n are an infinite cyclic group and a free Abelian group of rank n , respectively; the fundamental group of a 1-dimensional CW complex is a free group; and the fundamental group of an orientable 2-dimensional closed surface of \dagger genus p is a group having $2p$ generators $\{a_1, \dots, a_p, b_1, \dots, b_p\}$ and a relation $a_1 b_1 a_1^{-1} b_1^{-1} \dots a_p b_p a_p^{-1} b_p^{-1} = 1$. If x_0 is a fixed point of the circle S^1 , then the fundamental group can be defined as the set of all homotopy classes of continuous mappings $f: (S^1, x_0) \rightarrow (Y, y_0)$.

Extending the definition of the fundamental group by replacing I, S^1 with I^n, S^n , we obtain the n -dimensional homotopy group (\rightarrow 202 Homotopy Theory; 91 Covering Spaces).

G

171 (XXI.25) Galois, Evariste

Evariste Galois (October 25, 1811–May 31, 1832) was born in Bourg-la-Reine, a suburb of Paris. In 1828, while still in junior high school, he published a paper on periodic continued fractions. Although he published four papers, his most important works were submitted to the French Academy of Science and either lost or rejected. He was unsuccessful in his attempt to enter the Ecole Polytechnique and instead entered the Ecole Normale Supérieure in 1829. Active in political affairs, he was expelled from school, imprisoned, and died in a duel soon after his release.

The night before the duel, he left his research outline and manuscripts to his friend, A. Chevalier. These were published by J. Liouville in *J. Math. Pures Appl.*, first series, 11 (1846). The contents include the concept of groups and what essentially became the †Galois theory of algebraic equations. The manuscript also contained expressions such as “theory of ambiguity,” which seems to indicate that Galois intended to study the theory of algebraic functions along the same lines.

172 (III.7) Galois Theory

A. History

After the discovery of formulas giving the general solutions of algebraic equations of degrees 3 and 4 in the 16th century, efforts to solve equations of degree 5 remained unsuccessful. Early in the 19th century P. Ruffini and N. H. †Abel showed that a general algebraic solution is impossible. Shortly afterward, E. †Galois established a general principle concerning the construction of roots of algebraic equations by radicals. The principle was described in terms of the structure of a certain permutation group (the Galois group)

of the roots of the equation. Even in this original form of the theory (**Galois theory**), Galois not only completed the research started by J. L. Lagrange, P. Ruffini, and Abel, but also made an epochal discovery that opened the way to modern algebra. J. W. R. Dedekind (*Werke* III, 1894) interpreted this result as a duality theorem concerning the automorphism groups of a field. It was shown later that Galois theory plays an important role in the general theory of commutative fields established by E. Steinitz. In the 1920s, W. Krull generalized the idea of Dedekind, using the concept of topological algebraic systems, and obtained the Galois theory of infinite algebraic extensions (*Math. Ann.*, 100 (1928)). The Galois theory gives a model for a successful theory summarizing the essentials of separable algebraic extensions and has led to analogous theories for other algebraic systems. For example, E. R. Kolchin constructed an analogous theory for differential fields where the Galois groups are algebraic groups (→ 113 Differential Rings, Galois theory of differential fields). Another line of development of this theory, also originated by Dedekind (*Werke* III, 1876/77), led to the Galois theory of rings, an object of active research by N. Jacobson (*Ann. Math.*, 41 (1940)), T. Nakayama, and others since the 1940s. Also, recently, the Galois theory for some general algebraic systems containing inseparable fields has been constructed by M. E. Sweedler, U. S. Chase, and others in which Galois groups are replaced by Hopf algebras or bialgebras (→ 203 Hopf algebras).

B. Definitions

Given a group G of †automorphisms of a given †field L , the subfield $F(G) = \{a \in L \mid a^\sigma = a, \sigma \in G\}$ is called the **invariant field** associated with G . For any extension fields L, L' of K , an isomorphism of L into L' whose restriction to K is the identity is called a **K -isomorphism**. If L is a †normal extension of K , any K -isomorphism of L into L' is a K -automorphism of L . If an algebraic extension L of K is normal, the group $G(L/K)$ of all K -automorphisms of L is called the **Galois group** of L/K . A †separable normal algebraic extension of K is called a **Galois extension** of K . Let L/K be a finite normal extension; then there exist intermediate fields M and N of L/K such that M/K is a Galois extension and N/K is a †purely inseparable extension and $L = M \otimes_K N$ (→ 277 Modules J). Further, $G(L/K) = G(L/N) \simeq G(M/K)$ and the order of $G(L/K)$ is equal to the †separable degree of L/K , i.e. $[M:K]$. A necessary and sufficient condition for L/K to

be a Galois extension is that the invariant field associated with $G(L/K)$ be K . A Galois extension L/K is called an **Abelian extension** or a **cyclic extension** when $G(L/K)$ is \dagger Abelian or \dagger cyclic, respectively (\rightarrow 149 Fields).

C. Fundamental Theorem of Galois Theory

Let L/K be a finite Galois extension and G its Galois group. Then there exists a \dagger dual lattice isomorphism between the set of intermediate fields of L/K and the set of subgroups of G , under which an intermediate field M of L/K corresponds to the subgroup $H = G(L/M)$; conversely, a subgroup H of G corresponds to $M = F(H)$. The degree of extension $[L:M]$ is equal to the order of the corresponding subgroup H (in particular, $[L:K]$ is the order of G), and $[M:K]$ coincides with the index $(G:H)$. If subfields M and M' are \dagger conjugate over K , then the corresponding subgroups $G(L/M)$ and $G(L/M')$ are conjugate to each other in G , and vice versa. In particular, M/K is a Galois extension if and only if the subgroup H corresponding to M is a \dagger normal subgroup of G , and in this case, the Galois group $G(M/K)$ is isomorphic to the factor group G/H .

D. Extensions of a Ground Field

Let L/K be a finite Galois extension, K'/K any extension, and L' the \dagger composite field of L and K' . Then L'/K' is also a Galois extension, and its Galois group is isomorphic to $G(L/L \cap K')$ by the restriction map.

E. Normal Basis Theorem

Let L/K be a finite Galois extension with Galois group G . Then there exists an element u of L such that $\{u^\sigma \mid \sigma \in G\}$ forms a basis for L over K called a **normal basis**. If we denote by $K[G]$ the \dagger group ring of G over K , a $\dagger K[G]$ -module structure can be introduced in L by the operation $\sum a_\sigma \sigma(x) = \sum a_\sigma x^\sigma$; the existence of a normal basis implies that L is isomorphic to $K[G]$ itself as a $K[G]$ -module, or in other words, that the K -linear representation of G by means of L is equivalent to the \dagger regular representation of G .

F. Examples of Galois Extensions

(1) **\dagger Cyclotomic Fields.** Let m be a positive integer not divisible by the \dagger characteristic of K ; ζ a \dagger primitive m th root of unity, and $L = K(\zeta)$. Then L/K is an Abelian extension, and its Galois group is isomorphic to a subgroup of

the \dagger reduced residue class group $(\mathbb{Z}/m\mathbb{Z})^*$; in particular, if $K = \mathbb{Q}$, the subgroup coincides with $(\mathbb{Z}/m\mathbb{Z})^*$, by the irreducibility of \dagger cyclotomic polynomials. Hence the degree $[Q(\zeta):Q]$ is equal to $\varphi(m)$, where φ is \dagger Euler's function.

(2) **Finite Fields.** A \dagger finite field K has nonzero characteristic p , and the number q of elements of K is a power of p . Also, K is uniquely determined by q (up to isomorphism), hence it is denoted by $GF(q)$ or F_q . Thus $GF(q^n)$ is the only extension of $GF(q)$ of degree n ; moreover, it is a cyclic extension.

(3) **Kummer Extensions.** Assume that K contains a primitive m th root ζ of unity and the characteristic of K is 0 or is not a divisor of m . Denote by K^* the multiplicative group of K . An extension L of K can be expressed in the form $L = K(\sqrt[m]{a_1}, \dots, \sqrt[m]{a_r})$ ($a_i \in K$) if and only if L/K is an Abelian extension and all $\sigma \in G(L/K)$ satisfy $\sigma^m = 1$; in this case L/K is called a **Kummer extension of exponent m** . There exists a one-to-one correspondence between Kummer extension L of exponent m over K and finite subgroups $H/(K^*)^m$ of the factor group $K^*/(K^*)^m$, given by the relations $H = L^m \cap K^*$, $L = K(\sqrt[m]{H})$. Moreover, there exists a canonical isomorphism between $H/(K^*)^m$ and the \dagger character group of $G(L/K)$, so that $H/(K^*)^m$ is isomorphic to $G(L/K)$. Let $L = K(\theta)$ be a cyclic Kummer extension of degree m of K , and let σ be a generator of the Galois group $G(L/K)$. Then the **Lagrange resolvent** $(\zeta, \theta) = \theta + \zeta\theta^\sigma + \dots + \zeta^{m-1}\theta^{\sigma^{m-1}}$ satisfies $(\zeta, \theta)^\sigma = \zeta^{-1}(\zeta, \theta)$, $(\zeta, \theta)^m \in K$, and θ and its conjugates can be expressed in terms of (ζ, θ) . In particular, L is generated by (ζ, θ) over K .

(4) **Artin-Schreier Extensions.** Assume that K is of characteristic $p \neq 0$. For any element a of an extension of K , we denote by $\mathcal{P}a$ the element $a^p - a$ and by $(1/\mathcal{P})a$ a root of $\mathcal{P}X - a = 0$. A finite extension L of K is of the form $L = K((1/\mathcal{P})a_1, \dots, (1/\mathcal{P})a_r)$ ($a_i \in K$) if and only if L/K is a Galois extension whose Galois group is an Abelian group of \dagger exponent p ; in this case, L/K is called an **Artin-Schreier extension**. There exists a one-to-one correspondence between Artin-Schreier extensions L over K and finite subgroups $H/\mathcal{P}K$ of the additive group $K/\mathcal{P}K$, given by the relations $H = \mathcal{P}L \cap K$, $L = K((1/\mathcal{P})H)$; moreover, $H/\mathcal{P}K$ is isomorphic to the character group of $G(L/K)$ (therefore also to $G(L/K)$ itself). More generally, for Abelian extensions L of **exponent p^n** (i.e., Galois extensions whose Galois groups are Abelian groups of exponent p^n), we obtain similar descriptions by using the additive

group of \dagger Witt vectors of length n instead of K (\rightarrow 449 Witt Vectors).

G. Galois Group of an Equation

L/K is a finite Galois extension if and only if L is a \dagger minimal splitting field of a \dagger separable polynomial $f(X)$ in $K[X]$. In this case, we call $G(L/K)$ the **Galois group of the polynomial** $f(X)$ or of the **algebraic equation** $f(X)=0$. The equation $f(X)=0$ is called an **Abelian equation** or a **cyclic equation** if its Galois group is Abelian or cyclic, respectively, while $f(X)=0$ is called a **Galois equation** if L is generated by any root of $f(X)$ over K . Generally, $G(L/K)$ can be \dagger faithfully represented as a permutation group of roots of $f(X)=0$. If this group is \dagger primitive, then $f(X)=0$ is called a **primitive equation**. The index of the group in the group of all permutations of roots is called the **affect** of the equation $f(X)=0$; if the affect is 1, the equation $f(X)=0$ is called **affect-less**. Let u_1, \dots, u_n be \dagger algebraically independent elements over K . Then for the polynomial $F_n(X)=X^n-u_1X^{n-1}+\dots+(-1)^nu_n$ in $K(u_1, \dots, u_n)[X]$, the equation $F_n(X)=0$ is called a **general equation** of degree n . The Galois group of $F_n(X)=0$ is isomorphic to the \dagger symmetric group \mathfrak{S}_n of degree n , and if K is not of characteristic 2, then the quadratic subfield corresponding to the \dagger alternating group \mathfrak{A}_n is the field $K(\sqrt{D})$ obtained by adjoining the quadratic root of the \dagger discriminant D of $F_n(X)$.

H. Solvability of an Algebraic Equation

Assume that K is of characteristic 0, $f(X) \in K[X]$, and L is the minimal splitting field of $f(X)$. We say that the equation $f(X)=0$ is **solvable by radicals** if there is a chain of subfields $K=L_0 \subset L_1 \subset \dots \subset L_r=L$ such that $L_i=L_{i-1}(\sqrt[n_i]{a_i})$ with some $a_i \in L_{i-1}$, and this is the case if and only if the Galois group of $f(X)$ is \dagger solvable (Galois). In particular, Abelian equations are solvable by radicals. Cyclic equations are solved by using the Lagrange resolvent, and theoretically the general solvable equation can be solved by repeating this procedure. Since \mathfrak{S}_n is solvable if and only if $n \leq 4$, it follows that a general equation of degree n is solvable only if $n=1, 2, 3, 4$ (Abel). (For a method of solving these equations \rightarrow 10 Algebraic Equations D.) Also, a polynomial is solvable by square roots if and only if the order of the Galois group is a power of 2. This fact enables us to answer some questions concerning geometric construction problems such as trisection of an angle or division

of a circumference in equal parts (\rightarrow 179 Geometric Construction).

I. Infinite Galois Extensions

If a Galois extension L/K is infinite, then its Galois group is an infinite group. Let $\{M_v\}$ be the family of intermediate fields of L/K that are finite and normal over K , and put $H_v = G(L/M_v)$. Then by taking $\{H_v\}$ as a \dagger base of a neighborhood system of the unity element, G becomes a \dagger topological group. This topology is called the **Krull topology** (Krull, *Math. Ann.*, 100 (1928)). G is then isomorphic to the \dagger projective limit of the family of finite groups $\{G/H\}$ and is \dagger totally disconnected and \dagger compact. There is a one-to-one correspondence between the set of intermediate fields of L/K and the set of closed subgroups of G given by the map (Galois group) \leftrightarrow (invariant field), and thus we have a generalization of Galois theory for finite extensions as described in Section C. Various theories, including the theory of Kummer extensions, can be generalized to the case of infinite extensions (\rightarrow 423 Topological Groups).

J. Galois Cohomology

Let L/K be a finite Galois extension and G its Galois group. Then both the additive group L and the multiplicative group L^* have G -module structures. The \dagger cohomology groups of G with coefficient module L are 0 for all dimensions because of the existence of a normal basis (\rightarrow 200 Homological Algebra). As for the multiplicative group L^* , we have $\hat{H}^0(G, L^*) \cong K^*/N(L^*)$ (N is the \dagger norm $N_{L/K}$), $H^1(G, L^*)=0$ (**Hilbert's theorem 90** or the **Hilbert-Speiser theorem**). In particular, if G is a cyclic group with generator σ , then every element a such that $N(a)=1$ can be expressed in the form $a=b^{1-\sigma}$. $H^2(G, L^*)$ is isomorphic to the \dagger Brauer group of \dagger central simple algebras over K which have L as a \dagger splitting field. In the case of number fields, a number of G -modules arise, such as \dagger principal orders, \dagger unit groups, \dagger ideal groups, \dagger idele groups, and so on, whose cohomological considerations are important (\rightarrow 6 Adeles and Ideles; 59 Class Field Theory). Further, let A be a group (not necessarily commutative), and suppose that G acts on A . We denote by ${}^\sigma a$ the action of $\sigma \in G$ on $a \in A$. A is called a **G -group** if ${}^\sigma(ab) = {}^\sigma a {}^\sigma b$ for all $a, b \in A$ and $\sigma \in G$. Then, in the same way as for G -modules, we can define the **0th cohomology group** $H^0(G, A)$ to be the subgroup A^G of A consisting of all elements of A left fixed by G . The map $a: \sigma \mapsto a_\sigma$ from G into A such that $a_{\sigma\tau} = a_\sigma {}^\sigma a_\tau$ ($\sigma, \tau \in G$) is called a **1-cocycle** with

values in A . Denote by $Z^1(G, A)$ the set of the 1-cocycles of G with values in A . Two 1-cocycles a and a' in $Z^1(G, A)$ are called **cohomologous** if there exists an element $b \in A$ such that $a'_\sigma = b^{-1} a_\sigma b$ for all $\sigma \in G$. This is an equivalence relation in $Z^1(G, A)$ and the 1-cohomology set $H^1(G, A)$ of G with values in A is defined to be the set of cohomologous classes of $Z^1(G, A)$. $H^1(G, A)$ does not have the structure of a group in general, but there does exist an element called an identity, namely, the cohomologous class containing the trivial 1-cocycle. In general, a set X with an element p of X is called a **pointed set**; for any two pointed sets (X, p) and (Y, q) , a map $f: X \rightarrow Y$ is called a **morphism of pointed sets** if $f(p) = q$. For pointed sets (X, p) , (Y, q) , and (Z, r) , a sequence of morphisms $X \xrightarrow{f} Y \xrightarrow{g} Z$ of pointed sets is called **exact** if $\text{Im } f = \text{Ker } g$. The 1-cohomology set $H^1(G, A)$ with the identity can be regarded as a pointed set. Therefore, exact sequences of these sets make sense and possess some of the properties of cohomology groups in the commutative case. For example, let $1 \rightarrow A \rightarrow B \rightarrow C \rightarrow 1$ be an exact sequence of G -groups (and A is central in B); then

$$H^0(G, A) \rightarrow H^0(G, B) \rightarrow H^0(G, C) \\ \rightarrow H^1(G, A) \rightarrow H^1(G, B) \rightarrow H^1(G, C) (\rightarrow H^2(G, A))$$

is an exact sequence of pointed sets. For a Galois extension L/K with Galois group G , a linear algebraic L -group defined over K (\rightarrow 13 Algebraic Groups) has naturally the structure of a G -group, and we have $H^1(G, GL_n(L)) = 0$. Applying the above exact sequence to $1 \rightarrow SL_n(L) \rightarrow GL_n(L) \xrightarrow{\det} L^* \rightarrow 1$, we have $H^1(G, SL_n(L)) = 0$. Also, we have $H^1(G, Sp_{2n}(L)) = 0$ for any integer $n \geq 1$. It is difficult to define higher cohomology sets naturally, but various methods to define them have been obtained.

In many cases, we are more concerned with the \dagger category of Galois extensions of K with K -isomorphisms between them than with a single extension L/K . In other words, we consider a \dagger functor $L \rightarrow \mathfrak{F}(L)$ of the category of Galois extensions of K into the category of (Abelian) groups, and study the cohomology related to $G(L/K)$ -module or $G(L/K)$ -group structures derived from $\mathfrak{F}(L)$. In the case of infinite algebraic extensions, we consider the inductive limit of cohomology of subfields of finite degrees, making use of continuous cocycles of Galois groups relative to the Krull topology [8, 9].

Let L/K be a Galois extension with Galois group G . Consider objects X, Y defined over K on which the extension of the ground field is defined (such as K -linear spaces with certain tensors on them, algebras over K (associative

or not), K -varieties, or K -algebraic groups defined over K). When X and Y are isomorphic over L , Y is called a L/K -form of X . Let $E(L/K, X)$ be the set of all isomorphism classes of X over L . Let A be the group of all automorphisms over L of X . For a L/K -form Y of X and an isomorphism $f: X \rightarrow Y$ over L , since G acts on X and Y , one can define the isomorphism ${}^a f: X \rightarrow Y$ over L that satisfies ${}^a(f(x)) = {}^a f({}^a x)$. In particular, A is a G -group by this action. Further, for $\sigma \in G$, define $a_\sigma = f^{-1} \cdot {}^\sigma f \in A$, then $a: \sigma \mapsto a_\sigma$ is a 1-cocycle of G with values in A that corresponds to a L/K -form Y of X . This induces a bijection from $E(L/K, X)$ onto $H^1(G, A)$. Thus L/K -forms of X can be classified if one can determine $H^1(G, A)$. For example, $H^1(G, Sp_{2n}(L)) = 0$ is equivalent to saying that an L/K -form of a skew-symmetric bilinear form on a K -linear space of dimension $2n$ is unique up to K -isomorphisms. L/K -forms of a semisimple Lie algebra \mathfrak{g} over K can be classified by the 1-cohomology set of the algebraic group $\text{Aut}(\mathfrak{g} \otimes_K L)$. (For the L/K -forms of algebraic groups \rightarrow 13 Algebraic Groups M.) This descent theory can also be discussed for more general categories.

K. Galois Theory of Rings

The theory of \dagger centralizers in simple algebras can be interpreted as the theory of a certain Galois correspondence with respect to inner automorphism groups. Also, by using \dagger crossed products, we can deduce from the theory of centralizers in simple algebras the Galois theory of commutative fields. On the other hand, Jacobson obtained a Galois theory of \dagger division rings with respect to finite groups of outer automorphisms that is similar to the commutative case. Since then, many algebraists have proceeded with investigations that aim either at unifying these two theories by admitting inner automorphisms in the group of automorphisms, at extending the theory from division rings to general rings such as simple rings, \dagger primitive rings, or \dagger semiprimary rings, or at weakening the finiteness conditions. One principal method in these theories lies in considering first the endomorphism ring $\text{Hom}_R(S, S)$ for an extension S/R and then the roles of endomorphisms (or derivations) in it [6] (\rightarrow 29 Associative Algebras).

Let K be a field of characteristic $p > 0$ and L/K be a finite purely inseparable extension such that $L^p \subset K$. The set of all \dagger derivations of L/K forms a restricted Lie algebra $D(L/K)$ over K . Then there exists a one-to-one and dual lattice isomorphic correspondence between the set of intermediate fields M of L/K

and the set of restricted Lie subalgebras H of $D(L/K)$, given by the relations $H = D(L/M)$ and $M = \{a \in L \mid d(a) = 0, d \in H\}$ (Jacobson [7]). Namely, in the case of purely inseparable extensions, derivations or higher derivations play the role of automorphisms, and the bialgebras defined by such derivations correspond to Galois groups of Galois extension. Now, the group algebra KG of a group G over K and the (restricted) universal enveloping algebra of a (restricted) Lie algebra over K both have the structure of a * Hopf algebra. From this fact, unifying the Galois theory of Galois extensions and Jacobson's theory for purely inseparable extensions and using bialgebras or Hopf algebras, one can construct Galois theories of more general objects containing certain nonseparable field extensions (see M. E. Sweedler, *Ann. Math.*, 87 and 88 (1968); S. U. Chase and Sweedler, *Lecture notes in math.* 97, Springer, 1969).

173 (XIX.9) Game Theory

A. Introduction and Historical Highlights

Game theory consists of mathematical models used in the study of decision making in situations involving conflict and cooperation. A conflict arises when each player in a game

selects from a list of alternatives one which, possibly together with chance and random events, leads to various outcomes over which the players have different preferences; thus the behavior of one player aiming at his own favorable outcome might induce unfavorable outcomes for others. Although the potential outcomes usually bring about conflicts among the players, there may be room for cooperation among some of them. Game theory attempts to extract that which is common and essential to such situations, to handle them by means of mathematical methods, and to provide a normative guide to rational behavior for each of the players. Game theory thus goes beyond classical theories of probability and decision making that are sufficient to solve games involving just one player and chance.

Modern game theory started in 1944 with the publication of the monumental book by von Neumann and Morgenstern [1]. These authors presented many logical classifications of games, including a distinction between two-person and n -person games, between **constant-sum** (zero-sum) and **general-sum** games (depending upon whether the sum of payoffs to the players is constant (zero) or not), and between **noncooperative** and **cooperative** games (depending upon whether any collaboration among the players is prohibited or allowed). The second edition included a remarkable expected utility theory, which has become a mainstay of game theory. Von Neumann and Morgenstern also gave three representations of games. The first representation is the so-called extensive form; this representation has been slightly modified by Kuhn [2]. The second representation is the normal-form game; this is the form which the minimax theorem for two-person zero-sum games was established [3]. This theorem was generalized to n -person general-sum noncooperative games by Nash [4]. Finally, the characteristic-function form was the one in which the authors developed the theory of stable sets. Several other solution concepts, such as the core, the Shapley value, and the bargaining set, have since been defined for games in characteristic-function form. Historically, the development of game theory has been closely related to various areas of pure mathematics, such as analysis, topology, geometry, and the foundations of mathematics. A survey of game theory up to 1957 was presented by Luce and Raiffa [5]. In the 1950s and early 1960s, several major papers appeared in five issues of the *Annals of Mathematics Studies* [6]. Lucas [7] has presented a good survey of developments to 1972, and Shubik [8] has surveyed the development of the field through 1981. Current articles

appear mainly in the *International Journal of Game Theory*, and also in the journals in fields such as operations research, management science, economics, political science, and psychology.

B. The Extensive Form

An *n*-person game in extensive form is represented by a game †tree (i.e., a connected graph with no cycles (→ 186 Graph Theory)) having the following properties: There is one special vertex corresponding to the starting point of the game. Each nonterminal vertex corresponds either to a **move** of one of the *n* players or to a **chance move**. The edges ascending from a vertex denote the **alternatives** of the player at this vertex. For each terminal vertex there is an *n*-dimensional vector whose components represent the **payoffs** to each player. The state of a player's information at any stage can be described by certain subsets of the set of all his vertices, called **information sets**. At each of his moves, player *i* knows which information set he is in, but not which vertex he occupies within this set. A **local strategy** for player *i* is a †probability distribution over the set of all alternatives at each of his information sets. A **behavior strategy** for player *i* is a function which assigns a local strategy to all of his information sets. A **pure strategy** is a special behavior strategy that assigns a particular choice to each information set. Kuhn [2] showed the existence of pure optimal strategies for *n*-person general-sum noncooperative games with perfect information (i.e., games in which all information sets contain a single vertex) as a generalization of the result for two-person zero-sum games given in [1]). Kuhn also proved the existence of equilibrium behavior strategies for games with perfect recall (i.e., games in which player *i* at any of his information sets remembers all his prior moves but is not aware of the prior choices of the other players). The definition of "equilibrium strategy" is given in the next section. Because of the complexity of *n*-person general-sum games, research on them has been minimal since the work of Kuhn. Recently a new attack on them has begun; for example, the Nash equilibrium point in extensive forms has been reexamined by Selten [9].

C. The Normal Form (or Strategic Form)

An *n*-person game in normal form is specified by $\{N, \{X^i\}_{i \in N}, \{F^i\}_{i \in N}\}$, where $N = \{1, \dots, n\}$ is a set of players, X^i is the set of player *i*'s strategies, and F^i is a real-valued function on

the Cartesian product $\prod_{i=1}^n X^i$, called player *i*'s **payoff function**. Chance is incorporated by invoking an extra set X^0 of chance moves and a probability distribution on X^0 . A two-person zero-sum game or **matrix game** is the simplest case in which the existence of an equilibrium point has been established. Equilibrium follows from von Neumann's **minimax theorem**: Let $M^1 = \{1, \dots, m_1\}$, $M^2 = \{1, \dots, m_2\}$ be the sets of pure strategies that may be chosen by two players. Let a_{ij} be player 1's payoff when strategies *i* and *j* are taken by players 1 and 2. A **mixed strategy** for player *i* is a probability distribution on M^i . Sets of mixed strategies for players 1 and 2 are thus given by $X^1 = \{x \in R^{m_1} | \sum_{i=1}^{m_1} x_i = 1, x_i \geq 0 \forall i \in M^1\}$ and $X^2 = \{x \in R^{m_2} | \sum_{i=1}^{m_2} x_i = 1, x_i \geq 0 \forall i \in M^2\}$. If players 1 and 2 use the mixed strategies x^1 and x^2 , respectively, the expected payoff for player 1 is $F^1(x^1, x^2) = \sum_i \sum_j x_i^1 a_{ij} x_j^2$, which is a payoff function for player 1. Von Neumann [3] proved

$$\max_{x^1 \in X^1} \min_{x^2 \in X^2} F^1(x^1, x^2) = \min_{x^2 \in X^2} \max_{x^1 \in X^1} F^1(x^1, x^2).$$

We say that a pair (\hat{x}^1, \hat{x}^2) satisfying the foregoing minimax theorem is an **equilibrium point**. This pair (\hat{x}^1, \hat{x}^2) turns out to be a saddle point (→ 292 Nonlinear Programming A) of $F^1(x^1, x^2)$. The duality theorem (→ 255 Linear Programming B) is mathematically equivalent to this minimax theorem. A generalization of this equilibrium to *n*-person general-sum noncooperative games was presented by Nash [4]. An *n*-tuple $(\hat{x}^1, \dots, \hat{x}^n)$ ($\hat{x}^i \in X^i$) is a **Nash equilibrium** if, for each *i*,

$$F^i(\hat{x}^1, \dots, \hat{x}^{i-1}, \hat{x}^i, \hat{x}^{i+1}, \dots, \hat{x}^n) \geq F^i(\hat{x}^1, \dots, \hat{x}^{i-1}, x^i, \hat{x}^{i+1}, \dots, \hat{x}^n) \text{ for all } x^i \in X^i.$$

That is, no player can improve his payoff by changing his strategy if all other players continue to use the same strategies. Nash demonstrated the existence of this equilibrium for *n*-person general-sum noncooperative games with finite pure strategies. The existence of Nash equilibria for wider classes of noncooperative games is proved by means of fixed-point theorems (→ 153 Fixed-Point Theorems). Recently, **multistage games**, such as supergames and stochastic games in which games are played repeatedly, have become a major research topic of noncooperative game theory (with work being done on both extensive and normal forms). In two-person general-sum games or **bimatrix games**, there arise possibilities of cooperation (or bargaining) between two players. A solution concept for such situations, the **Nash bargaining solution**, was proposed by Nash [10]; this solution was subsequently discussed by Luce and Raiffa [5].

D. The Characteristic-Function Form (or Coalitional Form)

An n -person cooperative game in characteristic-function form is given by a pair (N, v) , where $N = \{1, \dots, n\}$ is a set of players and v is a real-valued function on a set of all subsets of N with $v(\emptyset) = 0$, called a **characteristic function**. Sometimes v is assumed to be **superadditive**, i.e., $v(S \cup T) \geq v(S) + v(T) \forall S, T \subseteq N$ with $S \cap T \neq \emptyset$. $v(S)$ represents the worth or the power achievable by the subset (coalition) S when its members cooperate regardless of the behavior(s) of the players in the complement of S . An n -dimensional vector $x = (x_1, \dots, x_n)$ is said to be an **imputation** if it satisfies (i) $x_i \geq v(\{i\}) \forall i \in N$ (individual rationality) and (ii) $\sum_{i \in N} x_i = v(N)$ (group rationality). The set of all imputations, denoted by A , represents all reasonable or realizable ways of distributing the available gains among the n players. An imputation x is said to **dominate** another imputation y if there is some nonempty coalition S such that (i) $x_i > y_i \forall i \in S$ and (ii) $\sum_{i \in S} x_i \leq v(S)$ (the effectiveness of S with respect to x). The original solution concept for games in characteristic-function form given by von Neumann and Morgenstern [1] is now called the **stable-set** or **von Neumann–Morgenstern solution**. A subset K of A is a stable set if (i) no dominance relation exists between any two elements of K (internal stability) and (ii) any imputation outside K is dominated by some imputation of K (external stability). The existence of stable sets was settled negatively by the ten-person example of Lucas [11]. This example, however, is rather specialized, and thus the existence of stable sets may yet be proved for a large class of games. Stable sets have been characterized for several classes of games, and these sets accurately reflect the coalition-forming processes among the players. Thus stable-set theory remains a major research topic in the theory of games in characteristic-function form. Many other solution concepts have been developed since that of the stable set. One of these is the **core**, defined by Gillies in [6] (its naive idea had already appeared in [1]). The core is the set $C = \{x \in A \mid \sum_{i \in S} x_i \geq v(S) \forall S \subseteq N\}$. This says that no coalition can protest against or block an imputation in the core on grounds that the coalition can expect more. For superadditive games the core coincides with the set of undominated imputations, and thus the core is a subset of any stable set if both exist. The condition for nonemptiness of the core was derived by Shapley [12] using the duality theorem. Another solution concept, defined by Shapley in [6], is known as the **Shapley value**. The Shapley value is a function $\varphi(v) = (\varphi_1(v),$

$\dots, \varphi_n(v))$ sending an arbitrary characteristic function v on N into an n -dimensional Euclidean space satisfying the conditions (i) $\varphi_{\pi i}(\pi v) = \varphi_i(v)$, where π is any permutation of N and $\pi v(\pi S) = v(S) \forall S \subseteq N$; (ii) $\sum_{i \in S} \varphi_i(v) = v(S) \forall S \subseteq N$ such that $v(T) = v(S \cap T) \forall T \subseteq N$; and (iii) $\varphi_i(v + w) = \varphi_i(v) + \varphi_i(w) \forall i \in N$ and for any two games v and w . These three axioms uniquely determine the value

$$\varphi_i(v) = \sum_{\substack{S \subseteq N \\ S \ni i}} \frac{(s-1)!(n-s)!}{n!} (v(S) - v(S - \{i\}))$$

for each i , where s is the number of players in S . The Shapley value is an imputation, and can be viewed as a fair-division solution since the three axioms are desirable properties for any equitable allocation scheme. From the above formula, the Shapley value can also be interpreted as the average of the marginal contributions of the players in a coalition. A **bargaining-set** concept was proposed by Aumann and Maschler in [6]. This set describes what payoffs are stable once a particular **coalition structure** (a \dagger partition of N) has formed. Briefly, a payoff associated with a coalition structure is stable or in a bargaining set if there is no objection to it from any player; or, even with an objection, if there exists a counterobjection to such an objection from other players. For details \rightarrow [6]. Since there are many different ways to define objection and counterobjection, there are various types of bargaining sets. Some of them are known to be nonempty. Two additional solution concepts, the **kernel** and the **nucleolus**, derive from investigations into particular bargaining sets. The kernel, introduced by Davis and Maschler [13], is always a nonempty subset of its bargaining set. More important is the nucleolus defined by Schmeidler [14], which is a unique imputation in the kernel and thus in the bargaining set. It is also in the core if the latter is nonempty. The “excess” of any nonempty $S \subseteq N$ for an imputation x is defined by $e(x, S) = v(S) - \sum_{i \in S} x_i$. The excess represents the dissatisfaction or the complaint of the coalition S with respect to x . The nucleolus is the imputation which minimizes the largest excess. If we have a tie, i.e., if the maximum excess attains a minimum at several imputations, then the next largest excess is to be compared, and so on. That is, the nucleolus is the \dagger lexicographical minimum in the ordering of these arrangements. It can be computed by solving a series of linear programs.

Several generalizations and variations of the classical von Neumann–Morgenstern formulation of games in characteristic-function form have also been investigated, such as the

games without side payments studied by Aumann and others (→ e.g., M. Shubik (ed.), *Essays in Mathematical Economics: In honor of Oskar Morgenstern*, Princeton Univ. Press, 1967); the **games in partition-function form** proposed by Thrall and Lucas (R. M. Thrall, and W. F. Lucas, *Naval Res. Logistics Quart.*, 10 (1963), 281–298); and the **games with infinitely many players**, in connection with which the Shapley value theory has become a major research topic [18].

E. Applications; Related Areas of Mathematics

Game theory has been applied to many fields, such as economics, political science, management science, operations research, information theory, and control theory, as well as to pure mathematics. Games in extensive form are now important tools for analyzing the effects of information, and thus for solving many decision problems with uncertainty. Non-cooperative games in normal form and Nash equilibria have been used in the study of many phenomena, including oligopolistic markets (Friedman [15]), bidding processes, electoral competition, resource allocation, and arms control. Cooperative games have been successfully applied to economics, and the relation between the core and competitive equilibria sheds further light on the theory of competitive economy. It is generally true that competitive equilibria are contained in the core. Debreu and Scarf [16] demonstrated that if the number of players approach infinity in a certain manner, the core shrinks to the set of competitive equilibria. By working in measure-theoretic terms, Aumann [17] was able to identify the core with the set of competitive equilibria. It was also demonstrated by Aumann and Shapley [18] that the set of competitive equilibria (and hence also the core) converges to the Shapley value under such formulations, provided certain conditions are satisfied. Another major application of cooperative game theory has arisen in political science, wherein value-type solutions, such as the Shapley value, are widely used as indices of the power of each participant in various voting situations. Major applications are to problems of cost allocation for public goods such as water resources [19], public transportation systems, and telephone systems; in such applications the core, the Shapley value, and the nucleolus have all been employed. The books [8, 20–22] are good references to the most recent applications of game theory.

Game theory also has many close relations with various areas of pure mathematics. The following are typical examples. The study of certain types of games in extensive form has

173 Ref. Game Theory

increased our understanding of the axiom of choice (→ 34 Axiom of Choice and Equivalents A) and other foundational questions. Nash equilibrium is closely related to fixed-point theorems (→ 153 Fixed-Point Theorems) and to separation theorems (→ 89 Convex Sets A). Cooperative game theory also has many connections to functional analysis and to convex analysis.

Finally, we mention that the study of differential games (→ 108 Differential Games) is also highly developed and widely used in areas such as economics and control theory.

174 (XIV.4) Gamma Function

A. The Gamma Function

The function $\Gamma(x)$ was defined by L. Euler (1729) as the infinite product

$$\frac{1}{x} \prod_{n=1}^{\infty} \left(1 + \frac{1}{n}\right)^x \left(1 + \frac{x}{n}\right)^{-1}.$$

Legendre later called it the **gamma function** or **Euler's integral of the second kind**. The latter name is based on the fact that for positive real x , we have

$$\Gamma(x) = \int_0^{\infty} e^{-t} t^{x-1} dt.$$

This function satisfies the functional relation

$$\Gamma(x+1) = x\Gamma(x),$$

and hence for positive integral x , we have $\Gamma(x+1) = x!$. C. F. Gauss denoted the function $\Gamma(x+1)$ by $\Pi(x)$ or $x!$, even when x is not a positive integer. The function $x!$ is also called the **factorial function**. The gamma function can also be defined as the solution of the functional equation $\Gamma(x+1) = x\Gamma(x)$ satisfying the conditions

$$\Gamma(1) = 1, \quad \lim_{n \rightarrow \infty} \frac{\Gamma(x+n)}{\Gamma(n)n^x} = 1.$$

Furthermore, we have

$$\frac{1}{\Gamma(x)} = x e^{Cx} \prod_{n=1}^{\infty} \left(1 + \frac{x}{n}\right) e^{-x/n}.$$

This expression is known as the **Weierstrass canonical form**. Here C is **Euler's constant**

$$C = \lim_{r \rightarrow \infty} \left(1 + \frac{1}{2} + \dots + \frac{1}{n} - \log n\right) \\ = 0.57721566490153286060651209 \dots,$$

which is conjectured to be [†]transcendental, but as yet even its irrationality remains unproved. However, it is known, that if C were rational, the numerator and the denominator would be integers of more than 30,000 digits (R. P. Brent, 1980).

The numerical value of C was calculated by Adams (1878) to 260 decimal places, and recently it has been calculated to more than 20,000 decimal places by means of an electronic computer. Seven thousand digits have been computed by W. A. Beyer and M. S. Waterman (*Math. Comp.*, 28 (1974)), and 20,000 digits have been computed by Brent et al. (1980).

$\Gamma(x)$ is [†]holomorphic on the complex x -plane except at the points $x = 0, -1, -2, \dots$, where it has simple [†]poles. When $\operatorname{Re} x > 0$, we have Hankel's integral representation

$$\Gamma(x) = -\frac{1}{2i \sin \pi x} \int_C (-t)^{x-1} e^{-t} dt,$$

$x \neq \text{integer},$

where the contour C lies in the complex plane cut along the positive real axis, starting at ∞ , going around the origin once counterclockwise, and ending at ∞ again.

Among various properties of this function (\rightarrow Appendix A, Table 17.I), the following two formulas are especially useful for numerical calculations: **Binet's formula**

$$\log \Gamma(x) = \left(x - \frac{1}{2}\right) \log x - x + \frac{\log 2\pi}{2} \\ + 2 \int_0^{\infty} \frac{\arctan(t/x)}{e^{2\pi t} - 1} dt, \quad \operatorname{Re} x > 0,$$

and the [†]asymptotic expansion formula that holds when $|\arg x| \leq (\pi/2) - \delta$ ($\delta > 0$),

$$\log \Gamma(x) \sim \left(x - \frac{1}{2}\right) \log x - x + \frac{\log 2\pi}{2} \\ + \sum_{n=1}^{\infty} \frac{(-1)^{n-1} B_{2n}}{2n(2n-1)x^{2n-1}}$$

(**Stirling's formula**), where the B_n are [†]Bernoulli numbers. This last formula can be rewritten as

$$\Gamma(x+1) = x! \sim x^x e^{-x} \sqrt{2\pi x},$$

which is used for large positive integers x .

The integrals

$$\int_0^{\lambda} e^{-t} t^{x-1} dt, \quad \int_{\lambda}^{\infty} e^{-t} t^{x-1} dt, \quad \operatorname{Re} x > 0,$$

are known as the **incomplete gamma functions** and are used in statistics, the theory of molecular structure, and other fields. The [†]exponential integral and the [†]error function (\rightarrow 167 Functions of Confluent Type D) are special cases of the incomplete gamma function.

B. Polygamma Functions

The derivatives of the logarithm of the gamma function are named the **digamma function** (or **psi function**) $\psi(x)=d\log\Gamma(x)/dx$; the **trigamma function** $\psi'(x)$; the **tetragamma function** $\psi''(x)$; the **pentagamma function** $\psi'''(x)$, etc. These functions are called **polygamma functions**. In particular, $\psi(x)$ is the solution of the functional equation

$$\psi(x+1)-\psi(x)=1/x,\quad \psi(1)=-C,$$
$$\lim_{n\rightarrow\infty}(\psi(x+n)-\psi(1+n))=0.$$

C. The Beta Function

Euler's integral of the first kind

$$B(x,y)=\int_0^1t^{x-1}(1-t)^{y-1}dt,$$

$\operatorname{Re} x>0,\quad \operatorname{Re} y>0,$

is called the **beta function** and is an analytic function of two variables x, y . This function is related to the gamma function as follows:

$$B(x,y)=\frac{\Gamma(x)\Gamma(y)}{\Gamma(x+y)}.$$

If the upper limit 1 in the integral is replaced by α , the result is called the **incomplete beta function** $B_\alpha(x,y)$.

175 (XXI.26)
Gauss, Carl Friedrich

Carl Friedrich Gauss (April 30, 1777–February 23, 1855) was born into a poor family in Braunschweig, Germany. From

childhood, Gauss showed genius in mathematics. He gained the favor of Grand Duke Wilhelm Ferdinand and under his sponsorship attended the University of Göttingen. In 1797, on proving the †fundamental theorem of algebra, he received his doctorate from the University of Halle. From 1807 until his death, he was a professor and director of the Observatory at the University of Göttingen.

On March 30, 1796, he made the discovery that it is possible to draw a 17-sided †regular polygon with ruler and compass, which motivated his decision to devote himself to mathematics. The publication of his *Disquisitiones arithmeticae* in 1801 opened an entirely new era in number theory. In pure mathematics, he did excellent research on †non-Euclidean geometry, †hypergeometric series, the theory of functions of a complex variable, and the whole theory of †elliptic functions.

In the field of applied mathematics he made outstanding contributions to astronomy, geodesy, and electromagnetism; he also studied the †method of least squares, the theory of surfaces (\rightarrow 111 Differential Geometry of Curves and Surfaces), and the theory of †potential. He considered perfection in papers for publication to be of utmost importance; thus his published works are few relative to his amount of research. However, the scope of his work can be seen in his diary and letters, some of which are included in his complete works, comprising 12 volumes. He is generally considered the greatest mathematician of the first half of the 19th century.

176 (XVII.13)
Gaussian Processes

A. Gaussian Systems

A system $\mathbf{X}=\{X_\lambda(\omega)|\lambda\in\Lambda\}$ of real-valued random variables on a probability space

(Ω, \mathbf{B}, P) is said to be **Gaussian**, or \mathbf{X} is a **Gaussian system**, if any finite linear combination of elements X_λ of \mathbf{X} is a * Gaussian random variable.

Any subsystem of a Gaussian system is again a Gaussian system. In particular, the joint distribution of (X_1, X_2, \dots, X_n) for any finite subsystem $\{X_j | 1 \leq j \leq n\}$ of a Gaussian system \mathbf{X} is a multidimensional Gaussian distribution. This distribution is supported on the whole of \mathbf{R}^n or on a hyperplane (at most $(n-1)$ -dimensional). Let m_j be the expectation of X_j , and let $V = (V_{j,k})$ be the (positive definite) * covariance matrix of $\{X_j\}$ given by

$$V_{j,k} = E\{(X_j - m_j)(X_k - m_k)\}, \quad 1 \leq j, k \leq n.$$

Suppose that the rank of the matrix V is r . Then the distribution of (X_1, X_2, \dots, X_n) is concentrated on an r -dimensional hyperplane of \mathbf{R}^n :

$$m + V\mathbf{R}^n, \quad m = (m_1, m_2, \dots, m_n).$$

When V is nondegenerate, that is, when $r = n$, the distribution is supported by the whole of \mathbf{R}^n and has a density function of the form

$$(2\pi)^{-n/2} |V|^{-1/2} \exp \left[-\frac{1}{2} (x - m) V^{-1} (x - m)' \right],$$

where $x = (x_1, x_2, \dots, x_n) \in \mathbf{R}^n$, $|V|$ and V^{-1} are the determinant and the inverse, respectively, of V , and where $(x - m)'$ denotes the (column) vector transpose to the (row) vector $(x - m)$. The above expression is the general form of the density of an n -dimensional Gaussian distribution. The characteristic function $\varphi(z)$ of this distribution is given by

$$\varphi(z) = \exp \left[i(m, z) - \frac{1}{2} (Vz, z) \right],$$

$$z = (z_1, z_2, \dots, z_n) \in \mathbf{R}^n,$$

where (\cdot, \cdot) denotes the inner product on \mathbf{R}^n . This distribution is denoted by $N(m, V)$. If, in particular, $m = 0$ and if V is the identity matrix, then it is called the n -dimensional standard Gaussian distribution.

For a general Gaussian system $\mathbf{X} = \{X_\lambda | \lambda \in \Lambda\}$ we are given the mean vector $m_\lambda = E(X_\lambda)$, $\lambda \in \Lambda$, and the covariance matrix $V_{\lambda, \mu} = E\{(X_\lambda - m_\lambda)(X_\mu - m_\mu)\}$, $\lambda, \mu \in \Lambda$, which is positive definite; for any $n \geq 1$, complex numbers $\alpha_1, \alpha_2, \dots, \alpha_n \in \mathbf{C}$, and $\lambda_1, \lambda_2, \dots, \lambda_n \in \Lambda$, we have

$$\sum_{j,k=1}^n \alpha_j \bar{\alpha}_k V_{\lambda_j, \lambda_k} \geq 0.$$

Conversely, given m_λ , $\lambda \in \Lambda$, and a positive definite $V = (V_{\lambda, \mu} | \lambda, \mu \in \Lambda)$, there exists a Gaussian system $\mathbf{X} = \{X_\lambda | \lambda \in \Lambda\}$, the mean vector and the covariance matrix of which coincide with (m_λ) and $V = (V_{\lambda, \mu})$, respectively. If there exists another system \mathbf{X}' with the same

property as \mathbf{X} , then \mathbf{X} and \mathbf{X}' have the same distribution.

A necessary and sufficient condition for the X_λ in a Gaussian system to be independent is that $V_{\lambda, \mu} = 0$ for every pair $\lambda \neq \mu$. For a Gaussian system $\mathbf{X} = \{X_n | n \geq 1\}$, the * convergence in probability of the sequence $\{X_n\}$ is equivalent to * convergence in the mean square. The limit of the sequence in this case is again Gaussian in distribution. Also for this system, the * almost sure convergence of the sequence implies the convergence in mean square.

There are many characterizations of Gaussian distributions and of Gaussian systems.

(i) A necessary and sufficient condition for a distribution to be Gaussian is that cumulants (* semi-invariants) γ_k of all orders exist and satisfy $\gamma_k = 0$ for all $k \geq 3$. (ii) Gaussian distributions have a self-reproducing property: If X and Y are independent Gaussian random variables, then their sum $S = X + Y$ is also Gaussian. A converse to this property holds: If the sum is Gaussian, then, assuming that they are independent, X and Y are both Gaussian as well (P. Lévy, H. Cramér). (iii) If X_1 and X_2 are independent and if $Y_1 = aX_1 + bX_1$ and $Y_2 = cX_1 + dX_2$ are also independent, then both X_1 and X_2 are Gaussian except for the trivial case $b = c = 0$ or $a = d = 0$. (iv) If for X and Y there exist U independent of X and V independent of Y satisfying $Y = aX + U$, $X = bY + V$ for some constants a, b , then there are only three possibilities: (1) (X, Y) is Gaussian, (2) X and Y are independent, (3) there is an affine relation between X and Y . (v) Suppose that a distribution has a finite mean m and a density function of the form $f(x - m)$. If the * maximum likelihood estimate of the mean is always given by the arithmetic mean of the samples, then the distribution is Gaussian (C. F. Gauss).

For any element X_λ of a Gaussian system \mathbf{X} and for a subsystem \mathbf{X}' of \mathbf{X} , the conditional expectation $E(X_\lambda | \mathbf{B}')$ is the orthogonal projection of X_λ onto $\overline{\mathbf{X}'}$, where \mathbf{B}' is the smallest σ -field with respect to which all the X_μ in \mathbf{X}' are measurable and where $\overline{\mathbf{X}'}$ is the closed linear subspace of $L^2(\Omega, P)$ spanned by \mathbf{X}' .

A system $\mathbf{X} = \{X_\lambda | \lambda \in \Lambda\}$, $X_\lambda = (X_\lambda^1, \dots, X_\lambda^d)$, of d -dimensional random variables is said to be Gaussian if the collection $\{X_\lambda^j | \lambda \in \Lambda, 1 \leq j \leq d\}$ is Gaussian.

B. Complex Gaussian Systems

Let Z be a complex-valued random variable with mean m , and denote it in the form $Z = X + iY + m$, $i = \sqrt{-1}$, X, Y real. If X and Y are independent and have the same Gaussian distribution with zero mean, then Z is called a

complex Gaussian random variable. A system $Z = \{Z_\lambda | \lambda \in \Lambda\}$ of complex-valued random variables is said to be **complex Gaussian** if any finite linear combination $\sum c_j Z_{\lambda_j}$, $c_j \in \mathbb{C}$, is complex Gaussian. A **complex Gaussian system** has properties similar to those of a Gaussian system discussed above. For instance, two complex Gaussian random variables are independent if and only if they are uncorrelated. Convergence properties are also similar. Furthermore, one can define complex Gaussian systems consisting of higher-dimensional random variables.

C. Gaussian Processes

A real-valued stochastic process $\{X_t\}$ is called a **Gaussian process** or a **normal process** if it forms a Gaussian system. If $\{X_t\}$ is a complex Gaussian system, it is called a complex Gaussian process. The most important example of a Gaussian process is [†]Brownian motion $\{B_t | t \geq 0\}$ with the properties $E(B_t) = 0$ and $E(B_t - B_s)^2 = |t - s|$. There are several generalizations of this process, among them: (i) [†]Brownian motion with a d -dimensional time parameter, (ii) a [†]Wiener process with d -dimensional time parameter, which is a Gaussian system $\{X_a | a = (a_1, \dots, a_d), \text{ all } a_j \geq 0\}$ with $E(X_a) = 0$ and $E(X_a, X_{a'}) = \prod_j \min\{a_j^1, a_j^2\}$, $a^i = (a_1^i, \dots, a_d^i)$, $i = 1, 2$.

Since a multidimensional Gaussian distribution is completely determined by its [†]mean vector and the [†]covariance matrix, a Gaussian process is strongly stationary if it is weakly stationary (\rightarrow 395 Stationary Processes); and such a process is called a **stationary Gaussian process**. The mean value m and the spectral measure $F(d\lambda)$ are associated with a weakly stationary process. The measure $F(d\lambda)$ is symmetric with respect to the origin since each X_t is real-valued. Conversely, given such $F(d\lambda)$ and m , we can construct a real weakly stationary process $\{X_t\}$ with mean value m and spectral measure $F(d\lambda)$. Generally, such a process $\{X_t\}$ is not determined uniquely; however, if $\{X_t\}$ is Gaussian, then there exists only one stationary Gaussian process with given m and $F(d\lambda)$. In view of this fact, stationary Gaussian processes can be regarded as being typical among weakly stationary processes.

The discussions so far on stationary Gaussian processes are generalized to the case of stationary complex Gaussian processes, for which symmetry of $F(d\lambda)$ need not be assumed. The [†]random measure $\{M(\Lambda)\}$ in the [†]spectral decomposition of a complex Gaussian process $\{X_t\}$ again forms a complex Gaussian system. Weakly stationary Gaussian random distributions can also be introduced.

D. White Noise and Gaussian Random Distributions

A real-valued weakly stationary process with discrete parameter is called a **white noise** if the mean $m = 0$ and the [†]covariance function $\rho(t) = 1$ ($t = 0$); $= 0$ ($t \neq 0$). Obviously the [†]spectral measure $F(d\lambda)$ is the [†]Lebesgue measure $d\lambda$. In the continuous parameter case, a weakly stationary random distribution (\rightarrow 407 Stochastic Processes C) is called a **white noise** if $m = 0$ and $\rho = \delta$ (δ is [†]Dirac's delta function: $\delta(\varphi) = \varphi(0)$). The spectral measure is, therefore, the Lebesgue measure. In both cases Gaussian white noise $\{X_t\}$ or $\{X_\varphi\}$ is determined uniquely. It has independent values at every point in the following sense: In the discrete parameter case, $X_{t_1}, X_{t_2}, \dots, X_{t_n}$ are mutually independent for any mutually distinct t_1, t_2, \dots, t_n . For a continuous parameter Gaussian white noise, often called simply white noise if no confusion occurs, $X_{\varphi_1}, X_{\varphi_2}, \dots, X_{\varphi_n}$ are mutually independent if the supports of $\varphi_1, \varphi_2, \dots, \varphi_n$ are disjoint. In the latter case Gaussian white noise is realized by taking the derivative of a Brownian motion. The [†]characteristic functional $c(\varphi)$ is given by

$$c(\varphi) = \exp \left[-\frac{1}{2} \|\varphi\|^2 \right],$$

where $\| \cdot \|$ is the $L^2(\mathbb{R}^1)$ -norm.

Characteristic functionals of general Gaussian random distributions are expressed in the form

$$c(\varphi) = \exp \left[im(\varphi) - \frac{1}{2} K(\varphi, \varphi) \right],$$

where m is the mean functional and K is the covariance functional.

E. Representations of Gaussian Processes

The family of [†]stochastic integrals $X_t = \int_a^t F(t, u) dB_u$, $t > a$ ($t > a$ if $a = -\infty$), based on Brownian motion, defines a Gaussian process $\{X_t | t \geq a\}$. The converse problem is, however, not obvious. Given a Gaussian process $\{X_t | t > a\}$ with $E(X_t) = 0$, the problem is to find a Brownian motion $\{B_t\}$ and a kernel F that give a representation of the above form (P. Lévy [10]). A more specific problem discussed below is important. If, in addition, the representation is formed in such a way that $B_t(X) = B_t(B)$ holds for every t , then the representation is called **canonical**, where $B_t(X)$ is the smallest σ -field with respect to which all the X_s , $s \leq t$, are measurable. The **canonical representation**, if it exists, is unique up to equivalence, i.e., $F(t, u)^2$ is unique. The existence of the canonical representation is, however, not

always guaranteed. Mean continuous, zero mean, purely nondeterministic stationary Gaussian processes have †backward moving average representations, which are nothing but the canonical representations. Once the canonical representation of $\{X_t\}$ is obtained, the kernel, together with known properties of $\{B_t\}$, tells us important properties of the given process, e.g., sample function properties, Markov properties, and so forth.

Let $\{X_t | t > a\}$ be a general Gaussian process with $E(X_t) = 0$, and let $M_t(X)$ be the subspace of $L^2(\Omega, P)$ spanned by the X_s , $s \leq t$. Assume that (i) $\{X_t\}$ is separable, i.e., $M_\infty(X)$ is separable and (ii) $\{X_t\}$ is purely nondeterministic in the sense that $\bigcap_s M_s(X) = \{0\}$. Then X_t is expressed as a sum of stochastic integrals:

$$X_t = \sum_j \int_a^t F_j(t, u) dB_u^j,$$

where the $\{B_u^j\}$, $j = 1, 2, \dots, N$ (N can be ∞), are mutually independent †additive Gaussian processes. In addition, the B_u^j can be taken in such a way that the measures $dv^j(u) = E(dB_u^j)^2$, $j = 1, 2, \dots, N$ is decreasing in j (i.e., $dv^1 \gg dv^2 \gg \dots$) and that $B_t(X) = \bigvee_j B_t(B^j)$ holds for every t . Such a representation is called a **generalized canonical representation** of $\{X_t\}$ [3]. It always exists under the above assumptions (i) and (ii), although it is not unique when $N \geq 2$. The number N , called the **multiplicity** of $\{X_t\}$, is independent of the choice of a generalized canonical representation. It is a good question to ask when $\{X_t\}$ has a simple unit multiplicity or when $\{X_t\}$ has the canonical representation. No interesting answer to this question has been given so far except for stationary Gaussian processes.

F. Gaussian Markov Properties

A †simple Markov Gaussian process $\{X_t | t \geq a\}$ has the canonical representation if it is separable and purely nondeterministic and if its covariance function never vanishes. It is of the form

$$X_t = f(t) \int_a^t g(u) dB(u),$$

$$f(t) \neq 0, \quad \int_a^t g(u)^2 du \neq 0 \quad \text{for } t > a.$$

A generalization of the simple Markov property of a Gaussian process is given in the following manner (suggested by P. Lévy [10]). If the †conditional expectations $E(X_{t_k} | B_t(X))$, for any choice of distinct $t_1, t_2, \dots, t_{N+j} > t$ ($j \geq 0$) span an N -dimensional subspace of $L^2(\Omega, P)$, then the process $\{X_t\}$ is called an **N -ple Markov Gaussian process**. If the canonical representation of an N -ple Markov Gaussian

process exists, then it is expressed in the form

$$X_t = \sum_{j=1}^N f_j(t) \int_a^t g_j(u) dB_u,$$

where $\det(f_j(t_i))$ never vanishes for any choice of distinct t_i ($> a$), $1 \leq i \leq N$, and where the g_j are linearly independent vectors in $L^2([a, t])$ for any $t > a$. Conversely, a Gaussian process given by the above expression is N -ple Markov. A stationary N -ple Markov Gaussian process has a †spectral density function $f(\lambda)$ of a specific form, namely, it is expressed in the form [3]

$$f(\lambda) = |Q(i\lambda)/P(i\lambda)|^2; \quad P, Q \text{ polynomials,}$$

$$\deg P = N \quad \text{and} \quad \deg Q < N$$

(**rational spectral density function**). Y. Okabe [14] proved that the roots of $P(x) = 0$ are all real, and introduced a multiple Markov property of a stationary Gaussian process $\{X_t\}$ in a much wider sense to prove that $\{X_t\}$ enjoys this property if and only if it has a rational spectral density.

A somewhat restricted definition of multiple Markov properties for a Gaussian process uses differential operators. Assume that X_t is $(N-1)$ -times differentiable with respect to the $L^2(\Omega, P)$ -norm. If there is an N th order differential operator $L = \sum_{k=0}^N a_k(t) D^{N-k}$ with $D = d/dt$ such that

$$LX_t = \dot{B}_t, \quad \dot{B}_t = dB_t/dt \text{ white noise,}$$

then $\{X_t\}$ is called an **N -ple Markov Gaussian process in the restricted sense**. Such a process is naturally N -ple Markov, and the canonical representation always exists. The kernel of the representation is the †Riemann function of the differential operator L that was used in the definition. The spectral density function corresponding to this process is of restricted form, namely, it is expressed in the form $1/|P(i\lambda)|^2$, where P is a polynomial of degree N , and $P(i\lambda) = 0$ has no root in the lower half-plane.

Many attempts have been made to define a Markov property of a Gaussian random field, namely, a Gaussian system with a multi-dimensional time parameter; however, only two significant approaches are mentioned here. Let $\{X_a | a \in \mathbb{R}^d\}$ be a Gaussian random field with d -dimensional time parameter. H. P. McKean [12] gave a Markov property in the following manner. Let \mathcal{F}_U be the σ -field generated by the X_x , $x \in U$, $U (\subset \mathbb{R}^d)$ open. For a closed set C , we set $\mathcal{F}_C = \bigcap_\varepsilon \mathcal{F}_{C_\varepsilon}$, where C_ε is the ε -neighbourhood of C . If, for any open set U , \mathcal{F}_U and \mathcal{F}_{U^c} become independent under the assumption that $\mathcal{F}_{\partial U}$ is known, then $\{X_a\}$ is called a **Markov Gaussian random field in the McKean sense**. It has been proved that a Brownian motion with d -dimensional time

parameter is Markov in this sense if d is odd, while it is not Markov if d is even. Further detailed investigations of Markov properties for Gaussian random fields have been given by L. Pitt, S. Kotani, Y. Okabe [17], and others.

Another definition of Markov properties of Gaussian random fields, in fact those of Gaussian random distributions, has been given by E. Nelson [13] in connection with Euclidean fields (invariant under Euclidean motion) in quantum theory. Let X_Φ be a Gaussian random field. For a smooth surface Γ in \mathbf{R}^d let \mathcal{F}_Γ be the σ -field generated by X_Φ , $\Phi = \psi \otimes \delta(n)$, ψ being a smooth function with compact support and n being normal to Γ . If \mathcal{F}_D and \mathcal{F}_{D^c} become independent under the assumption that \mathcal{F}_Γ , $\Gamma = \partial D$, is given, then $\{X_\Phi\}$ is called a **Markov Gaussian random field in the Nelson sense**. Given a Gaussian Euclidean field which is Markov in the Nelson sense, then under some reasonable assumptions, one can form a field (in the sense of quantum field theory) satisfying the Wightman axiom by changing imaginary time to real time.

G. Sample Function Properties

Some finer results about the smoothness of sample functions have been obtained for stationary Gaussian processes. G. A. Hunt proved that if the spectral measure $F(d\lambda)$ of a stationary Gaussian process $\{X_t\}$ has finite moment of order α , then almost all its sample functions satisfy the following Hölder condition of order α [5]: For every finite interval I and every constant C , there exists a sufficiently small $h_0 = h_0(I, C)$ such that

$$|X_{t+h} - X_t| < C|h|^\alpha (\log 1/|h|)^{1/2}$$

for any $t \in I$ and $|h| < h_0$. The following result is due to Yu. K. Belyaev: Sample functions of a stationary Gaussian process are with probability 1 either continuous or unbounded on every finite interval.

Other conditions for continuity of sample functions are given in terms of the covariance function. Let $v(s, t)$ be the covariance function of a Gaussian process $\{X_t | t \in [0, 1]\}$. If v satisfies

$$|v(s_1, t) - v(s_2, t)| \leq c|s_1 - s_2|^\alpha$$

$$(0 < \alpha \leq 1, \quad v(0, s) = 0, \quad s_1, s_2 \in [0, 1]),$$

then

$$P\left(\limsup_{\delta \downarrow 0, |t_1 - t_2| \leq \delta} \frac{|X_{t_1} - X_{t_2}|}{|t_1 - t_2|^{1/2} |\log |t_1 - t_2||^{1/2}} < c_1 c^{1/2} / \alpha^2\right) = 1,$$

where c_1 is a constant. This result is due to Z. Ciesielski.

Conditions for continuity of sample functions have also been given for Gaussian processes with multidimensional time parameters. For $\{X_t | t \in [0, 1]^n\}$, set $d(s, t) = E[(X_s - X_t)^2]^{1/2}$. If there exists a function φ monotone increasing on some interval $0 < u < \alpha$ such that

$$d(s, t) \leq \varphi(\|s - t\|),$$

where $\| \cdot \|$ is the metric in \mathbf{R}^n , and such that

$$\int_0^{+\infty} \varphi(e^{-x^2}) dx < \infty,$$

then almost all sample functions are continuous (X. Fernique [2]). Conversely, if there exists a monotone increasing function φ satisfying $d(s, t) = \varphi(\|s - t\|)$ and if sample functions are continuous with positive probability, then the above integral should be finite.

Suppose that $\{X_t\}$ is a stationary Gaussian field. R. M. Dudley [11] proved that if there exists a number $q > 1$ and a neighborhood $V = V(0)$ in \mathbf{R}^n such that

$$\sum_k q^{-k} (\log N(V, q^{-k}))^{1/2} < \infty,$$

where $N(V, \varepsilon)$ is the minimum number of ε -balls (relative to the metric d) that cover V , then almost all sample fields of $\{X_t\}$ are continuous, and Fernique [18] proved that the converse statement is also true. Thus the problem of continuity of the sample fields of stationary Gaussian fields has been completely solved.

H. Gaussian Measures

Let $\{X_t, t \in T\}$, T an interval, be a Gaussian process. It gives a probability distribution on the measurable space $(\mathbf{R}^T, \mathcal{B})$, where \mathcal{B} is the σ -field of Borel subsets of \mathbf{R}^T . Such a measure P is called a Gaussian measure. Let P^i , $i = 1, 2$, be Gaussian measures induced by Gaussian processes $\{X_t^i, t \in T\}$, $i = 1, 2$, respectively. Then for these measures concepts such as absolute continuity, equivalence, and singularity are introduced in the usual manner. The most significant property for Gaussian measures is that two measures P^1 and P^2 are either equivalent or singular. A powerful criterion for testing this dichotomy is the entropy of P^2 with respect to P^1 , given by

$$H(P^2 | P^1) = \sup_\alpha \sum_i \left\{ P^2(A_i) \log \frac{P^2(A_i)}{P^1(A_i)} \right\},$$

where the sup is taken over all finite partitions $\alpha = \{A_1, \dots, A_n\}$, $A_i \in \mathcal{B}$, $\bigcup A_i = \mathbf{R}^T$ (Yu. A. Rozanov [15]). The measures P^1 and P^2 are equivalent (resp. singular) if and only if

$H(P^2|P^1) < \infty$ (resp. $= \infty$). This statement can be paraphrased in terms of the Hilbert spaces $H(X^i)$, $i = 1, 2$, spanned by $\{X_t^i\}$, $i = 1, 2$, respectively. For simplicity, assume that $E(X_t^i) = 0$. Then, P^1 and P^2 are equivalent if and only if the following two conditions hold: (i) A mapping A determined by $AX_t^1 = X_t^2$ is extended to an invertible linear transformation from $H(X^1)$ to $H(X^2)$; (ii) There exists a symmetric operator B of Hilbert-Schmidt type such that $(A\xi, A\eta)_2 = ((I - B)\xi, \eta)_1$, where $(\xi, \eta)_i = E(\xi\eta)$ is the inner product in $H(X^i)$. Next, suppose that $\{X_t^i\}$, $i = 1, 2$, are not centered. Set $E(X_t^i) = m_t^i$, $i = 1, 2$. Then P^1 and P^2 are equivalent if and only if $\{\bar{X}_t^i\}$ with $\bar{X}_t^i = X_t^i - m_t^i$ satisfy the following condition: (iii) in addition to conditions (i) and (ii) above, there exists an element ξ_0 in $H(X^1)$ such that $m_t^1 - m_t^2 = E[\xi_0 X_t^1]$, $t \in T$.

Given equivalent Gaussian measures P^1 and P^2 on $(\mathbf{R}^T, \mathcal{B})$, $T = [0, t_0]$, it is in general not easy to obtain the \dagger Radon-Nikodym derivative; however, if one of them, say P^1 , is the \dagger Wiener measure, then one can obtain $\varphi = dP^1/dP^2$ explicitly (M. Hitsuda [4]). Assume that P^2 is derived from $\{X_t\}$. By assumption, X_t has the \dagger canonical representation

$$X_t = B_t - \int_0^t \left\{ \int_0^s l(s, u) dB_u + a(s) \right\} ds, \quad t \in T,$$

where $\{B_t\}$ is the \dagger Brownian motion from which P^1 is assumed to be derived and where $l \in L^2(T^2)$, $a \in L^2(T)$. With this notation, we can write

$$\varphi = \frac{dP_1}{dP_2} = \exp \left[\int_0^{t_0} \left\{ \int_0^s l(s, u) dB_u + a(s) \right\} dB_s - \frac{1}{2} \int_0^{t_0} \left(\int_0^s l(s, u) dB_u + a(s) \right)^2 ds \right].$$

This result yields a remark about general Gaussian measures: If P^1 and P^2 are equivalent, $\{X_t^1, t \in T\}$ has a canonical representation if and only if $\{X_t^2, t \in T\}$ does.

1. Nonlinear Functionals

Start with nonlinear functionals of a Brownian motion $\{B_t, t \in \mathbf{R}^1\}$, and call them **Brownian functionals**. If $\{\varphi_n\}$ is a complete orthonormal system in $L^2(\mathbf{R}^1)$, then the collection $\{X_n = \int \varphi_n(u) dB_u\}$ of \dagger stochastic integrals forms a Gaussian system of independent standard Gaussian random variables. A **Fourier-Hermite polynomial** based on $\{\varphi_n\}$ is a polynomial in X_n expressible as a finite product in the form

$$c \prod_j H_{n_j}(X_j/\sqrt{2}), \quad c \text{ a constant.}$$

The sum $n = \sum n_j$ is the degree of this polynomial. If $n > 0$, its mean is zero and the variance

is $|c|^2 \prod_j (n_j! 2^{n_j})$. Taking c to be $\prod_j (n_j! 2^{n_j})^{-1/2}$, the collection of all Fourier-Hermite polynomials based on $\{\varphi_n\}$ forms a complete orthonormal system in the Hilbert space (L^2) consisting of all Brownian functionals with finite variance. Denote by \mathcal{H}_n the subspace of (L^2) spanned by all the Fourier-Hermite polynomials of degree n . Then the Hilbert space (L^2) admits a direct-sum decomposition:

$$(L^2) = \sum_{n=0}^{\infty} \oplus \mathcal{H}_n,$$

which is called the **Wiener-Itô decomposition** [7]. The subspace \mathcal{H}_n is eventually independent of the choice of a complete orthonormal system $\{\varphi_n\}$. A member X of \mathcal{H}_n is referred to as a **multiple Wiener integral** of degree n and is expressed in the form

$$X = \int_{\mathbf{R}^n} \dots \int f(s_1, s_2, \dots, s_n) dB_{s_1} dB_{s_2} \dots dB_{s_n},$$

where f is a symmetric $L^2(\mathbf{R}^n)$ -function. In addition, $E(X^2) = n! \|f\|^2$, $\|\cdot\|$ being the $L^2(\mathbf{R}^n)$ -norm.

Brownian functionals can be expressed as functionals of white noise, so that the Hilbert space $L^2(\mu)$ is viewed as a realization of (L^2) , where μ is the probability distribution of the Gaussian white noise introduced in Section D.

Nonlinear functionals of a general Gaussian process can be dealt with in a similar but somewhat more complicated manner. If the process has a canonical representation, then the functionals can easily be rewritten as Brownian functionals.

J. Applications to Prediction Theory

If a Gaussian process $\{X_t | t \geq a\}$ has the canonical representation

$$X_t = \int_a^t F(t, u) dB_u,$$

then the best \dagger predictor $E(X_t | \mathcal{B}_s(X))$, $s < t$, is given by

$$\int_a^s F(t, u) dB_u.$$

This is in agreement with the best \dagger linear predictor.

No systematic approach for nonlinear prediction theory has been established so far. We illustrate this theory only in a typical case that arises from a stationary Gaussian process. Let $\{X_t\}$ be a real-valued stationary Gaussian process. Without loss of generality, we can assume that $E(X_t) = 0$. We consider the continuous parameter case, since the discrete parameter case is easier and can be inferred from it.

Let $\mathbf{M}_t(X)$ be the subspace of $L^2(\Omega, P)$ de-

finned in the same way as in Section E, and let $L_t = L^2(\Omega, \mathbf{B}_t(X))$. If the process is purely non-deterministic in the sense that $\bigcap_t \mathbf{M}_t(X) = \{0\}$, then X_t has the backward moving average representation

$$X_t = \int_{-\infty}^t f(t-s) dB_s,$$

where $\{B_t\}$ is a Brownian motion. Furthermore, this representation is canonical, i.e., $\mathbf{B}_t(X) = \mathbf{B}_t(B)$. Since \mathbf{B} is assumed to be $\bigvee_t \mathbf{B}_t$, every Y in (L^2) can be expressed in the form

$$Y = \sum_{p=0}^{\infty} \int_{-\infty}^{\infty} \dots \int_{-\infty}^{s_3} \int_{-\infty}^{s_2} f_p(s_1, s_2, \dots, s_p) dB_{s_1} dB_{s_2} \dots dB_{s_p},$$

in terms of multiple Wiener integrals. The predictor of Y based on the known values $X_s, s \leq 0$, that is, the projection of Y on L_0 is given by truncating the domain of the integral as

$$\sum_{p=0}^{\infty} \int_{-\infty}^0 \dots \int_{-\infty}^{s_3} \int_{-\infty}^{s_2} f_p(s_1, s_2, \dots, s_p) dB_{s_1} dB_{s_2} \dots dB_{s_p}.$$

K. Extrapolation and Interpolation

Extrapolation of a stationary Gaussian process is used to find the best estimate of the unknown values of a given process when we have been given the only some of the past values of the process. M. G. Kreĭn [8] obtained some results by using the theory of the inverse spectral problem discussed by I. M. Gelfand and B. Levitan.

In contrast to extrapolation is the interpolation of a stationary Gaussian process. There is an important contribution to this problem by H. Dym and H. P. McKean [1] who developed the Kreĭn theory by applying the de Branges method to the theory of entire functions.

177 (XIV.2) Generating Functions

A. General Remarks

A power series $g(t) = \sum_{n=0}^{\infty} a_n t^n$ in t that converges in a certain neighborhood of $t=0$ defines the sequence of numbers $\{a_n\}$. The function $g(t)$ is called the **generating function** of

the sequence. Similarly, the series $K(x, t) = \sum_{n=0}^{\infty} f_n(x) t^n$ that is convergent for x and t in a certain domain in (x, t) -space is called the **generating function** of the sequence of functions $\{f_n(x)\}$. Sometimes the function $g(t) = \sum_{n=0}^{\infty} (a_n/n!) t^n$ is called the **exponential generating function** of the sequence $\{a_n\}$. For example, the generating functions of the \dagger binomial coefficients and \dagger Legendre polynomials are $(1+t)^n$ and $(1-2tx+t^2)^{-1/2}$, respectively. When a generating function of $\{a_n\}$ or $\{f_n(x)\}$ is given, we can obtain a_n or $f_n(x)$ by integral expressions; for example, in the latter case we have

$$f_n(x) = \frac{1}{2\pi i} \int_C \frac{K(x, t)}{t^{n+1}} dt,$$

where the contour C is a sufficiently small circle going counterclockwise around the origin. A generating function can be continued beyond the domain of convergence of the power series. Simple generating functions are known for many important orthogonal systems of functions (\rightarrow 317 Orthogonal Functions). Generating functions are widely used because they enable us to derive analytically the properties of sequences of numbers or functions. For a system of numbers or functions depending on a continuous parameter instead of the integral parameter n , we define the generating function in the form of a \dagger Laplace or \dagger Fourier transform. In particular, for a probability \dagger distribution function $F(x)$, the exponential generating function $f(t) = \int_{-\infty}^{\infty} e^{-tx} dF(x)$ for the moments $\{a_n\}$ of $F(x)$ is called the **moment-generating function** of $F(x)$. There is another kind of generating function for the sequence $a_n: \sum a_n n^{-s}$ in the form of \dagger Dirichlet series; it is frequently used in number-theoretic problems.

B. Bernoulli Polynomials

A system of polynomials

$$B_n(x) = \sum_{k=0}^n \binom{n}{k} B_k(0) x^{n-k}$$

is defined by the generating function

$$\frac{te^{xt}}{e^t - 1} = \sum_{n=0}^{\infty} B_n(x) \frac{t^n}{n!}.$$

$B_n(x)$ is called the **Bernoulli polynomial** of degree n . Since $B_k(0)$ is the coefficient of $t^k/k!$ in

$$\frac{t}{e^t - 1} = \sum_{n=0}^{\infty} B_n(0) \frac{t^n}{n!},$$

we have $B_0(0) = 1$, $B_1(0) = -1/2$, $B_2(0) = 1/6$, ...; $B_{2n+1}(0) = 0$ for $n \geq 1$; and $(-1)^{n-1} B_{2n}(0) > 0$ for $n \geq 1$. The n th **Bernoulli number** B_n (\rightarrow Ap-

pendix B, Table 3) is usually defined by $|B_n(0)|$. Sometimes other definitions, such as $B_n = B_n(0)$ or $B_n = B_{2n}(0)$, are used. Bernoulli polynomials satisfy the relations

$$B_n(x+1) - B_n(x) = nx^{n-1},$$

$$dB_n(x)/dx = nB_{n-1}(x),$$

which are used in \dagger interpolation. For example, a polynomial solution of the \dagger difference equation $f(x+1) - f(x) = \sum_{n=0}^m a_n x^n$ is given by $f(x) = \sum_{n=0}^m a_n B_{n+1}(x)/(n+1) + (\text{arbitrary constant})$. In particular, we have $1^n + 2^n + \dots + p^n = (B_{n+1}(p+1) - B_{n+1}(1))/(n+1)$.

C. Euler Polynomials

A system of polynomials

$$E_n(x) = \sum_{k=0}^n \binom{n}{k} a_k x^{n-k}$$

is defined by the generating function

$$\frac{2e^{xt}}{e^t + 1} = \sum_{n=0}^{\infty} E_n(x) \frac{t^n}{n!}.$$

We call $E_n(x)$ the **Euler polynomial** of degree n . Here a_k is defined by $a_k = E_k(0)$ and

$$\frac{2}{e^t + 1} = \sum_{n=0}^{\infty} a_n \frac{t^n}{n!},$$

so that we have $a_0 = 1$, $a_1 = -1/2$, $a_3 = 1/4$, ...; $a_{2n} = 0$ for $n \geq 1$. The n th Euler number is sometimes taken as a_n , but more often it is defined by

$$E_n = (-1)^n \sum_{\mu=0}^n 2^\mu \binom{n}{\mu} a_\mu,$$

i.e., by

$$\frac{2}{e^x + e^{-x}} = \text{sech } x = \sum_{n=0}^{\infty} (-1)^n \frac{E_n}{n!} x^n$$

(\rightarrow Appendix B, Table 3). All the E_n are integers, $E_{2m+1} = 0$ ($m = 0, 1, \dots$) and $E_{2m} > 0$ ($m = 0, 1, \dots$); in the decimal expressions for E_n the last digit is 5 for E_{4m} ($m \geq 1$) and 1 for E_{4m+2} ($m \geq 0$). Sometimes E_{2n} is denoted by E_n . We have the relations

$$\sec x = \sum_{n=0}^{\infty} \frac{E_n x^n}{n!},$$

$$E_n(x) + E_n(x+1) = 2x^n,$$

$$E_n(1-x) = (-1)^n E_n(x),$$

$$\frac{dE_n(x)}{dx} = nE_{n-1}(x),$$

and in particular,

$$\begin{aligned} -1^n + 2^n - 3^n + 4^n - \dots + (-1)^p p^n \\ = ((-1)^p E_n(p+1) - E_n(1))/2. \end{aligned}$$

D. Application to Combinatorics

Let $p(n)$ denote the number of ways of dividing n similar objects into nonempty class. This is called the **number of partitions** of n . Euler noticed that the following formula is valid for the generating function of $p(n)$:

$$1 + \sum_{n=1}^{\infty} p(n)x^n = \left[\prod_{n=1}^{\infty} (1 - x^n) \right]^{-1},$$

whence we obtain $p(n) = p(n-1) + p(n-2) - p(n-5) - p(n-7) + p(n-12) + p(n-15) - \dots = \sum_{k=1}^{\infty} (-1)^{k-1} [p(n - (3k^2 - k)/2) + p(n - (3k^2 + k)/2)]$ (\rightarrow 328 Partitions of Numbers). Let $B(n)$ denote the number of ways of dividing n completely dissimilar objects into nonempty classes. These are called **Bell numbers**. The first few are 1, 1, 2, 5, 15, 52, 203, 877, 4140, 21147, ... [2]. For this sequence with $B(0) = 1$, the formal generating function $\sum_{n=0}^{\infty} B(n)x^n$ does not converge except at $x=0$. However, the exponential generating function $g(x) = \sum_{n=0}^{\infty} B(n)(n!)^{-1}x^n$ is convergent for all complex numbers x and is equal to e^{e^x-1} . The differential equation $g' = e^x g$ gives rise to a recursive formula

$$B(n+1) = \sum_{k=0}^n \binom{n}{k} B(k).$$

178 (VII.6) Geodesics

A. General Remarks

In the study of global differential geometry, geodesics play an essential role because the behavior of geodesics on a complete Riemannian m -manifold ($m \geq 2$) M without boundary heavily influences its topological structure. A significant merit of using geodesics is that one can make elementary and intuitive observations on M (as in Euclidean geometry), which often yields fruitful results.

Riemannian structure induces in a natural way a distance function d on M , and hence M is a metric space. A smooth curve γ of constant

speed is by definition a **geodesic** if and only if every point on γ is contained in a nontrivial subarc whose length realizes the distance between its endpoints. M is equipped with the Levi-Civita connection ∇ (\rightarrow 80 Connections) by means of which a geodesic is characterized as an autoparallel curve. In local coordinates, γ is obtained as a solution of an ordinary differential equation of order two (\rightarrow 80 Connections L). It follows from the properties of solutions of the equation for geodesics that every point $p \in M$ has a neighborhood in which every two points can be joined by a unique shortest geodesic that depends smoothly on both of the endpoints. A classical result of J. H. C. Whitehead (*Quart. J. Math.*, 3 (1932)) states that every point $p \in M$ has a metric ball B centered at p such that every two points in B are joined by a unique shortest geodesic whose image is contained in B . Let M_p be the tangent space to M at p , and let $\tilde{M}_p \subset M_p$ be the set of all vectors $v \in M_p$ such that the solution of geodesic γ with initial condition $\gamma(0) = p$, $\dot{\gamma}(0) = v$ is well defined on $[0, 1]$. \tilde{M}_p contains an open neighborhood of the origin and is star-shaped with respect to the origin. The exponential mapping $\exp_p: \tilde{M}_p \rightarrow M$ is defined to be $\exp_p v = \gamma(1)$. This mapping \exp_p is smooth and has the maximal rank at the origin. Small balls around p are obtained as the image under the exponential mapping of the corresponding balls in \tilde{M}_p centered at the origin, and the restriction of \exp_p to these balls are diffeomorphisms. Thus the topology of M as a metric space is equivalent to the original one of M . The fundamental Hopf-Rinow theorem (*Comment. Math. Helv.*, 3 (1931)) states that (1) M is complete as a metric space if and only if $\tilde{M}_p = M_p$ for some $p \in M$; (2) M is complete if and only if every closed metric ball is compact; and (3) if M is complete, then every two points can be joined by a shortest geodesic, namely, a geodesic with length realizing the distance between the endpoints.

In the following discussion M is assumed to be connected, complete, and without boundary. Let $\gamma: [0, 1] \rightarrow M$ be a geodesic. A piecewise smooth 1-parameter variation V along γ is a continuous mapping $V: [0, 1] \times (-\epsilon, \epsilon) \rightarrow M$ with a finite partition $0 = t_0 < t_1 < \dots < t_k = 1$ such that $V|_{[t_i, t_{i+1}] \times (-\epsilon, \epsilon)}$ is smooth and $V(t, 0) = \gamma(t)$ for all $t \in [0, 1]$. Then the first and second variation formulas for V are

$$L'(0) = \langle Y, \dot{\gamma} \rangle|_0^1 / L(\gamma)$$

and

$$L''(0) = \sum_{i=1}^k \left[\int_{t_{i-1}}^{t_i} (\langle Y_i', Y_i' \rangle - \langle R(Y_i, \dot{\gamma}) \dot{\gamma}, Y_i \rangle) dt + \langle \nabla_{\partial/\partial s} Y_i, \dot{\gamma} \rangle|_{t_{i-1}}^{t_i} \right] / L(\gamma),$$

respectively, where $Y_i(t) = \partial V(t, s)/\partial s|_{s=0}$ for $t \in [t_{i-1}, t_i]$ is the variation vector field associated with $V|_{[t_{i-1}, t_i] \times (-\varepsilon, \varepsilon)}$, $L(s)$ is the length of the variation curve $t \rightarrow V(t, s)$, and $Y'_i = \nabla_{\dot{\gamma}} Y_i$ and R is the curvature tensor.

A smooth vector field J along a geodesic $\gamma: [0, 1] \rightarrow M$ is called a **Jacobi field** if and only if it satisfies $J'' + R(J, \dot{\gamma})\dot{\gamma} = 0$. The set of all Jacobi fields along γ forms a vector space isomorphic to $M_{\gamma(0)} \times M_{\gamma(1)}$ by the natural correspondence $J \rightarrow (J(0), J'(0))$. Every Jacobi field is associated with a 1-parameter geodesic variation V along γ . Namely, every variation curve of V is a geodesic, V is smooth, and $J(t) = \partial V(t, s)/\partial s|_{s=0}$ for all $t \in [0, 1]$. Conversely, the variation vector field of any 1-parameter geodesic variation V along γ is a Jacobi field. Especially, if A is a tangent vector to M_p at $\dot{\gamma}(0)$, then $d(\exp_p)_{\dot{\gamma}(0)} A = J(1)$, where J is the Jacobi field associated with the 1-parameter geodesic variation $V(t, s) = \exp_p(t(\dot{\gamma}(0) + sA))$, and A is identified under the canonical parallel translation in M_p . A point $\gamma(t_0)$ is said to be **conjugate** to $p = \gamma(0)$ along γ if and only if there exists a nontrivial Jacobi field along γ that vanishes at 0 and t_0 . A theorem of Morse and Schoenberg states that if the sectional curvature K of M satisfies $0 < A \leq K \leq B < \infty$, then every unit speed geodesic $\gamma: [0, l] \rightarrow M$ has a point conjugate to $\gamma(0)$ if $l \geq \pi/\sqrt{A}$ and has no point conjugate to $\gamma(0)$ if $l < \pi/\sqrt{B}$. Especially, every geodesic γ on M with $K \leq 0$ contains no conjugate point on it, and \exp_p is locally regular for any $p \in M$. Thus a complete and simply connected M with $K \leq 0$ is diffeomorphic to \mathbf{R}^m (Hadamard and Cartan).

Let γ be a unit speed geodesic with $\gamma(0) = p$. If $t_1 > 0$ satisfies $d(p, \gamma(t)) = t$ for all $t \in [0, t_1]$ and $d(p, \gamma(t)) < t$ for all $t > t_1$, then the point $\gamma(t_1)$ is called a **cut point** to p along γ . It appears no later than the first conjugate point to p along γ . The set $C(p)$ of all cut points to p is called the **cut locus** of p . Let U be the set of vectors $tv \in M_p$, $0 \leq t < 1$, where $\exp_p v$ is the cut point to p along $\gamma(t) = \exp_p tv$. U is a nonempty open set and $\exp_p|_U: U \rightarrow M - C(p)$ is a diffeomorphism, where $M - C(p)$ is diffeomorphic to an m -disk. The cut locus possesses essential information on the topology of M .

The **metric comparison theorems** of H. Rauch (*Ann. Math.*, (2) 54 (1951)) and M. Berger (*Illinois J. Math.*, 6 (1962)) are stated as follows: Let $\inf_M K = \delta > -\infty$ and $\sup_M K = \Delta < \infty$, and let $\gamma: [0, 1] \rightarrow M$ be a nontrivial geodesic. Let $M(c)$ be a complete and simply connected space form of constant curvature c . Fix geodesics $\gamma_\delta, \gamma_\Delta: [0, 1] \rightarrow M(\delta), M(\Delta)$, respectively, with the same speed as γ . If J, J_δ , and J_Δ are Jacobi fields along γ, γ_δ , and γ_Δ respectively such that $J(0) = J_\delta(0) = J_\Delta(0) = 0$ and $\|J'(0)\| = \|J'_\delta(0)\| = \|J'_\Delta(0)\|$, then $\|J_\Delta(t)\| \leq$

$\|J(t)\| \leq \|J_\delta(t)\|$ holds for all $t \in [0, t_\Delta]$, where $\gamma_\Delta(t_\Delta)$ is the first conjugate point to $\gamma_\Delta(0)$ along γ_Δ (Rauch). If the Jacobi fields satisfy $\|J(0)\| = \|J_\delta(0)\| = \|J_\Delta(0)\|$ and $J'(0) = J'_\delta(0) = J'_\Delta(0) = 0$, then $\|J_\Delta(t)\| \leq \|J(t)\| \leq \|J_\delta(t)\|$ holds for all $t \in [0, t'_\Delta]$, where t'_Δ is the first zero point of J_Δ (Berger). They are often applied to compare curve lengths as follows. Let $c: I \rightarrow \mathbf{R}^m$ be a piecewise smooth curve with $\|c(t)\| \leq t_\Delta$. Fix points $p \in M, p_\delta \in M(\delta)$, and $p_\Delta \in M(\Delta)$ with fixed isometric identifications of the tangent spaces with \mathbf{R}^m . Then $L(\exp_{p_\Delta} \circ c) \leq L(\exp_p \circ c) \leq L(\exp_{p_\delta} \circ c)$. If P, P_δ , and P_Δ are unit parallel fields along corresponding geodesics $\sigma, \sigma_\delta, \sigma_\Delta: I \rightarrow M, M(\delta), M(\Delta)$, respectively, which have the same speed, and if $\langle P, \dot{\sigma} \rangle = \langle P_\delta, \dot{\sigma}_\delta \rangle = \langle P_\Delta, \dot{\sigma}_\Delta \rangle$, then for every piecewise smooth function $f: I \rightarrow [0, t'_\Delta]$ the curves $u(s) = \exp_{\sigma(s)} f(s)P(s)$ and $u_\delta(s), u_\Delta(s)$ defined in the same way on $M(\delta), M(\Delta)$, respectively, have lengths $L(u_\Delta) \leq L(u) \leq L(u_\delta)$. They play important roles in the theory of geodesics.

A geodesic triangle is a triple $(\gamma_0, \gamma_1, \gamma_2)$ of shortest geodesics (for convenience they are parametrized on $[0, 1]$) such that $\gamma_i(1) = \gamma_{i+1}(0)$ for all $i = 0, 1, 2$ with mod 3. The vertices p_0, p_1, p_2 and the angles $\theta_0, \theta_1, \theta_2$ of a geodesic triangle $(\gamma_0, \gamma_1, \gamma_2)$ are defined by $p_{i+1} = \gamma_i(0)$ and $\theta_{i+1} = \cos^{-1}\{\langle \dot{\gamma}_i(0), -\dot{\gamma}_{i-1}(1) \rangle / \|\dot{\gamma}_i\| \|\dot{\gamma}_{i-1}\|\}$, where angles are always taken in $[0, \pi]$. The **triangle comparison theorem** of Toponogov (*Amer. Math. Soc. Transl.*, 37 (1964)) is stated as follows. Let $K \geq \delta > -\infty$ be satisfied on M . For any geodesic triangle $(\gamma_0, \gamma_1, \gamma_2)$ on M there is a geodesic triangle $(\tilde{\gamma}_0, \tilde{\gamma}_1, \tilde{\gamma}_2)$ on $M(\delta)$ such that $L(\tilde{\gamma}_i) = L(\gamma_i)$ and the angles $\tilde{\theta}_i$ of this triangle satisfy $\tilde{\theta}_i \leq \theta_i$ for $i = 0, 1, 2$. It turns out that if $\delta > 0$ then the circumference of any geodesic triangle on M does not exceed $2\pi/\sqrt{\delta}$.

For details of the basic facts stated above we refer the reader to [1–3].

B. Curvature and Fundamental Groups

The fundamental group $\pi_1(M)$ of M (\rightarrow 170 Fundamental Groups) is influenced by the curvature of M . A basic idea, going back to Hadamard (*J. Math. Pures Appl.*, 4 (1898)) and Cartan, states that every nontrivial free homotopy class $\delta \in \pi_1(M)$ of loops on a compact M contains a closed geodesic of minimal length whose preimage under the covering projection $\pi: \tilde{M} \rightarrow M$ in the universal Riemannian covering \tilde{M} is either closed (when δ is of finite order) or a straight line (when δ is of infinite order) that is translated along itself by the deck transformation δ .

(1) By using the second variational formula, an even-dimensional compact M with $K > 0$

either is simply connected or has $\pi_1(M) = \mathbf{Z}_2$ (Synge, *Quart. J. Math.*, 7 (1936)). A beautiful result of Myers (*Duke Math. J.*, 8 (1941)) states that if the Ricci curvature Ric of M is bounded below by $\delta > 0$, then the diameter $d(M)$ is not greater than $\pi/\sqrt{\delta}$ and hence M is compact and $\pi_1(M)$ is finite. It is proved in [3] that if $K \geq 0$, then there exists a finite normal subgroup Φ of $\pi_1(M)$ such that $\pi_1(M)/\Phi$ is a Bieberbach group (\rightarrow 92 Crystallographic Groups). The splitting theorem (\rightarrow Section F(2)) is used in the proof.

(2) When $K \leq 0$ is satisfied on M , \tilde{M} is diffeomorphic to \mathbf{R}^m , and hence $\pi_i(M) = 0$ for all $i \geq 2$. A basic tool used in the study of $\pi_1(M)$ in this case is that the displacement function $\tilde{x} \rightarrow \tilde{d}(\tilde{x}, \delta(\tilde{x}))$, $\tilde{x} \in \tilde{M}$, of every isometry δ on \tilde{M} is convex [4], where a function on M is said to be **convex** if and only if its restriction to every geodesic is convex. A classical result of Preissmann (*Comment. Math. Helv.*, 15 (1943)) states that every nontrivial Abelian subgroup of $\pi_1(M)$ of a compact M with $K < 0$ is an infinite cyclic subgroup. It is proved in [4] that if $K < 0$ holds on M and if every deck transformation on \tilde{M} translates some geodesic along itself, then $\pi_1(M)$ is a disjoint union of infinite cyclic subgroups, and any two commuting elements belong to the same cyclic subgroup. Moreover, if M is compact and $K \leq 0$ and if $\pi_1(M)$ is a direct product $\Gamma_1 \times \Gamma_2$ such that $\pi_1(M)$ is \dagger centerless, then M is isometric to the Riemannian product $M_1 \times M_2$, and $\pi_1(M_i) = \Gamma_i$ holds for $i = 1, 2$ [5, 6]. It is shown in [7] that the fundamental group of M with $K \leq 0$ occurs as that of an $(m+1)$ -dimensional M' with $K \leq c < 0$, which is diffeomorphic to $M \times \mathbf{R}$. The warped product [4] is used to construct such a metric on $M \times \mathbf{R}$.

C. Cut Locus

The **injectivity radius** $i(M)$ of M is defined to be the infimum of the continuous function $x \rightarrow d(x, C(x))$, $x \in M$. As is seen in Section D, the estimate of injectivity radii provides many fruitful results on the topology of Riemannian manifolds. It follows from Synge's result that an even dimensional compact and orientable M with $0 < K \leq 1$ has its injectivity radius $i(M) \geq \pi$ [3]. However, such an estimate cannot be obtained in odd dimensions. The examples discussed in [8] show that there are infinitely many homotopically distinct homogeneous Riemannian 7-manifolds of positive curvature. The injectivity radii of such examples are estimated precisely in [9], according to which there is no positive lower bound for them. The **sphere theorem** of Klingenberg (*Comment. Math. Helv.*, 35 (1961))

states that if M is compact and simply connected and if $1/4 < K \leq 1$, then $i(M) \geq \pi$, and M is a topological sphere. This extends the pioneering work by H. Rauch (*Ann. Math.*, (2) 54 (1951)). A **rigidity theorem** of M. Berger (*Ann. Scuola Norm. Sup. Pisa*, 14 (1962)) states that if $\dim M$ is even, M is simply connected, and $1/4 \leq K \leq 1$, then M is homeomorphic to S^m (if $d(M) > \pi$) or isometric to one of the symmetric spaces of compact type of rank 1 (if $d(M) = \pi$). A slight generalization of the triangle comparison theorem is used to prove that for given positive constants d , V , and S , there exists a constant $C_m(d, V, S) > 0$ such that if K , $d(M)$ and the volume $v(M)$ satisfy $|K| < S$, $d(M) < d$, and $v(M) > V$, then $i(M) \geq C_m(d, V, S)$ [10].

D. Finiteness Theorem

Finiteness theorems are a natural extension of the sphere theorem. They provide *a priori* estimates for the number of various topological types of manifolds (for instance, homology, homotopy, homeomorphism, diffeomorphism types, etc.), which admit certain classes of Riemannian metrics characterized by geometric quantities. The basic idea of the estimates is to find a constant $c > 0$ that depends only on geometric information which characterizes the class of manifolds so that if M belongs to the class, then $i(M) \geq c$. Then a number N is found from the information given *a priori* such that every element M of the class has an open cover of at most N balls whose radii are all less than c . It is proved in [11] that for given $\delta \in (0, 1)$ and m , there exists a number $N(\delta, m)$ such that there are at most $N(\delta, m)$ homotopy types for the class of all simply connected $2m$ -dimensional manifolds with $\delta \leq K \leq 1$. Furthermore, for given positive numbers d , V , and S , there are at most finitely many homeomorphism (or diffeomorphism) types for the class of all m -manifolds M , each of which has the property that $d(M) < d$, $v(M) > V$, and $|K| < S$ [10]. This result is applied to obtain a result in [12], which states that there exists for given m , $V > 0$ and an $\varepsilon > 0$ such that if M is compact, $-1 - \varepsilon \leq K \leq -1$, and $v(M) > V$, then M admits a metric of constant negative curvature.

For an $\varepsilon \geq 0$, M is said to be ε -**flat** if and only if $\sup_M K \cdot d(M)^2 \leq \varepsilon$ is satisfied for M . Every compact flat manifold is ε -flat for all $\varepsilon \geq 0$. M is called a **nilmanifold** if and only if it admits a transitive action of a \dagger nilpotent Lie group. It is shown in [13] that for a compact M with $\dim M = m$, there exists a number $\varepsilon(m) > 0$ such that if M is $\varepsilon(m)$ -flat, then (1) there is a maximal nilpotent normal divisor $N \subset \pi_1(M)$, (2)

the order of $\pi_1(M)/N$ is bounded by a constant which depends only on m , and (3) the finite cover of M which corresponds to N is diffeomorphic to a nilmanifold. Moreover, if M is $\varepsilon(m)$ -flat then M is diffeomorphic to \mathbf{R}^m . If M is $\varepsilon(m)$ -flat and if $\pi_1(M)$ is commutative, then M is diffeomorphic to a torus.

E. Uniqueness Theorem

Uniqueness of topological structures (as in the sphere theorem) of certain classes of compact Riemannian manifolds is discussed here.

The discovery of exotic 7-spheres by J. Milnor (*Ann. Math.*, (2) 64 (1956)) gave rise to the question of whether in the sphere theorem the conclusion (homeomorphism to the sphere) could be replaced by diffeomorphism. Since the number of differentiable structures on a topological sphere depends on its dimension (\rightarrow 114 Differential Topology), it has been thought that in order to get the standard sphere in the sphere theorem the best possible restriction for the curvature might also depend upon dimension. The appropriate **differentiable pinching problem** is to find a sequence $\{\Delta_m\}$ so that if M is compact and simply connected and if $\delta \leq K \leq 1$ for some $\delta > \Delta_m$, then M is diffeomorphic to S^m , and Δ_m is the least possible with this property. D. Gromoll and Y. Shikata proved independently [14, 15] that $\Delta_m < 1$ holds for all $m \geq 2$. Later it was proved that there exists a $\delta_0 \in (1/4, 1)$ such that $\Delta_m \leq \delta_0$ holds for all $m \geq 2$ [16]. The **diffeotopy theorem**, which plays an essential role in the proof of finding such a δ_0 , provides a sufficient condition for a diffeomorphism on S^{m-1} to be isotopic to the identity mapping.

A different idea is put forth in [17], which imitates the Gauss normal mapping of a closed convex hypersurface in \mathbf{R}^{m+1} . It is proved that if the curvature operator is sufficiently closed to the identity, then M is diffeomorphic to S^m . This idea is used to obtain a diffeomorphism between M and a spherical space form. A generalization of the sphere theorem states that if M is compact and if $(d(M)/\pi)^2 \inf_M K > 1/4$, then M is a topological sphere [18].

F. Noncompact Manifolds

Let M be noncompact. It is due to the nature of noncompactness that through each point on M there passes a ray $\gamma: [0, \infty) \rightarrow M$, e.g., γ is a unit speed geodesic any of whose subarc is minimizing.

(1) Busemann Functions. A Busemann function $F_\gamma: M \rightarrow \mathbf{R}$ with respect to a ray γ is defined by

$F_\gamma(x) = \lim_{t \rightarrow \infty} [t - d(x, \gamma(t))]$. The original definition of it was used by H. Busemann to define a parallel axiom on straight G -spaces (\rightarrow Section H). F_γ has the property $F_\gamma^{-1}((-\infty, t_1]) = \{x \in F_\gamma^{-1}((-\infty, t_2]) \mid d(x, \partial F_\gamma^{-1}((-\infty, t_2])) \geq t_2 - t_1\}$ for any $t_2 \geq t_1$, and hence $F_\gamma(x) = t_2 - d(x, \partial F_\gamma^{-1}((-\infty, t_2]))$ for all t_2 and x with $F_\gamma(x) \leq t_2$. It has been proved, by using the second variation formula, that if $\text{Ric} \geq 0$, $K \geq 0$ [19] or if, in the case where M is Kählerian, the holomorphic bisectional curvature [20] is nonnegative, then F_γ is subharmonic (sh), convex or plurisubharmonic (psh), respectively, where the holomorphic bisectional curvature is defined as $R(X, JX, JY, Y)$ for the complex structure J and orthonormal vectors X and Y . If the holomorphic bisectional curvature [20] is positive, then F_γ is strictly psh. If $K \geq 0$, then the triangle comparison theorem implies that $F = \sup\{F_\gamma \mid \gamma(0) = p\}$ is convex and is an exhaustion [21], where the sup is taken over all rays emanating from a point $p \in M$, and a function f is said to be an **exhaustion** if and only if $f^{-1}((-\infty, a])$ is compact for all $a \in \mathbf{R}$. A well-known theorem of H. Grauert (*Math. Ann.*, 140 (1960)) states that if M admits a strictly psh exhaustion function, then M is a Stein manifold (\rightarrow 21 Analytic Functions of Several Complex Variables). In this context, various conditions for curvatures on Kähler manifolds under which they become Stein manifolds have been found [20].

Let H be complete and simply connected, and $K \leq 0$. Busemann functions on H are differentiable of class C^2 , and the horosphere $F_\gamma^{-1}(\{t\})$ is a C^2 -surface [22]. On a parabolic visibility manifold (\rightarrow Section F(3)) the negative of every Busemann function is C^1 -convex without minimum [7].

(2) Ends and Splitting Theorems. Ends of a noncompact M are defined as follows: If A_1 and A_2 are compact subsets of M with $A_1 \subset A_2$, then any component of $M - A_2$ is contained in a unique component of $M - A_1$. An **end** is the limit of an inverse system $\{\text{components of } M - A; A\}$ directed by the inclusion relation as indicated above and indexed by $\{A \mid A \text{ compact}\}$.

It has been shown that if $\text{Ric} > 0$ [23] (or ≥ 0 [19]), then M has exactly one end (or at most two ends). A visibility manifold has at most two ends if it is not Fuchsian [7]. If M admits a locally nonconstant convex function, then M has at most two ends [24].

If M has more than one end, then there exists a straight line $\gamma: \mathbf{R} \rightarrow M$ which is by definition a nontrivial geodesic any of whose subarcs is minimizing. A classical result of Cohn-Vossen (*Mat. Sb.*, 1 (1936)) states that if $\dim M = 2$, $K \geq 0$ and if M contains a straight

line, then the total curvature is 0 and hence M is isometric to either a plane or a cylinder $S^1 \times \mathbf{R}$. Generalizations of this result state that if M admits k independent straight lines and if $K \geq 0$ (Toponogov, *Amer. Math. Soc. Transl.*, 37 (1964)) (or if $\text{Ric} \geq 0$ [19]), then M is isometric to the Riemannian product $N \times \mathbf{R}^k$.

(3) Structure Theorems. The structure theorem of 2-dimensional M with $K > 0$ was proved by Cohn-Vossen (*Compositio Math.*, 2 (1935)). It has been shown that M is diffeomorphic to \mathbf{R}^m if $K > 0$ [23] and that if $K \geq 0$, then there exists a compact totally geodesic submanifold S without boundary such that M is homeomorphic to the total space of the †normal bundle over S [21]. Here, homeomorphism can be replaced by diffeomorphism, and if $K > 0$ outside a compact set of M , then M is diffeomorphic to \mathbf{R}^m [26].

For a ray γ and a point x on H , if σ is a ray with $\sigma(0) = x$ and if $d(\gamma(t), \sigma(t))$, $t > 0$, is bounded above, then σ is called an **asymptotic ray** (a ray asymptotic) to γ . The asymptotic relation is an equivalence relation on the set of all geodesics on H . A **point at infinity** of H is an equivalence class on geodesics on H , and the set of all points at infinity of H is denoted by $H(\infty)$. With a suitable topology, the set of all points at infinity of H constitutes a bounding sphere such that $\bar{H} = H \cup H(\infty)$ is a closed m -cell. For a properly discontinuous group D of isometries acting on H , a closed D -invariant limit set $L(D)$ is obtained in $H(\infty)$ as the set of all accumulation points of $\delta(p)$, $\delta \in D$. $M = H/D$ is a **visibility manifold** if and only if H satisfies the following axiom: any two distinct points on $H(\infty)$ can be joined by at least one geodesic. If $K \leq c < 0$ is satisfied on M , then M is a visibility manifold [7]. By investigating limit sets, visibility manifolds are classified into three types [7]. (1) M is parabolic; M is diffeomorphic to $N \times \mathbf{R}$ and is characterized by the fact that it has a convex function without minimum. (2) M is axial; M is a vector bundle over S^1 , and hence it is diffeomorphic to either $S^1 \times \mathbf{R}^{m-1}$ or the product of a Möbius strip with \mathbf{R}^{m-2} . (3) M is Fuchsian; M has more than two ends, and a strong algebraic restriction is imposed on the fundamental group of M .

(4) Convex Functions. Some elementary properties of C^∞ convex functions on M have been investigated and it was proved in [4] that if M admits a C^∞ convex function without minimum and if $K \leq 0$, then M is diffeomorphic to $N \times \mathbf{R}$, where N is a level hypersurface. When $K > 0$, F can be replaced by a strongly convex exhaustion function. Namely, for every compact set $A \subset M$ there is a $\delta > 0$

such that the second difference quotient along every geodesic at any point on A is bounded below by δ [20]. A standard †convolution smoothing procedure yields smooth convex approximations in neighborhoods of compact sets for every strongly convex function such that their second derivatives along every geodesic is positive. Global approximations can be constructed [27]. Let $\varphi: M \rightarrow \mathbf{R}$ be a convex function which is not constant on any open set. It has recently been proved that (1) if $b > \inf_M \varphi \geq -\infty$, then there is a homeomorphism $H: \varphi^{-1}(\{b\}) \times (\inf_M \varphi, \infty) \rightarrow M - \{\text{minimum set of } \varphi, \text{ if any}\}$ such that $\varphi \circ H(y, \alpha) = \alpha$ for all $y \in \varphi^{-1}(\{b\})$ and for all $\alpha \in (\inf_M \varphi, \infty)$; (2) if φ takes a minimum, then the continuous extension $\bar{H}: [\inf_M \varphi, \infty) \rightarrow M$ of H is proper and surjective [24].

G. Manifolds All of Whose Geodesics Are Closed

As is well known, every symmetric space of compact type of rank 1 (it is abbreviated CROSS as in [28]) has the property that all geodesics are simply closed and of the same length. Let M be a compact Riemannian manifold with the property that all geodesics on M are simply closed and that they have the same length (SC property). The problem discussed here is whether such an M is isometric (or at least the topology of such an M is equivalent) to some CROSS, or if it is possible to classify all such manifolds.

An example of a nontrivial SC-manifold was first constructed by Zoll (*Math. Ann.*, 57 (1903)) on S^2 as a surface of revolution in \mathbf{R}^3 , which is not isometric to a standard sphere. Blaschke conjectured that every SC-structure on $\mathbf{P}\mathbf{R}^2$ is the standard real projective space. This has been solved affirmatively by L. W. Green (*Ann. Math.*, 78 (1963)). In higher dimensions it has been proved that every infinitesimal deformation of the standard SC-structure on $\mathbf{P}\mathbf{R}^m$ is trivial [29]. A general result for a SC-manifold M states that the volume of M (with $\dim M = m$) with period 2π is the integral multiple of the volume of the standard unit m -sphere and this integer is a topological invariant [30]. For a point $p \in M$, if every geodesic segment with length l emanating from p is a simple geodesic loop at p , then M is called a **SC^p-manifold**. It has been proved that the †integral cohomology ring of every SC^p-manifold is isomorphic to one of the CROSS [31], which is a generalization of Bott's theorem (*Ann. Math.*, 60 (1954)).

An essential difference between the metrics of a Zoll surface and a standard sphere is seen

on the cut locus and the conjugate locus of a point. The (tangent) cut locus of any fixed point of a CROSS coincides with the (tangent) first conjugate locus; however, this does not hold on a Zoll surface. This observation gives rise to the definition of a Blaschke manifold: For distinct points $p, q \in M$, let $\Lambda(p, q) \subset M_q$ be the set of all unit vectors tangent to the minimizing geodesics from q to p . M is said to be a **Blaschke manifold at a point p** if for every $q \in C(p)$, $\Lambda(p, q)$ is a great sphere of the unit hypersphere in M_q centered at the origin. M is called a **Blaschke manifold** if it is so at every point of it. The following statements are equivalent [28]: (1) M is a Blaschke manifold at p , (2) the tangent cut locus C_p at p is spherical in M_p , (3) along every geodesic starting from p , the first conjugate point p appears at a constant length and the multiplicity of it is independent of the initial direction. Then such an M can be exhibited as $D \cup_a E$, where D is a closed ball with center p , E a C^∞ -closed k -disk bundle over an $(m-k)$ -dimensional C^∞ -compact manifold with boundary ∂E diffeomorphic to S^{m-1} , and $a: \partial D \rightarrow \partial E$ an attaching diffeomorphism. Conversely, if M is exhibited as $D \cup_a E$ then there exists a metric g on M such that (M, g) is a pointed Blaschke manifold at p , where p is the center of D . A generalized Blaschke's conjecture states that every Blaschke manifold is isometric to a CROSS. A partial solution to this conjecture has been obtained by M. Berger and states that if (S^m, g) is a Blaschke manifold, then it is isometric to a standard sphere [28].

H. G -Spaces

G -spaces were created by Busemann to show that many global theorems of differential geometry are independent of the Riemannian character of the metric and also of smoothness. This approach naturally led to novel questions and results. (Many facts hold even when the distance is not symmetric; \rightarrow [34].) The symbol G suggests that the principal property of G -spaces is the existence of geodesics with the same properties as in complete Riemannian manifolds without boundary except for differentiability. A **G -space X** is defined as follows: (1) X is metric with (symmetric) distance d ; (2) every bounded infinite set has at least one point of accumulation; (3) given two distinct points $p, r \in X$, there is a point $q \in X$ such that $p \neq q \neq r$ and $d(p, q) + d(q, r) = d(p, r)$; (4) to each point $x \in X$ a positive number ρ_x is assigned such that for any $p, q \in X$ with $d(p, x) < \rho_x$, $d(q, x) < \rho_x$ there is a point r with $d(p, q) + d(q, r) = d(p, r)$; (5) if

$d(p, q) + d(q, r) = d(p, r)$ and if $d(p, q) + d(q, r') = d(p, r')$, then $d(q, r) = d(q, r')$ implies $r = r'$.

From (2) and (3) it follows that any two points on X can be joined by a curve called a **segment** whose length realizes the distance between them. A **geodesic arc** (or for simplicity **geodesic**) $\gamma: [a, b] \rightarrow X$ is a curve such that any subarc contained in a ρ_x -ball around some point $x \in X$ is a segment. From (4) and (5) it follows that every geodesic arc has a unique infinite extension to both sides. If a geodesic arc is extended infinitely to both sides, then it is called a **geodesic line**.

The absence of smoothness causes an essential difference in the fact that the distance function to a fixed point on X is not necessarily convex in a small ball around it, in contrast to the Whitehead theorem (\rightarrow Section A) for Riemannian manifolds (or 'Finsler spaces). Here a function on X is called **convex** if and only if its restriction to every arc length-parametrized geodesic line is convex.

Every two points on X have neighborhoods which are homeomorphic to each other. Thus the topological dimension of X (\rightarrow 117 Dimension Theory) is well defined. A 1-dimensional X is either a circle S^1 or the whole real line. If $\dim X = 2$ [33] or if $\dim X = 3$ [36], then X is a topological manifold.

It should be noted that G -space theory not only proves known Riemannian theorems under weaker conditions, but also leads to many facts which were either not considered previously or well understood in (or thought to be very different from) the Riemannian case. Among many fruitful topics discussed by Busemann [33], only two are included below.

(1) **G -Surfaces.** For each point p on a 2-dimensional G -space \mathcal{S} , which is called a **G -surface**, let $S_p = \{x \in \mathcal{S} \mid d(x, p) = \rho\}$, where $0 < \rho < \rho_p/4$ is a fixed number. S_p is homeomorphic to a circle and bounds a 2-disk. An **angle A** at p is the set of all segments emanating from p and passing through the points on a connected subarc of S_p . An angular measure $|\cdot|$ for the angles at p is a nonnegative function which satisfies: (1) $|A| = \pi$ if and only if p is the midpoint of the segment joining two points on S_p which bounds A ; (2) if the intersection of two angles A_1 and A_2 is a unique segment, then $|A_1 \cup A_2| = |A_1| + |A_2|$. If a triple of points (p_0, p_1, p_2) on \mathcal{S} are contained in a sufficiently small ball, then the three segments joining them define a **triangle**, and each vertex p_i has the angle $|p_{i-1}p_i p_{i+1}|$ determined by the two segments. An **excess** $\varepsilon(p_0 p_1 p_2)$ of a triangle (p_0, p_1, p_2) is defined to be $\varepsilon(p_0 p_1 p_2) = |p_0 p_1 p_2| + |p_1 p_2 p_0| + |p_2 p_0 p_1| - \pi$. A degenerate triangle has excess 0. If a triangle (a, b, c) , which consists of geodesic arcs, is simplicially decomposed

into a finite number of triangles (a_i, b_i, c_i) , $i = 1, \dots, k$, then $\varepsilon(abc) = \sum_{i=1}^k \varepsilon(a_i b_i c_i)$, and this is independent of the choice of finite decomposition. If \mathcal{S} is compact and orientable, the **total excess** $\varepsilon(\mathcal{S})$ of \mathcal{S} is defined by $\varepsilon(\mathcal{S}) = \sum_{i=1}^k \varepsilon(a_i b_i c_i)$, where \mathcal{S} is simplicially decomposed into nondegenerate finite triangles (a_i, b_i, c_i) , $i = 1, \dots, k$. Then $\varepsilon(\mathcal{S}) = 2\pi\chi(\mathcal{S})$, where $\chi(\mathcal{S})$ is the Euler characteristic of \mathcal{S} . The results obtained by Cohn-Vossen [35] on the total curvature of complete open surfaces have also been generalized to G -surfaces with angular measure uniform at π . Although no angular measure leading to a true analog of the Gauss-Bonnet theorem exists even in G -surfaces [34], many of its applications, in particular the results by Cohn-Vossen, can be proved by using angular measures which are uniform at π [33].

If every two points on X can be joined by a unique geodesic line, then all geodesic lines on X are simultaneously either straight lines or circles of the same length l . If in the latter case $\dim X > 1$, then X has a two-fold universal covering space \tilde{X} whose geodesic lines are all circles of the same length $2l$, and they have the property that all geodesics through a point on \tilde{X} meet at the same point at length l . For the Riemannian case it is a Blaschke manifold (\rightarrow Section G). If every two points on \mathcal{S} can be joined by a unique geodesic line, then \mathcal{S} is either a plane or a projective plane.

(2) G -Spaces with Nonpositive Curvature. Let (p_0, p_1, p_2) be a triple of points on X which are contained in a small ball. X , by definition, is of **nonpositive curvature** if and only if for any such triple of points

$$d(p_1, p_{i+1}) \geq 2d(p'_i, p_{i+1}) \quad \text{for } i=0, 1, 2, \quad (*)$$

where p'_i is the midpoint of the unique segment joining p_{i-1} to p_{i+1} . If the above inequality is strict for any nondegenerate small triangle, then X is said to be of **negative curvature**. X of curvature 0 is defined in the same way. It should be noted that a G -space of curvature 0 is a locally Minkowskian space [33]. The sectional curvature of a Riemannian manifold M is nonpositive if and only if (*) holds for all small triangles on it. Because of $d(p_0, p'_0) \leq d(p_0, p'_1) + d(p'_1, p'_0) \leq \{d(p_0, p_1) + d(p_0, p_2)\}/2$, the distance function to a point $x \in X$ of nonpositive curvature is convex on a small ball around x . X is called **straight** if and only if all nontrivial geodesic lines on X are straight lines. If X has nonpositive curvature, then the universal covering space \tilde{X} is straight. Moreover, for any two geodesic lines $\gamma, \sigma: \mathbf{R} \rightarrow X$, the function $t \rightarrow d(\sigma(t), \gamma(t))$ is convex. In particular, the distance function to every fixed point on \tilde{X} is convex, and (*) holds for any

triangle on \tilde{X} . Thus \tilde{X} is contractible. Every nontrivial element of the homotopy class of loops on X with base point $x \in X$ contains a geodesic loop at x which has the minimum length. This fact and the strict convexity of $t \rightarrow d(\sigma(t), \gamma(t))$ for any two arc length parametrized geodesic lines γ, σ on the universal covering \tilde{X} of X with negative curvature imply that if X is compact, then every Abelian subgroup of the fundamental group $\pi_1(X)$ of X is infinite cyclic. This is a generalization of the Preissmann theorem (\rightarrow Section B).

179 (VI.5) Geometric Construction

A. General Remarks

A **geometric construction problem** is a problem of drawing a figure satisfying given conditions by using certain prescribed tools only a finite number of times. If the problem is solvable, then it is called a **possible construction problem**; if it is unsolvable, even though there exist figures satisfying the given conditions, then it is an **impossible construction problem**. If there does not exist a figure satisfying the given conditions, then we say that the problem is **inconsistent**.

Among problems of geometric construction, the oldest and the best known are those of constructing plane figures by means of **ruler** and **compass**. In this article, we call these problems simply problems of elementary geometric construction. The following are some of the more famous problems of this kind; the first four are possible construction problems.

(1) Suppose that we are given three straight lines l, m, n and three points P, Q, R in a plane. Draw a triangle ABC in such a way that vertices A, B, C lie on l, m, n and sides BC, CA, AB pass through P, Q, R (**Steiner's problem**).

(2) Suppose that we are given a circle O and three points P, Q, R not lying on O . Draw a triangle ABC inscribed in O in such a way that the sides BC, CA, AB pass through P, Q, R (**Cramer-Castillon problem**).

(3) Draw a circle tangent to all of three given circles (**Apollonius' problem**).

(4) Suppose that we are given a triangle. Draw three circles inside this triangle in such a way that each is tangent to two sides of the triangle and any two of the circles are tangent to each other (**Malfatti's problem**).

(5) Let n be a natural number. For the division of the circumference of a circle into n equal parts (consequently, the construction of a n -gon) to be a possible construction problem, it is necessary and sufficient that the representation of n as a product of prime numbers take the form $n = 2^\lambda p_1 \dots p_k$, where $\lambda \geq 0$, p_1, \dots, p_k are all different prime numbers of the form $2^h + 1$ (h -Fermat number) (C. F. Gauss, 1801).

(6) The following are three famous impossible construction problems of Greek origin: (i) divide a given angle into three equal parts (**trisection of an angle**); (ii) construct a cube whose volume is double that of a given cube (**duplication of a cube** or the **Delos problem**); and (iii) construct a square whose area is that of a given circle (**quadrature of a circle**). P. L. Wantzel (1837) proved that problems (i) and

(ii) are impossible except for the special cases of $\pi/2$, $\pi/4$, etc. for (i); and C. L. F. Lindemann (1882) proved the impossibility of (iii) while proving that the number π is \dagger transcendental.

B. Conditions for Constructibility

A problem of elementary geometric construction amounts to a problem of determining a certain number of points by drawing straight lines that pass through given pairs of points, and circles having given points as centers and passing through given points. Let (a_1, b_1) , (a_2, b_2) , ..., (a_n, b_n) be rectangular coordinates of given points, and let K be the smallest \dagger number field containing the numbers a_1 , ..., b_n . Straight lines that join given pairs of points and circles that have given points as centers and that pass through given points are represented by equations of the first or second degree with coefficients belonging to K . Consequently, the coordinates of points of intersection of these straight lines and circles belong to a quadratic extension $K' = K(\sqrt{d})$ of K . Let A be the set of coordinates of the points that are to be determined. Then the problem is solvable if and only if any number α in A is contained in a field $L = K(\sqrt{d_1}, \sqrt{d_2}, \dots, \sqrt{d_r})$, where $d_{i+1} \in K(\sqrt{d_1}, \dots, \sqrt{d_i})$ ($i = 0, 1, \dots, r-1$). Thus L is a \dagger normal extension field of K whose degree over K is a power of 2. Using this theorem we can prove the impossibility of trisection of an angle and duplication of a cube.

Since the 18th century, besides the problem of construction by ruler and compass, problems of construction by ruler alone or by compass alone have also been studied. We state here some of the more notable results: (1) If by drawing a straight line we mean the process of finding two different points on that line, then we can solve all the problems of elementary geometric construction by means of compass alone (G. Mohr, L. Mascheroni). (2) If by drawing a circle we mean the process of finding its center and a point on its circumference, and if a circle and its center are given, then we can solve any problem of elementary geometric construction by means of ruler alone. (3) It is not possible to find the center of a given circle by ruler alone (D. Hilbert). (4) It is impossible to bisect a given segment by ruler alone. (5) When two intersecting circles or concentric circles are given, we can find the centers of these circles by ruler alone. When nonintersecting and nonconcentric circles are given, it is not possible to find their centers by ruler alone (D. Cauer).

Cases have been considered in which the radius of a circle we can draw by compass or

the length of a segment we can draw by ruler is required to satisfy certain conditions. Also, various considerations have been made concerning cases in which we can use tools other than ruler and compass. For example, it is known that although not all possible elementary geometric construction problems are solvable by ruler alone, all these problems are possible if we have either a pair of parallel rulers, a square, or a triangle having a fixed acute angle. If we use a square and a compass, then the trisection of an angle and the duplication of a cube are possible (L. Bieberbach). Also, when a conic section other than a circle is given, the trisection of an angle and the duplication of a cube become possible by ruler and compass (H. J. S. Smith and H. Kortum). By ruler and \dagger transfer of constant lengths, we can solve Malfatti's problem but not Apollonius' problem (Feldblum).

Even when a problem is possible, the method of construction may be rather complicated and impractical. In these cases, various methods of highly accurate approximate construction have been investigated.

180 (XX.15) Geometric Optics

A. General Remarks

Geometric optics is a mathematical theory of light rays. It is not concerned with the properties of light rays as waves (e.g., their wavelength and frequency), but studies their properties as pencils of rays that follow three laws: the law of rectilinear propagation, the law of reflection (i.e., angles of incidence and reflection on a smooth plane are equal (Euclid)), and the law of refraction (i.e., if θ and θ' are angles of incidence and refraction of a light ray refracted from a uniform medium to a second uniform medium and if n , n' are the refractive indices of the first and the second medium, respectively, then $n \sin \theta = n' \sin \theta'$ (R. W. Snell, Descartes)). These three laws follow from **Fermat's principle**, which states that the path of a light ray traveling from a point A' to A in a medium with refractive index $n(P)$ at P is such that the integral $\int_A^{A'} n(P) ds$ attains its

extremal value, where ds is the line element along the path. This line integral is called the **optimal distance** from A' to A . Therefore Fermat's principle can be taken as a foundation of geometric optics and is, in a way, similar to the \dagger variational principle in particle dynamics (**Maupertuis's principle**),

$$\delta \int \sqrt{2h - 2U(P)} ds = 0,$$

which is satisfied by the path of a particle of unit mass having constant energy h passing through a field of \dagger potential $U(P)$. The quantity $\sqrt{2h - 2U}$ corresponds to the refractive index n .

In an optical system, express the position of a point on the path of a light ray by orthogonal coordinates (x, y, z) , and define the \dagger Lagrangian $L = n\sqrt{1 + \dot{x}^2 + \dot{y}^2}$ ($\dot{x} = dx/dz$, $\dot{y} = dy/dz$), **optical direction cosines** $p = \partial L / \partial \dot{x}$, $q = \partial L / \partial \dot{y}$, and the \dagger Hamiltonian $H = \dot{x}p + \dot{y}q - L = -\sqrt{n^2 - p^2 - q^2}$. Then the \dagger canonical equations of the path are obtained as in particle dynamics; x, y and p, q are called \dagger canonical variables. Due to the variational principle, the integral of the linear differential form $p dx + q dy - H dz = \omega_d$ along a light path is a function $S(A', A)$ of the endpoints A', A of the path, and the optical direction cosines and the Hamiltonians of the system at A and A' are given by

$$\frac{\partial S}{\partial x'} = -p', \quad \frac{\partial S}{\partial y'} = -q', \quad \frac{\partial S}{\partial z'} = H',$$

$$\frac{\partial S}{\partial x} = p, \quad \frac{\partial S}{\partial y} = q, \quad \frac{\partial S}{\partial z} = -H.$$

Hence we obtain \dagger Hamilton-Jacobi differential equations

$$\left(\frac{\partial S}{\partial x'}\right)^2 + \left(\frac{\partial S}{\partial y'}\right)^2 + \left(\frac{\partial S}{\partial z'}\right)^2 = n'^2,$$

$$\left(\frac{\partial S}{\partial x}\right)^2 + \left(\frac{\partial S}{\partial y}\right)^2 + \left(\frac{\partial S}{\partial z}\right)^2 = n^2.$$

As a corollary to these relations we obtain **Malus's theorem**, which states that a pencil of light rays perpendicular to a common surface (locally) at a given moment is also perpendicular to a common surface (locally) after an arbitrary number of reflections and refractions.

Suppose that light rays travel from an object space into an image space through an optical apparatus. If all the rays starting from any one point of the object space converge to a point of the image space and if the mapping given by this correspondence is \dagger bijective, then we say that this imaging is **perfect**. Examples of perfect imaging systems are realized by optical apparatus such as **Maxwell's fisheye** (having refractive index $n(r) = a/(b + r^2)$, where

r denotes the distance from the center of the system) and **Luneburg's lens** ($n(r) = \sqrt{a - r^2}$).

Perfect imaging conserves optical distance, yields the relation $n(A')ds' = n(A)ds$, and gives a \dagger conformal mapping, with the magnification inversely proportional to the refractive index.

B. Gauss Mappings

Consider an optimal system with a symmetrical axis of rotation, its **optical axis**. A ray of light that is near the optical axis and has a small inclination to the axis is called a **paraxial ray**. A mapping realizable by paraxial rays where the canonical variables x, y, p, q can be considered to be infinitesimal variables whose squares are negligible, is called a **Gauss mapping** (**Gauss map**). When the positions of an object point and its image under a Gauss mapping are represented by homogeneous coordinates, the mapping is represented as a linear transformation, i.e., a \dagger collineation, which maps a point to a point and a line to a line. A point in one space corresponding to the point at infinity in the other space is called a **focus**. If we take a focus as the origin of a coordinate system in each space and use the \dagger homogeneous coordinates x_i such that $x = x_1/x_4$, $y = x_2/x_4$, $z = x_3/x_4$, then a Gauss mapping can be represented as $x_1 = x'_1$, $x_2 = x'_2$, $x_3 = f x'_4$, $f' x'_4 = x'_3$. The ratio of x to x' , i.e., the lateral magnification, is $x/x' = z/f = f'/z'$, where x' is the length of an object orthogonal to the axis and x is the length of its image. The distance f between a focus and a point where the lateral magnification is 1 (such a point is called a **principal point**) is called **focal length** in each space. The telescopic mapping, i.e., $x_1 = x'_1$, $x_2 = x'_2$, $x_3 = a x'_3$, $x_4 = b x'_4$, is also a Gauss mapping, in which the lateral magnification is constant.

C. Aberration

When a mapping is realized not only by paraxial rays but also by rays having larger inclinations, a departure from the Gauss mapping arises. This departure is generally called **aberration**. Suppose that a light ray that passes through the point (x', y', z') of a plane perpendicular to the optical axis at a fixed z' and has optical direction cosines p', q' is transformed by the optical apparatus into a light ray that passes through the point (x, y, z) of a plane perpendicular to the optical axis at a fixed z and has optical direction cosines p, q there. Then by the variational principle, $p dx + q dy - p' dx' - q' dy' = dW$ (dW is an \dagger exact differential). Therefore the transformation $(x', y', p', q') \rightarrow (x, y, p, q)$ is a \dagger canonical transformation. The

mapping can be described by

$$p = \frac{\partial W}{\partial x}, \quad q = \frac{\partial W}{\partial y},$$
$$p' = -\frac{\partial W}{\partial x'}, \quad q' = -\frac{\partial W}{\partial y'}$$

in terms of W and can also be represented in terms of $V = W + p'x' + q'y'$ or $U = W + p'x' + q'y' - px - qy$. For a given optical system, one of these functions W, U, V (called a **characteristic function** or **eikonal**) can be used to estimate the aberration. By developing such a characteristic function in power series of canonical variables and observing its terms of less than the fifth power, we can single out five kinds of aberration: spherical aberration, curvature of image field, distortion, coma, and astigmatism in a rotationally symmetric optical system. To eliminate these aberrations an optical system must satisfy Abbe's sine condition (the elimination of spherical aberration and coma), Petzval's condition (the elimination of astigmatism and curvature of image field), and the tangent condition (the elimination of distortion).

The path of a charged particle in an electromagnetic field can be treated in the same way as the path of a light ray. Let ϵ represent the specific charge of the particle, h the energy, A_0 the electrostatic potential, and A_x, A_y, A_z vector potentials. Then the index of refraction is $\sqrt{2(h - \epsilon A_0) + \epsilon(A_x dx/ds + A_y dy/ds + A_z dz/ds)}$. In this case, the index of refraction shows the anisotropy caused by the existence of the magnetic field. The paths of paraxial rays are determined by a set of linear differential equations of the second order, and the Gauss mapping is realized as in geometric optics.

Geometry

The Greek word for geometry, which means *measurement of the earth*, was used by the

historian Herodotus, who wrote that in ancient Egypt people used geometry to restore their land after the inundation of the Nile. Thus the theoretical use of figures for practical purposes goes back to pre-Greek antiquity. Tradition holds that Thales of Miletus knew some properties of congruent triangles and used them for indirect measurement, and that the Pythagoreans had the idea of systematizing this knowledge by means of proofs (\rightarrow 24 Ancient Mathematics; 187 Greek Mathematics). \dagger Euclid's *Elements* is an outgrowth of this idea [1]. In this work, we can see the entire mathematical knowledge of the time presented as a logical system. It includes a chapter (Book V) on the theory of quantity (i.e., the theory of positive real numbers in present-day terminology) and chapters on the theory of integers (Books VII–IX), but for the most part, it treats figures in a plane or in space and presents number-theoretic facts in geometric language.

Geometry in today's usage means the branch of mathematics dealing with spatial figures. In ancient Greece, however, all of mathematics was regarded as geometry. In later times, the French word *géomètre* or the German word *Geometer* was sometimes used as a synonym for *mathematician*. In a fragment of his *Pensées*, B. Pascal speaks of the *esprit de géométrie* as opposed to the *esprit de finesse*. The former means simply the mathematical way of thinking.

Algebra was introduced into Europe from the Middle East toward the end of the Middle Ages and was further developed during the Renaissance. In the 17th and the 18th centuries, with the development of analysis, geometry achieved parity with algebra and analysis.

As R. Descartes pointed out, however, figures and numbers are closely related [2]. Geometric figures can be treated algebraically or analytically by means of \dagger coordinates (the method of **analytic geometry**, so named by S. F. Lacroix [3]); conversely, algebraic or analytic facts can be expressed geometrically. Analytic geometry was developed in the 18th century, especially by L. Euler [4], who for the first time established a complete algebraic theory of \dagger curves of the second order. Previously, these curves had been studied by Apollonius (262–200? B.C.) as \dagger conic sections. The idea of Descartes was fundamental to the development of analysis in the 18th century. Toward the end of that century, analysis was again applied to geometry. For example, G. Monge's contribution [5] can be regarded as a forerunner of \dagger differential geometry.

However, we cannot say that the analytic method is always the best manner of dealing with geometric problems. The method of treating figures directly without using coordinates

is called **synthetic** (or **pure**) **geometry**. In this vein, a new field called \dagger projective geometry was created by G. Desargues and B. Pascal in the 17th century. It was further developed in the 19th century by J.-V. Poncelet, L. N. Carnot, and others. In the same century, J. Steiner insisted on the importance of this field (\rightarrow 343 Projective Geometry).

On the other hand, the \dagger axiom of parallels in Euclid's *Elements* has been an object of criticism since ancient times. In the 19th century, by denying the a priori validity of Euclidean geometry, J. Bolyai and N. I. Lobachevskii formulated non-Euclidean geometry, whose logical consistency was shown by models constructed in both Euclidean and projective geometry (\rightarrow 285 Non-Euclidean Geometry).

In analytic geometry, physical spaces and planes, as we know them, are represented as 3-dimensional or 2-dimensional Euclidean spaces E^3 , E^2 . It is easy to generalize these spaces to n -dimensional Euclidean space E^n . A "point" of E^n is an n -tuple of real numbers (x_1, \dots, x_n) , and the distance between two points (x_1, \dots, x_n) , (y_1, \dots, y_n) is $((y_1 - x_1)^2 + \dots + (y_n - x_n)^2)^{1/2}$. The geometries of E^2 , E^3 are called **plane geometry** and **space** (or **solid**) **geometry**, respectively. The geometry of E^n is called **n -dimensional Euclidean geometry**. We obtain n -dimensional projective or non-Euclidean geometries similarly. F. Klein [7] proposed systematizing all these geometries in group-theoretic terms. He called a "space" a set S on which a group G operates and a "geometry" the study of properties of S invariant under the operations of G (\rightarrow 137 Erlangen Program).

B. Riemann [6] initiated another direction of geometric research when he investigated n -dimensional \dagger manifolds and, in particular, \dagger Riemannian manifolds and their geometries. Some aspects of Riemannian geometry fall outside of geometry in the sense of Klein. It was a starting point for the broad field of modern differential geometry, that is, the geometry of \dagger differentiable manifolds of various types (\rightarrow 109 Differential Geometry).

The reexamination of the system of axioms of Euclid's *Elements* led to D. Hilbert's \dagger foundations of geometry and to the axiomatic tendency of present-day mathematics. The study of algebraic curves, which started with the study of conic sections, developed into the theory of algebraic manifolds, the algebraic geometry that is now developing so rapidly (\rightarrow 12 Algebraic Geometry). Another branch of geometry is topology, which has developed since the end of the 19th century. Its influence on the whole of mathematics today is considerable (\rightarrow 114 Differential Topology; 426 Topology). Geometry has now permeated all

branches of mathematics, and it is sometimes difficult to distinguish it from algebra or analysis. The importance of geometric intuition, however, has not diminished from antiquity until today.

182 (V.10) Geometry of Numbers

A. History

H. Minkowski introduced the notions of lattice and convex set in the \dagger algebraic theory of numbers. He developed a simple yet powerful method of arithmetic investigation using these geometric notions to simplify the analytic theory of \dagger Diophantine approximation, which had been developed by P. G. L. Dirichlet and C. Hermite. His theory, the **geometry of numbers**, has continued its development and contributed to various fields of mathematics (\rightarrow 83 Continued Fractions).

B. Lattices

Let E^n be an n -dimensional Euclidean space identified with the linear space \mathbf{R}^n . For a point

P in E^n , we denote the corresponding vector in \mathbf{R}^n by $v(P) = \langle x_1, \dots, x_n \rangle$. A subset Λ of E^n is called an n -dimensional (**homogeneous**) **lattice** if there exists a basis $\{v_1, \dots, v_n\}$ of \mathbf{R}^n such that $\Lambda = \{P \in E \mid v(P) = \sum_{i=1}^n \lambda_i v_i, \lambda_i \in \mathbf{Z}\}$. The set of points $\{X_1, \dots, X_n\}$ such that $v(X_i) = v_i$ ($i = 1, \dots, n$) is called a **basis** of the lattice Λ . A typical example of a lattice is the point set corresponding to \mathbf{Z}^n in \mathbf{R}^n . The free module generated by v_i ($i = 1, \dots, n$) is denoted by Λ^* and is called the **lattice group** of Λ . We have $\Lambda^* = \{v \in \mathbf{R}^n \mid v = v(P), P \in \Lambda\}$. If $\{u_1, \dots, u_n\}$ is another basis of the free module Λ^* , then there exists an element (α_{ij}) of $GL(n, \mathbf{Z})$ (i.e., $\alpha_{ij} \in \mathbf{Z}$ and $|\det(\alpha_{ij})| = 1$) such that $u_j = \sum_{i=1}^n \alpha_{ij} v_i$. Hence the quantity $|\det(v_1, \dots, v_n)|$ is independent of the choice of the basis $\{v_1, \dots, v_n\}$. We denote this quantity by $d(\Lambda)$ and call it the **determinant of the lattice**. We denote the minimum distance between the points belonging to Λ by $\delta(\Lambda)$.

A subset L of the space E^n is called an **inhomogeneous lattice** if there exists a homogeneous lattice Λ in E^n and a point P_0 in E^n such that $L = \{P \in E^n \mid v(P) - v(P_0) \in \Lambda^*\}$. Thus an inhomogeneous lattice is obtained from a homogeneous lattice by translation. In this article we restrict ourselves to the case of homogeneous lattices and henceforth omit the adjective "homogeneous."

Suppose we are given a sequence of lattices $\Lambda_1, \Lambda_2, \dots$, in E^n with bases $\{X_1^{(1)}\}, \{X_1^{(2)}\}, \dots$. If the sequence of points $X_i^{(v)}$ converges to X_i ($i = 1, \dots, n$) and the set $\{X_1, \dots, X_n\}$ forms a basis of a lattice Λ , we call Λ the **limit of the sequence** $\{\Lambda_v\}$; we also say that the sequence $\{\Lambda_v\}$ **converges** to the lattice Λ . In this case we have $d(\Lambda_v) \rightarrow d(\Lambda)$, $\delta(\Lambda_v) \rightarrow \delta(\Lambda)$. The notion of convergence of lattices gives rise to a topology of the space M_0 of all the lattices in E . A sequence $\{\Lambda_v\}$ of lattices is said to be **bounded** if there exist positive numbers c and c' such that $d(\Lambda_v) \leq c$, $\delta(\Lambda_v) \geq c'$ for all v . A bounded sequence of lattices has a convergent subsequence.

Let S be a subset of the space E^n . A lattice Λ is called **S -admissible** if we have $\Lambda \cap S^i = \{O\}$, where S^i is the interior of S and O is the origin. We denote the set of S -admissible lattices by $A(S)$. Given a closed subset M of M_0 , we put $\Delta(S \setminus M) = \inf_{\Lambda \in A(S) \cap M} d(\Lambda)$ if $A(S) \cap M$ is non-empty, while if $A(S) \cap M$ is empty, we put $\Delta(S \setminus M) = \infty$. When $M = M_0$, we write $\Delta(S \setminus M) = \Delta(S)$ and call it the **critical determinant** of S . Generally, a lattice Λ in M is said to be **critical in M with respect to S** if $\Lambda \in A(S)$ and $d(\Lambda) = \Delta(S \setminus M)$. Suppose that we have $0 < \Delta(S \setminus M) < \infty$. Then for a lattice critical in M with respect to S to exist it is necessary and sufficient that there exist a bounded sequence $\{\Lambda_v\}$ such that $\Lambda_v \in M \cap A(S)$ and $d(\Lambda_v) \rightarrow \Delta(S \setminus M)$.

C. Successive Minima and Minkowski's Theorem

A subset S of the space E^n is called a **bounded star body** (symmetric with respect to the origin) if there exists a continuous function F defined on the space E satisfying the following four conditions: (i) $F(O) = 0$; (ii) if $X \neq O$, then $F(X) > 0$; (iii) for an arbitrary real number t and a point X , we have $F(tX) = |t|F(X)$; (iv) $S = \{X \mid F(X) \leq 1\}$. A bounded closed convex body that is symmetric with respect to the origin is a bounded star body. If we are given a star body S , the associated function F , and a lattice Λ , there exist a set of points $\{P_1, \dots, P_n\}$ in Λ and a set of positive numbers $\{p_1, \dots, p_n\}$ satisfying the following four conditions: (1) $v(P_1), \dots, v(P_n)$ are linearly independent; (2) $F(P_i) = p_i$ ($i = 1, \dots, n$); (3) $p_1 \leq \dots \leq p_n$; (4) if P is a point in Λ and $v(P)$ is not contained in the subspace spanned by $\{v(P_1), \dots, v(P_{n-1})\}$, then $F(P) \geq p_n$. The set $\{p_1, \dots, p_n\}$ is uniquely determined by S and Λ . The numbers p_i are called the **successive minima** of S in Λ ; the points P_i are the **successive minimum points** of S in Λ .

Minkowski's theorem: Let Λ be a lattice in a Euclidean space E^n and S a bounded subset of E^n . Then we have the following:

(I) If the volume $V(S)$ is larger than $d(\Lambda)$, then there exist points X_1 and X_2 in S such that $X_1 \neq X_2$ and $v(X_1) - v(X_2) \in \Lambda^*$. Suppose, moreover, that S is convex and symmetric with respect to the origin. Then, if $V(S) > 2^n d(\Lambda)$, there exists a point X in $S \cap \Lambda$ different from the origin. Hence we have $2^n \Delta(S) \geq V(S)$ ($n = \dim E^n$).

(II) Let S be a bounded closed convex body that is symmetric with respect to the origin, and let p_1, \dots, p_n be the successive minima of S in Λ . Then we have $p_1 \dots p_n \cdot V(S) \leq 2^n d(\Lambda)$.

D. Minkowski-Hlawka Theorem

Suppose that we are given a subset S of the n -dimensional Euclidean space E^n such that the characteristic function $\chi(X)$ of S is integrable in the sense of Riemann. Then we have the **Minkowski-Hlawka theorem**: (i) If $n \geq 2$ and S is open, then $\Delta(S) \leq V(S)$, and (ii) if, moreover, S is symmetric with respect to the origin, then $2\Delta(S) \leq V(S)$; (iii) if S is a symmetric star body with respect to the origin, then $2\zeta(n)\Delta(S) \leq V(S)$, where $\zeta(n)$ is the Riemann zeta function.

A proof for the theorem was given by E. Hlawka (1944); (iii) and (iv) were conjectured by Minkowski. C. L. Siegel obtained another proof (1945), and C. A. Rogers simplified the original proof by Hlawka (1947). There are

results concerning the estimation of $\Delta(S)/V(S)$ for various subsets S .

E. Siegel's Mean Value Theorem

In an attempt to obtain a proof for the latter half of the Minkowski-Hlawka theorem, Minkowski observed the necessity of establishing the arithmetic theory of the linear transformation groups. Siegel was inspired by this observation and obtained the following theorem, **Siegel's mean value theorem**, which implies the Minkowski-Hlawka theorem: Let F be a \dagger fundamental region of the group $SL(n, \mathbf{R})$ with respect to a discrete subgroup $SL(n, \mathbf{Z})$. Let ω be the \dagger invariant measure on $SL(n, \mathbf{R})$ such that $\int_F d\omega = 1$ (\rightarrow 225 Invariant Measures). Let f be a bounded Riemann integrable function with compact \dagger support defined on the space \mathbf{R}^n . Note that the lattice \mathbf{Z}^n is stabilized by the subgroup $SL(n, \mathbf{Z})$. We have

$$\int_F \sum_{\substack{x \in \mathbf{Z}^n \\ x \neq 0}} f(g \cdot x) d\omega(g) = \int_{\mathbf{R}^n} f(x) dx,$$

where the right-hand side of the equation is the usual Riemann integral of the function f . A. Weil considered this theorem in a more general setting (*Summa Brasil. Math.*, 1 (1946)).

F. Diophantine Approximation

Minkowski initiated the notion of Diophantine approximation in reference to the problem of estimating the absolute value $|f(x)|$ of a given function f , where x varies in \mathbf{Z} or in a given ring of \dagger algebraic integers. (A \dagger Diophantine equation is an equation $f(x)=0$, where x varies in \mathbf{Z} .) Today Diophantine approximation (in the wide sense) refers to the investigation of the scheme of values $f(x)$, where x varies in a suitable ring of algebraic integers. The geometry of lattices is a powerful tool in this investigation. A typical problem in this field of study is that of approximating irrational numbers by rational numbers; here \dagger continued fractions play an important role (\rightarrow Section G). For the problem of uniform distribution considered by H. Weyl, the analytic method, especially that of trigonometric series, is useful (\rightarrow Section H). **Dirichlet's drawer principle** (to put n objects in m drawers with $n > m$, it is necessary to put more than one object in at least one drawer) is one of the basic principles used in the theory of Diophantine approximation. Recently, the theory has been applied to the theory of \dagger transcendental numbers and the theory of \dagger Diophantine equations.

G. Approximation of Irrational Numbers by Rational Numbers

Given an irrational number θ , we have the problem of finding rational integers x (> 0) and y such that $|\theta - y/x| < \varepsilon/x$, where ε is a given positive number. Suppose that we are given a positive integer N . Using Dirichlet's drawer principle we can show the existence of x ($\leq N$) and y such that $|\theta - y/x| < 1/xN$. Let $M(\theta)$ be the supremum of positive numbers M such that the inequality $|\theta - y/x| < 1/Mx^2$ holds for infinitely many pairs of integers x, y . We have $1 \leq M(\theta) (\leq \infty)$. Two irrational numbers θ and θ' are said to be **equivalent** if there exists an element $(a_{ij}) \in GL(2, \mathbf{Z})$ such that $\theta' = (a_{11}\theta + a_{12})/(a_{21}\theta + a_{22})$. In this case we have $M(\theta) = M'(\theta)$.

If the irrational number θ satisfies the quadratic equation $a\theta^2 + b\theta + c = 0$ (a, b, c are rational integers), then we have $M(\theta) = k^{-1} \sqrt{b^2 - 4ac}$, where $k = \min\{ax^2 + bxy + cy^2 | x, y \in \mathbf{Z}, x \neq 0, y \neq 0\}$. In general, for an irrational number θ of degree two, we have $M(\theta) \geq \sqrt{5}$. The equality $M(\theta) = \sqrt{5}$ holds if θ is equivalent to $\theta_1 = (1 + \sqrt{5})/2$. If θ is not equivalent to θ_1 , then $M(\theta) \geq \sqrt{8}$; the equality holds if θ is equivalent to $\theta_2 = 1 + \sqrt{2}$. Similarly, we have $\theta_3, \theta_4, \dots$; and $M(\theta_n) \rightarrow 3$ ($n \rightarrow \infty$). If $M(\theta) < 3$, there exists a θ_n such that θ is equivalent to θ_n . The set of irrational numbers θ satisfying $M(\theta) = 3$ is uncountable (A. A. Markov [13]). We have no information about $M(\theta)$ for the general algebraic irrational number θ . Let $\mu(\theta)$ be the supremum of real numbers μ such that the inequality $|\theta - y/x| < 1/x^\mu$ holds for infinitely many pairs of integers x, y . Given a number $\kappa > 2$, it can be shown that the \dagger Lebesgue measure of the set of real numbers θ such that $\mu(\theta) \geq \kappa$ is zero. If θ is a real algebraic number of degree n , then $\mu(\theta) \leq n$ (J. Liouville). Concerning $\mu(\theta)$, results have been obtained by A. Thue, Siegel, A. O. Gel'fond, and F. J. Dyson. K. F. Roth (1954) proved that $\mu(\theta) = 2$ (**Roth's theorem** [12]), which settled the problem of $\mu(\theta)$. Roth's theorem means that if κ is larger than 2, then there exist only a finite number of pairs x, y satisfying $|\theta - y/x| < 1/x^\kappa$. This can be generalized to the case of the approximation of an element θ that is algebraic over an A -field k by an element of the field k (S. Lang [9]). (An A -field is either an algebraic number field of finite degree or an algebraic function field in one variable over a finite constant field.)

In 1970 W. M. Schmidt [20] obtained theorems on simultaneous approximation which generalize Roth's theorem. Thus, if $\alpha_1, \dots, \alpha_n$ are real algebraic numbers such that $1, \alpha_1, \dots, \alpha_n$ are linearly independent over the

field of rational numbers, then for every $\varepsilon > 0$ there are only finitely many positive integers q with

$$\|q\alpha_1\| \dots \|q\alpha_n\| q^{1+\varepsilon} < 1,$$

where $\|\xi\|$ denotes the distance from a real number ξ to the nearest integer; in particular, we have

$$|\alpha_i - p_i/q| < q^{-(n+1)/n-\varepsilon}, \quad i = 1, \dots, n,$$

for only finitely many n -tuples of rationals $p_1/q, \dots, p_n/q$. A dual to this result is as follows. Let $\alpha_1, \dots, \alpha_n, \varepsilon$ be as before. Then there are only finitely many n -tuples of nonzero integers q_1, \dots, q_n with

$$\|q_1\alpha_1 + \dots + q_n\alpha_n\| \cdot |q_1 \dots q_n|^{1+\varepsilon} < 1.$$

This last theorem can be used to prove that if α is an algebraic number, k a positive integer, and $\varepsilon > 0$, then there are only finitely many algebraic numbers ω of degree at most k such that $|\alpha - \omega| < H(\omega)^{-k-1-\varepsilon}$, where $H(\omega)$ denotes the height of ω . See also [16, 22].

The work of Thue, Siegel, and Roth had the basic limitation of noneffectiveness. A. Baker (1968) succeeded in proving that for any algebraic number θ of degree $n \geq 3$ and any $\kappa > n$, there exists an effectively computable number $c = c(\theta, \kappa) > 0$ such that $|\theta - y/x| > cx^{-n} \exp(\log x)^{1/\kappa}$ for all integers x, y ($x > 0$) [15]. This result is an immediate consequence of the following effective version of a classical theorem on binary Diophantine equations (Thue, 1909): Let $f = f(x, y)$ be an irreducible binary form of degree $n \geq 3$ with integer coefficients, and suppose that $\kappa > n$. Then for any positive integer m , all integer solutions x, y of the equation $f(x, y) = m$ satisfy $\max(|x|, |y|) < c \exp(\log m)^\kappa$, where $c > 0$ is an effectively computable number depending on n, κ , and the coefficients of f . Baker obtained this result by making use of his theorems which give effective estimates of moduli of linear forms in the logarithms of algebraic numbers with algebraic coefficients. A typical theorem reads as follows: Let $\alpha_1, \dots, \alpha_n$ be nonzero algebraic numbers with $\log \alpha_1, \dots, \log \alpha_n$ linearly independent over the rationals, and let β_0, \dots, β_n be algebraic numbers, not all 0, with degrees and heights at most d and H , respectively. Then for any $\kappa > n + 1$, we have $|\beta_0 + \beta_1 \log \alpha_1 + \dots + \beta_n \log \alpha_n| > c \exp(-(\log H)^\kappa)$, where $c > 0$ is an effectively computable number depending only on $n, \kappa, \log \alpha_1, \dots, \log \alpha_n$, and d [14, 19].

Results of this kind have many important applications in number theory. For instance, we obtain a generalization of the Gel'fond-Schneider theorem on transcendental numbers. Furthermore, the imaginary quadratic number fields of class number 1 can be com-

pletely determined on the basis of Baker's result. This was actually done by Baker (1966) and independently by H. M. Stark (1966) (\rightarrow 347 Quadratic Fields).

Refinements and generalizations of Thue's theorem on the finiteness of solutions of binary Diophantine equations have been obtained by Baker and his collaborators. (\rightarrow [17], and also [16]). Also, p - and p -adic analogs of Baker's results are known [18].

There are a number of unsettled problems on the irrationality of particular numbers, such as the Euler constant C , π^e , or $\zeta(2k+1)$ with k a positive integer. R. Apéry (1978) proved that there exist a positive number ε and a sequence of positive integers $\{q_n\}$ such that $0 < \|q_n \zeta(3)\| < e^{-\varepsilon n}$ for all $n \geq 1$, so that $\zeta(3)$ is irrational.

H. Uniform Distribution

Let θ be a real number, x a positive integer, and $[\theta x]$ the maximum integer not larger than θx . We write $(\theta x) = \theta x - [\theta x] \equiv \theta x \pmod{1}$. Jacobi showed that if θ is irrational, then the set $\{(\theta x) | x \in \mathbb{N}\}$ is densely distributed in the interval $(0, 1)$ (\mathbb{N} is the set of positive integers). In general, let f be a real-valued function defined on \mathbb{N} . We say that $f(x) \pmod{1}$ is **uniformly distributed** in the unit interval, or $f(x)$ is **uniformly distributed (mod 1)**, if the following condition is satisfied: Let α, β be an arbitrary pair of real numbers such that $0 \leq \alpha < \beta \leq 1$, and let N be a given positive integer. Let $T(N)$ be the number of positive integers x such that $x \leq N$, $\alpha \leq (f(x)) < \beta$, where $(f(x)) = f(x) - [f(x)]$. Then $\lim_{N \rightarrow \infty} T(N)/N = \beta - \alpha$. In order for $f(x) \pmod{1}$ to be uniformly distributed, it is necessary and sufficient that $\lim_{N \rightarrow \infty} N^{-1} \sum_{x=1}^N e^{2\pi i h f(x)} = 0$ for any non-zero integer h (**Weyl's criterion**, 1914). Weyl proved that if θ is an irrational number, then $\theta x \pmod{1}$ is uniformly distributed.

The following theorem, given by J. G. van der Corput, is often useful: Let f be a real-valued function defined on \mathbb{N} . Consider the function $f_h(x) = f(x+h) - f(x)$ for an arbitrary positive integer h . If $f_h(x) \pmod{1}$ is uniformly distributed (mod 1) for all such h , then $f(x) \pmod{1}$ is also uniformly distributed (mod 1).

Utilizing this theorem, it can be shown that if $f(x) = \theta_r x^r + \theta_{r-1} x^{r-1} + \dots + \theta_1 x$, where at least one of the coefficients θ_i is irrational, then $f(x) \pmod{1}$ is uniformly distributed.

The notion of uniform distribution of sequences of real numbers has an analog in compact Hausdorff spaces and in various topological groups. A systematic treatment of such generalized notions of uniform distribution can be found in [21].

183 (VII.23) Global Analysis

Mathematics that treats, by using functional analytical techniques, various problems concerning the [†]calculus of variations, [†]singularities, infinite-dimensional Lie groups, or [†]non-linear partial differential equations, such as equations of fluids or of gravitation in general relativity, may be called global analysis if it uses as a main tool an infinite-dimensional version of differential geometry and topology analogous to that for finite-dimensional manifolds. The term **global analysis** therefore has no precise definition. However, it can be said that it is analysis on manifolds, and the concept of [†]infinite-dimensional manifolds is the central abstract idea in it.

Suppose one considers a nonlinear differential operator on a finite-dimensional manifold. Then by using functional analytical techniques it often happens that its domain is neither a linear space nor its open subset but an infinite-dimensional manifold, and that such a nonlinear operator can be regarded as a [†]differentiable mapping between infinite-dimensional manifolds. The [†]differential at a point in that source manifold is called a **linearized operator**, to which one can apply various theories of linear functional analysis.

“Global analysis” seems to have first appeared in the literature in the late 1960s [1, 2]. However, the phrase “infinite-dimensional manifold” has been used widely since about 1960. By that early date, local theories of infinite-dimensional manifolds, sometimes called “general analysis,” such as definitions of differentiability, the [†]implicit function theorem, [†]Taylor’s theorem, the existence and uniqueness of [†]ordinary differential equations, and the [†]Frobenius theorem, had already been established in [†]Banach spaces [3]. Therefore, with these regarded as a local theory, the concept of infinite-dimensional manifolds could be defined naturally, and the concept of infinite-

dimensional Lie groups as well [4]. A few years later, R. Palais and S. Smale [5] and J. Eells and J. Sampson [6] showed that such concepts are useful in the calculus of variations, and R. Abraham and J. Robbin [7] remarked that \dagger transversality theorems initiated by R. Thom can be easily proved by using an infinite-dimensional version of \dagger Sard's theorem [8].

The so-called \dagger Atiyah-Singer index theorem [9], announced in 1963, gave impetus to the field as people sought the theorem's most natural expression; the work finally resulted in the theorem classifying separable \dagger Hilbert manifolds by homotopy type (\rightarrow 105 Differentiable Manifolds).

After the appearance of these theorems announcing the nonexistence of differential topology on separable infinite-dimensional Hilbert manifolds, global analysis moved toward more concrete problems and applications to various branches of mathematics. However, many of these applications are formulated not on \dagger Banach or Hilbert manifolds, but on manifolds modeled on Fréchet spaces (\dagger Fréchet manifolds) or on \dagger nuclear spaces. For such situations we have in general no local theories. Neither the implicit function theorem nor the Frobenius theorem holds on such manifolds. However, since these theorems are crucial for nonlinear problems, various kinds of sufficient conditions for the validity of these theorems are being studied by many people (\rightarrow 286 Nonlinear Functional Analysis).

As for the calculus of variations, **Yamabe's problem** is being studied extensively, for this seems to be a typical problem not satisfying the so-called \dagger Condition C. The original paper of H. Yamabe [13], insisting that every compact Riemannian manifold can be conformally deformed into a manifold of constant scalar curvature, contains a serious gap, and the problem is still open, though many cases are known where the statement holds (\rightarrow 364 Riemannian Manifolds H). The harmonic mappings defined in [6] are also being studied extensively (\rightarrow 195 Harmonic Mappings).

In differential geometry or the \dagger general theory of relativity definitions of various curvatures, such as Riemannian, Ricci or scalar, or Gauss, can be sometimes regarded as nonlinear differential equations on manifolds. Proof of the global existence of solutions to these equations has long been sought, and several theorems have recently appeared [14–16].

Infinite-dimensional groups such as $GL(E)$, or $GL_c(E)$ with uniform topology, are called \dagger Banach-Lie groups, and they have been studied in the operator calculus. On the other

hand, infinite groups studied by S. Lie and E. Cartan were in fact infinite-dimensional germs of transformation groups defined on a neighborhood of a point in a manifold. These were not groups in the strict sense. Recently, H. Omori [17] has given a definition of abstract infinite-dimensional Lie groups that includes Banach-Lie groups and many infinite-dimensional transformation groups studied by Cartan. An application of these groups to \dagger fluid dynamics can be found in [18]. Moreover, \dagger unitary representation theories of these groups are now being constructed [19, 20].

Though global analysis consists at present of a rather disorganized combination of many nonlinear problems in analysis on manifolds and in mathematical physics, it is nevertheless one of the most active branches of mathematics.

184 (XXI.27) Gödel, Kurt

Kurt Gödel (April 28, 1906–January 14, 1978) was born in Brno, Czechoslovakia (at that time Brünn, Austria-Hungary). He studied mathematics and physics at the University of Vienna, where he took the Ph.D. degree in 1930. After he had taught mathematics at the University of Vienna from 1933 to 1938, he was invited to the Institute for Advanced Study at Princeton, where he became professor in 1953. In 1976, he was named professor emeritus; he died in Princeton in 1978.

Gödel contributed important fundamental results covering all aspects of mathematical logic. Among his famous works are the proof of the \dagger completeness of the first-order predicate calculus, the incompleteness of the consistent axiomatic system containing Peano's arithmetic (incompleteness theorem), and the \dagger consistency of the axiom of choice and the generalized continuum hypothesis. He also introduced the notion of \dagger recursive functions and found the Gödel solution of Einstein's equations of relativity. In addition to mathematical works, he left philosophical papers on set theory and the foundations of mathematics.

185 (I.8) Gödel Numbers

A. General Remarks

K. Gödel [1] devised the following method to prove his incompleteness theorems (\rightarrow Section C).

Let \mathfrak{S} be a \dagger formal system. In this article, we call its basic symbols, \dagger terms, \dagger formulas, and formal proofs the “constituents” of \mathfrak{S} . Let g be an \dagger injection from the constituents of \mathfrak{S} into the natural numbers satisfying the following two conditions: (1) Given a constituent C , we can compute the value $g(C)$ in a finite number of steps. (2) Given a natural number n , there exists a finitary procedure to find out whether there exists a constituent C of \mathfrak{S} such that $g(C) = n$; furthermore, when such a C exists, it can actually be specified in a finite number of steps.

If such a mapping g is given for the system \mathfrak{S} , then the mapping g is called a **Gödel numbering** and the number $g(C)$ is called the **Gödel number** of the constituent C (with respect to g).

B. An Example of Gödel Numbers

(1) Let $\alpha_0, \alpha_1, \dots$ be the basic symbols of \mathfrak{S} . With each α_i we associate a distinct odd number q_i : $g(\alpha_i) = q_i$ ($i = 0, 1, \dots$). (2) Let F be a constituent of \mathfrak{S} . If F is constructed from any other constituents F_0, F_1, \dots, F_k of \mathfrak{S} by a rule peculiar to \mathfrak{S} (for convenience we write this $F = (F_0, F_1, \dots, F_k)$), and if, for each F_i , $g(F_i)$ is already defined, then we put $g(F) = \langle g(F_0), g(F_1), \dots, g(F_k) \rangle$, where $\langle a_0, a_1, \dots, a_k \rangle$ denotes the number $p_0^{a_0} p_1^{a_1} \dots p_k^{a_k}$ (p_i is the $(i+1)$ st prime number). For example, suppose that \mathfrak{S} contains $0, =, v_j$ (variables), and \neg (negation) among the basic symbols, and let their Gödel numbers be 7, 9, 11^{j+1} , and 13, respectively. Since the formula $\neg(0 = v_j)$ can be analyzed in the form $(\neg, (0, =, v_j))$, its Gödel number is $\langle 13, \langle 7, 9, 11^{j+1} \rangle \rangle$. For details \rightarrow [1, 4].

C. Gödel's Incompleteness Theorems

By means of a Gödel numbering any metamathematical notion about the constituents of a formal system \mathfrak{S} can be interpreted as a number-theoretic notion. For example, the notion “formula” is interpreted as the number-theoretic predicate $\text{Form}(x)$ which means that x is the Gödel number of a formula. The provability of a formula is interpreted as the number-theoretic predicate $\text{Prov}(x)$, which means that x is the Gödel number of a prov-

able formula; accordingly, for any formula A of \mathfrak{S} , the proposition $\text{Prov}(g(A))$ means that A is provable. This interpretation is called the **arithmetization** of metamathematics.

Let the formal system \mathfrak{S} include formal elementary number theory. Then many metamathematically useful number-theoretic predicates can be expressed by the respective formulas of \mathfrak{S} ; for example, there exist formulas **Form**(x) and **Prov**(x) expressing the predicates **Form**(x) and **Prov**(x), respectively. Furthermore, Gödel proved the existence of a closed formula U such that the formula $\neg \text{Prov}(g(U)) \leftrightarrow U$ is provable. This closed formula U is one of the so-called **formally undecidable propositions**, and in fact it is shown that neither U nor $\neg U$ is provable in \mathfrak{S} if \mathfrak{S} is consistent in a strong sense. This result is called Gödel's **first incompleteness theorem**.

By use of the formulas **Form**(x) and **Prov**(x) the consistency of the formal system \mathfrak{S} is expressed by the formula **Consis** which is an abbreviation of $\exists x(\text{Form}(x) \wedge \neg \text{Prov}(x))$. Gödel obtained the result that the formula **Consis** is not provable in \mathfrak{S} if \mathfrak{S} is consistent, on the basis of the following three facts: (1) U is not provable in \mathfrak{S} if \mathfrak{S} is consistent; (2) **Consis** $\rightarrow \neg \text{Prov}(g(U))$ is provable in \mathfrak{S} ; (3) $\neg \text{Prov}(g(U)) \rightarrow U$ is not provable in \mathfrak{S} . This result is called Gödel's **second incompleteness theorem**.

The method of arithmetization is important and useful in the study of mathematical logic. The notion of Gödel numbers of recursive functions is one of its applications (\rightarrow 356 Recursive Functions).

D. Tarski's Theorem Concerning Truth Definitions

Let a consistent formal system \mathfrak{S} and a \dagger model of \mathfrak{S} be given. By means of a Gödel numbering, the truth notion of closed formula is interpreted as the number-theoretic predicate **Tr**(x) which means that x is the Gödel number of a true closed formula; accordingly, for any closed formula A of \mathfrak{S} , the proposition $\text{Tr}(g(A))$ means that A is true.

In relation to the foregoing fact, if there exists a formula **Tr**(x) of a single variable and the formula $\text{Tr}(g(A)) \leftrightarrow A$ is provable for every closed formula A , then that formula **Tr**(x) is called a **truth definition**. A. Tarski proved the fact that there is no truth definition in \mathfrak{S} if the formal system \mathfrak{S} is consistent.

186 (XVI.12) Graph Theory

A. Overview of Graph Theory

Two aspects of graphs are the object of **graph theory**. One is that a graph expresses a binary relation over a set V , and the other is the fact that a graph is a CW-complex of 1 dimension, an object of study in algebraic topology. Because of its special nature as an object of 1 dimension, we can consider various concrete properties in detail. Hence graph theory has close connection with other areas, such as network theory, system theory, automata theory, and the theory of computational processes, and it has many useful applications.

The notion of a “graph” as currently used in graph theory was first discussed by L. Euler [1]. It is said that J. J. Sylvester coined the word “graph” as we presently understand it. However, up to now, there were few unifying principles, and graph theory seemed like a large collection of miscellaneous problems and ad hoc techniques. The terminology has not yet been standardized; different usages prevail in different schools. The resulting confusion can be seen in reference books such as [2]–[5]. Recently, infinite graphs have also been studied. But here we restrict ourselves to finite graphs, since only they give a typical theory.

B. Definition of Graph

The notion of a **graph** $G = (V, E, \delta^+, \delta^-)$ is a composite notion of two finite sets V and E

and two maps $\partial^+ : E \rightarrow V$ and $\partial^- : E \rightarrow V$. An element of V is called a **vertex**, and an element of E is called an **edge**. The maps ∂^\pm are called **incidence relations**. The terms **point**, or **node** instead of vertex, and **arc**, **line**, or **branch** instead of edge have also been used (sometimes with slightly different meanings). For an edge $e \in E$, $\partial^+ e \in V$ is called the **initial vertex** and $\partial^- e \in V$ is called the **terminal vertex**. Both are called the **end vertices** of e . The inverse map δ^\pm of $\partial^\pm : V \rightarrow 2^E$ is defined by $\delta^\pm v = \{e \in E | \partial^\pm e = v\}$ and has the following properties: (i) If $v \neq v'$, then $\delta^+ v \cap \delta^+ v' = \delta^- v \cap \delta^- v' = \emptyset$. (ii) $\bigcup_{v \in V} \delta^+ v = \bigcup_{v \in V} \delta^- v = E$. Conversely, if the maps $\delta^\pm : V \rightarrow 2^E$ have the properties (i) and (ii), then there exist corresponding maps ∂^\pm . For a vertex $v \in V$, $|\delta^+ v|$ is called the **outdegree** or **positive degree**, $|\delta^- v|$ is called the **indegree** or **negative degree**, and the sum $|\delta^+ v| + |\delta^- v|$ is called the **degree**. We always have the relation $\sum_{v \in V} |\delta^+ v| = \sum_{v \in V} |\delta^- v| = |E|$, and $\sum_{v \in V} (|\delta^+ v| + |\delta^- v|) = 2|E|$. The number of vertices with odd degree is always even. Two end vertices of an edge are called mutually **adjacent**, and two edges with at least one common end vertex are also called mutually **adjacent**. An edge satisfying $\partial^+ e = \partial^- e$ is called a **self-loop**, and a vertex satisfying $\delta^+ v = \delta^- v = \emptyset$ is called an **isolated vertex**.

When permutation groups P_V operating over V and P_E operating over E are given, we can naturally define the permutation (π_V, π_E) over the graph $G(\pi_V \in P_V, \pi_E \in P_E)$. A graph is classified into equivalence classes by P_V, P_E . When P_V, P_E are all the permutations of V, E , respectively, each equivalence class is called an **unlabeled graph**, whereas when P_V, P_E consist only of an identity transformation, G is called a **labeled graph**.

For a given graph $G = (V, E, \delta^+, \delta^-)$ and a subset $E' \subset E$, we can define the **reoriented graph** of edges in E' by $G' = (V, E, \delta'^+, \delta'^-)$, where $\delta'^+ e = \partial^+ e$ if $e \notin E'$ and $\delta'^\pm e = \partial^\mp e$ if $e \in E'$. We have an equivalence relation by identifying the reoriented graphs. Each class by this equivalence relation is called an **undirected graph** or an **unoriented graph**. In contrast, the graph in the original sense is called a **directed graph** or an **oriented graph**.

C. Examples of Special Graphs

(1) A **complete graph** is a graph such that there exists one and only one edge with end vertices v and v' for every different pair of vertices v and v' . (2) A **bipartite graph** is a graph with a partition $V^+ \cup V^- = V$ such that $V^+ \cap V^- = \emptyset$ and for every $e \in E$, we have $\partial^+ e \in V^+$ and $\partial^- e \in V^-$. If there always exists an edge e with $\partial^+ e = v, \partial^- e = v'$ for every pair $v \in V^+$ and

$v' \in V^-$, it is called a **complete bipartite graph**. (3) A **regular graph** is a graph whose degree at each vertex is the same. (4) A **partial graph** is defined as follows: Let E' be a subset of E in a graph $G = (V, E, \delta^+, \delta^-)$. The graph $G' = (V', E', \delta'^+, \delta'^-)$ is called a **partial graph** of G , where $V' = \partial^+ E' \cup \partial^- E'$, and δ'^\pm are the restrictions of δ^\pm on E' , respectively. When $E' = E$, the partial graph is the graph obtained by deleting all isolated vertices from G . Similarly, for a subset V' of V , the graph $G'' = (V'', E'', \delta''^+, \delta''^-)$, defined by $E'' = \delta^+ V'' \cup \delta^- V''$ and with δ''^\pm being the restriction of δ^\pm on E'' , is called a **section graph** of G .

D. Representation of a Graph

When we want to process by computer a problem concerning a graph, we must represent a graph in a suitable form (\rightarrow 96 Data Processing). A commonly used method is the following **list representation**: Let $V = \{v_1, v_2, \dots, v_M\}$ and $E = \{e_1, e_2, \dots, e_n\}$. For each $v_\alpha \in V$ ($\alpha = 1, \dots, M$), we arrange the edges in $\delta^+ v_\alpha$ and in $\delta^- v_\alpha$ in suitable orders. Then (i) for each $v_\alpha \in V$, record $|\delta^+ v_\alpha|, |\delta^- v_\alpha|, B_\alpha^+, \bar{B}_\alpha^+, B_\alpha^-, \bar{B}_\alpha^-$, where B_α^\pm and \bar{B}_α^\pm are the first and the last index of the edges in $\delta^\pm v_\alpha$, respectively. We define the corresponding values to be 0 if the $\delta^\pm v_\alpha$ are empty. (ii) For each $e_\kappa \in E$, record $\partial_\kappa^+, \partial_\kappa^-, E_\kappa^+, \bar{E}_\kappa^+, E_\kappa^-, \bar{E}_\kappa^-$, where ∂_κ^\pm are the number of vertices $\partial^\pm e_\kappa$, and $E_\kappa^\pm, \bar{E}_\kappa^\pm$ are the number of edges immediately after or before e_κ among the edges with the same initial (for $^+$) or terminal (for $^-$) vertex as that of e_κ . If e_κ is the last or the first among such edges, we define the corresponding values to be 0.

E. Deformation of a Graph

Let $G = (V, E, \delta^+, \delta^-)$ be a graph. A graph obtained by **opening** an edge e is the graph $G' = (V, E - \{e\}, \delta'^+, \delta'^-)$, where δ'^\pm is the restriction of δ^\pm on $E - \{e\}$. The graph obtained by deleting all isolated vertices from G' is a partial graph of G over $E - \{e\}$. A graph obtained by **shortening** an edge e is the graph $G'' = (V'', E - \{e\}, \delta''^+, \delta''^-)$, where $V'' = (V - \{\partial^+ e, \partial^- e\}) \cup \{\delta\}$, δ being a new vertex not contained in V , and $\delta''^\pm = \varphi \cdot \delta^\pm$, $\varphi : V \rightarrow V''$ being defined by $\varphi(v) = v$ for $v \neq \partial^\pm e_\kappa$ and $= \delta$ when $v = \partial^+ e_\kappa$ or $v = \partial^- e_\kappa$. A graph obtained by opening and shortening several different edges is similarly defined, and the result is independent of the order of opening or shortening process. A graph obtained by opening edge(s) or by shortening edge(s) or by both processes is called a **subgraph**, a **contraction**, or a **subcontraction**, respectively.

F. Connectedness

Let $G=(V,E,\partial^+,\partial^-)$ be a graph, and let v_α and v_β be two vertices. A **path** from v_α to v_β of **length** l is a sequence $P=(v_\alpha=v_{\alpha_0},e_1e_{\kappa_1},v_{\alpha_1},e_2e_{\kappa_2},\dots,e_l e_{\kappa_l},v_{\alpha_l}=v_\beta)$, where e_i are $+1$ or -1 , and for every $i=1,\dots,l$, we have $\partial^+e_{\kappa_i}=v_{\alpha_{i-1}}$, $\partial^-e_{\kappa_i}=v_{\alpha_i}$ if $e_i=+1$, and $\partial^+e_{\kappa_i}=v_{\alpha_i}$, $\partial^-e_{\kappa_i}=v_{\alpha_{i-1}}$ if $e_i=-1$. When $v_\alpha=v_\beta$, it is called a **closed path** considering P as a cyclic sequence. If in the sequence P of a path no edge appears more than once, it is called a **simple path**. Similarly, if no vertex appears more than once, it is called **elementary**. If all $e_i=+1$, it is called a **direct path**. **Direct closed paths**, etc., are similarly defined.

If we define $v\sim v'$ by the existence of a path from v to v' , this \sim is an equivalence relation. Let us denote the equivalence classes by V_1,\dots,V_s . The section graph $G_i=(V_i,E_i,\partial_i^+,\partial_i^-)$ determined by V_i is called a **connected component**, or simply a **component**, of G . The sets E_1,\dots,E_s are mutually disjoint and the union is E . If we denote by $v\rightarrow v'$ the existence of a direct path from v to v' , the relation \rightarrow is a \dagger pseudo-order. The relation $v\leftrightarrow v'$ defined by $v\rightarrow v'$ and $v'\rightarrow v$ is an equivalence relation in V , and the equivalence classes $\tilde{V}_1,\dots,\tilde{V}_t$ or the section graphs $\tilde{G}_i=(\tilde{V}_i,\tilde{E}_i,\tilde{\partial}_i^+,\tilde{\partial}_i^-)$ determined by \tilde{V}_i are called **strongly connected components** of G . $\tilde{E}_1,\dots,\tilde{E}_t$ are mutually disjoint, but their union is not always E . Among the sets $\tilde{V}_1,\dots,\tilde{V}_t$, we can define an order relation $\tilde{V}_i\rightarrow\tilde{V}_j$ by the existence of $v\in\tilde{V}_i, v'\in\tilde{V}_j, v\rightarrow v'$. Classification by \leftrightarrow is a refinement of that by \sim . When $s=1$, the graph G is called **connected**, and when $t=1$, G is called **strongly connected**.

For a different pair $v, v'\in V$, a set $S\subset V-\{v,v'\}$ is called a **separator** of v and v' if every path from v to v' contains at least one vertex of S . When every separator S for any pair v, v' has at least k elements, the graph G is called **k -connected**. For $k\geq 3$, there are several variations of the definition of k -connectedness. 1-connectedness is equivalent to connectedness in the sense defined above.

A simple path containing all edges of a graph is called an **Euler path**. Euler direct paths, etc., are similarly defined. A graph with an Euler path is called an **Euler graph**. A graph is an Euler graph if and only if (i) it is connected, and (ii) the number of vertices with odd degrees is 0 or 2 (Euler's unicursal graph theorem [1]). Similar results are known for Euler closed paths or Euler direct paths. An elementary path containing all vertices of a graph is called a **Hamilton path**. Hamilton closed paths, etc., are similarly defined. The criteria for the existence of a Hamilton path for any given graph is unknown. This is known to be an \dagger NP-complete problem (\rightarrow 71

Complexity of Computations). Various sufficient conditions or necessary and sufficient conditions for special graphs have been given (\rightarrow e.g., [6]).

G. Tieset, Cutset, Tree, and Cotree

For a graph $G=(V,E,\partial^+,\partial^-)$, we define its **incidence matrix** $[\bar{D}_\kappa^\alpha(\alpha=1,\dots,M(=|V|),\kappa=1,\dots,n(=|E|))]$ by defining D_κ^α to be 1 if $v_\alpha=\partial^+e_\kappa\neq\partial^-e_\kappa$, -1 if $v_\alpha=\partial^-e_\kappa\neq\partial^+e_\kappa$, and 0 if $\partial^+e_\kappa=\partial^-e_\kappa$ or $e_\kappa\notin\partial^+v_\alpha\cup\partial^-v_\alpha$. Similarly we define its **adjacency matrix** $[\Gamma_\beta^\alpha(\alpha,\beta=1,\dots,M)]$ by defining Γ_β^α to be 0 if v_α and v_β are not mutually adjacent and 1 if v_α and v_β are mutually adjacent.

A set of edges forming a closed path is called a **tieset**. A set of edges of the form $\{e|\partial^+e\in W, \partial^-e\in V-W\}\cup\{e|\partial^-e\in W, \partial^+e\in V-W\}$ for a partition $(W,V-W)$ of V is called a **cutset**. A maximal subset of edges containing no tiesets is called a **tree**, and a maximal subset of edges containing no cutsets is called a **cotree**. A tree is sometimes called a **spanning tree** of G . Every tree is the complement (with respect to E) of a cotree, and vice versa.

The number of elements of a tree is always the same and equal to the \dagger rank m of the incidence matrix. This value m is called the **rank** of the graph G . Similarly, the number k of elements of a cotree is always the same, which is called the **nullity** or the **cyclomatic number** of the graph G . Always, $k=n-m$.

Let K be a field, K^n, K^M be vector spaces over K of dimensions n and M , respectively, and K^{n*}, K^{M*} be the \dagger dual spaces of K^n, K^M . The incidence matrix defines two mutually contragradient linear mappings $\partial:K^n\rightarrow K^M$ and $\delta:K^{M*}\rightarrow K^{n*}$ with respect to their canonical bases. A minimal set among the family of supports (in E) of nonzero vectors in the kernel $\text{Ker } \partial$ is a tieset corresponding to an elementary closed path. Similarly, a minimal set among the family of supports (in E) of nonzero vectors of the image $\text{Im } \delta$ is a minimal cutset.

Let $T(\subset E)$ be a tree and $\bar{T}=E-T$ be a cotree. Let us renumber the edges so that $T=\{e_1,\dots,e_m\}$, $\bar{T}=\{e_{m+1},\dots,e_n\}$. For each $e_{m+p}\in\bar{T}$, there is a unique vector $R_p^k(p=1,\dots,k(n-m))$ in $\text{Ker } \partial$ whose support is in $\{e_{m+p}\}\cup T$ and whose e_{m+p} - equals $+1$. Similarly, for each $e_a\in T(a=1,\dots,m)$, there is a unique vector $D_a^k(a=1,\dots,m)$ in $\text{Im } \delta$ whose support is in $\{e_a\}\cup\bar{T}$ and whose e_a - component equals $+1$. $\{R_1^k,\dots,R_k^k\}$ is a basis of $\text{Ker } \partial$, and $\{D_1^k,\dots,D_m^k\}$ is a basis of $\text{Im } \delta$. Both matrices $R_p^k(k\times n)$ and $D_a^k(m\times n)$ are **totally unimodular**, i.e., every minor determinant is 0, $+1$, or -1 . Furthermore, the following relations hold: $R_p^{m+q}=\delta_p^q(p,q=1,\dots,k), D_b^a=\delta_b^a(a,b=1,\dots,m), R_p^a+$

$D_{m+p}^a = 0$ ($a = 1, \dots, m; p = 1, \dots, k$). The matrices R_p^k and D_k^a are called the **fundamental tieset matrix** and the **fundamental cutset matrix**, respectively, with respect to the tree-cotree pair (T, \bar{T}) . The minor of the matrix R_p^k consisting of all rows and k columns $\kappa_1, \dots, \kappa_k$ is $+1$ or -1 if and only if $\{e_{\kappa_1}, \dots, e_{\kappa_k}\}$ is a cotree, and 0 otherwise. Similarly, the minor of the matrix D_k^a consisting of all rows and m columns $\kappa_1, \dots, \kappa_m$ is $+1$ or -1 if and only if $\{e_{\kappa_1}, \dots, e_{\kappa_m}\}$ is a tree, and 0 otherwise.

H. Planarity of a Graph

Let there be a natural one-to-one correspondence between the sets of edges of two graphs $G_i = (V_i, E_i, \partial_i^+, \partial_i^-)$ ($i = 1, 2$), and suppose that under the correspondence a tree T_1 in G_1 corresponds to a tree T_2 in G_2 and that the fundamental cutset matrices D_1 and D_2 with respect to $(T_i, E_i - T_i)$ are mutually equal. Then G_1 and G_2 are said to be **2-isomorphic**. The definition is equivalent to the one given by the equality of fundamental tieset matrices. 2-isomorphism is an equivalence relation. If G_1 and G_2 are 2-isomorphic, the families of trees, cotrees, tiesets and cutsets are mutually corresponding. The coincidence of one of the families is a sufficient condition for the 2-isomorphism of G_1 and G_2 as undirected graphs. A 3-connected graph has no 2-isomorphic graph other than itself.

Similarly, when a tree T_1 of G_1 corresponds to a cotree \bar{T}_2 of G_2 and if the fundamental cutset matrix of G_1 with respect to $(T_1, E_1 - T_1)$ is equal to the fundamental tieset matrix of G_2 with respect to $(E_2 - T_2, T_2)$ as matrices, then we say that G_2 is **dual** to G_1 . In this case, G_1 is dual to G_2 also. If G_1 is dual to G_2 and G_2 is dual to G_3 , then G_1 and G_3 are 2-isomorphic. The duality is a relation among the equivalence classes of graphs by 2-isomorphisms.

Any graph $G = (V, E, \partial^+, \partial^-)$ can be "drawn" in 3-dimensional Euclidean space in the following sense: Each vertex is a (distinct) point, and an edge e is an arc connecting two points $\partial^+ e$ and $\partial^- e$ with a direction pointing from $\partial^+ e$ to $\partial^- e$ in such a way that no two arcs intersect. A graph representable on a plane or on a 2-dimensional sphere in the above sense is called a **planar graph**. A graph G is planar if and only if it has a dual graph (H. Whitney [7]). Another necessary and sufficient condition is that as an undirected graph, neither the complete five-point graph K_5 nor the bipartite complete graph of three-three points $K_{3,3}$, appear in any subcontraction of the graph G . (This is a version of the criterion of C. Kuratowski [8].)

I. Coloring of Graphs

A **coloring** of the vertices of a graph $G = (V, E, \partial^+, \partial^-)$ is a mapping ψ from V to the set of integers N satisfying the condition $\psi(v) \neq \psi(v')$ for all adjacent vertices v and v' . $\gamma(G) = \min\{|\psi(V)| \mid \psi \text{ is a coloring of the vertices of } G\}$ is called the **chromatic number** of G . If the graph G is drawn over a 2-dimensional closed surface with a 1-dimensional \dagger Betti number b , we have $\gamma(G) \leq \lfloor (7 + \sqrt{1 + 24b})/2 \rfloor$, where $\lfloor \cdot \rfloor$ denotes the integral part. Except for the \dagger Klein bottle (with $b = 2$), where $\gamma(G) \leq 6$, this is the best possible, i.e., there exists a graph whose $\gamma(G)$ equals the upper bound on the right-hand side. As for $b \geq 1$, the inequality was first proved by P. J. Heawood (1890), and final results were established by J. W. T. Young and G. Ringel [10]. When $b = 0$, $\gamma(G) \leq 5$ was shown by A. B. Kempe (1879), but the **four color conjecture**: " $\gamma(G) \leq 4$?" has remained unsolved for more than a hundred years. The conjecture is believed to have been solved affirmatively recently through checking a huge number of cases on a large computer [11, 12].

A subset $W \subset V$ is called an **independent set** or an **internally stable set** if no two vertices in W are mutually adjacent. $\alpha(G) = \max\{|W| \mid W \text{ is an independent set of } G\}$ is called the **number of independence** of G . A subset W of V is called a **dominating set** or **externally stable set** of G if every vertex $v \in V$ is either $v \in W$ or adjacent to a vertex of W . $\beta(G) = \min\{|W| \mid W \text{ being a dominating set of } G\}$ is called the **number of domination** of G . For every graph G , we have $\alpha(G) \geq \beta(G)$ and $\gamma(G) \cdot \alpha(G) \geq |V|$.

J. Decision Problems and Graphs

There are many interesting topics in decision problems concerning graphs, especially from the standpoint of \dagger complexity of computations (\rightarrow e.g., [13]). The following are some typical problems: (i) Problems for which algorithms of polynomial order are known: Is the given graph k -connected, strongly connected, a Euler graph, or a planar graph? (ii) \dagger NP-complete problems: Is the given graph a Hamilton graph? Do we have $\alpha(G) = k$, $\beta(G) = k$, or $\gamma(G) = k$?

Let G_1 and G_2 be two graphs. The problem of whether they coincide as unlabeled graphs is called the **isomorphism problem**, and has been studied for many years in connection with problems concerning the structure of chemical compounds. Unfortunately, no algorithm of polynomial order is known; nor do we know whether this is an NP-complete problem. As for the isomorphism problem for

planar graphs, algorithms of polynomial order are known.

K. Perfectness Theorem

Let the number of independence and the chromatic number of a graph $G = (V, E, \partial^+, \partial^-)$ be $\alpha(G)$ and $\gamma(G)$, respectively. Let V_1, \dots, V_r be a disjoint decomposition of V . We denote by $\theta(G)$ the minimal number of r such that every section graph of G over V_i contains a complete graph. Furthermore, we denote by $\omega(G)$ the maximum value of $|W|$ for a subset $W \subset V$ such that the section graph of G over W contains a complete graph. We always have $\alpha(G) \leq \theta(G)$ and $\gamma(G) \leq \omega(G)$. G is called α -**perfect** if every section graph H of G satisfies $\alpha(H) = \theta(H)$. Similarly, G is called γ -**perfect** if $\gamma(H) = \omega(H)$ for every section graph H of G . The conjecture that γ -perfectness and α -perfectness are equivalent has recently been solved affirmatively [14]. This is called the **perfectness theorem**.

187 (XXI.2) Greek Mathematics

It is generally believed that theoretical mathematics originated with the Greeks. The Greeks learned the arts of land surveying and commercial arithmetic from earlier civilizations; but they developed theoretical mathematics themselves, toward the middle of the 4th century B.C. The creation of a mathematics that transcends practical purposes was one of the most remarkable events in the history of human culture, and one that had an immense impact on the development of all branches of science. We owe the reestablishment of important Greek mathematical texts and the reconstruction of the development of Greek mathematics to the historians of the 19th century (the oldest extensive exposition of the history of mathematics before Euclid is due to Proklos (Proclus) (410–485)).

The earliest known Greek mathematicians are Thales of Miletus (c. 639–546 B.C.) and Pythagoras of Samos (fl. 510? B.C.). Both were Ionians, but the latter went to what is now southern Italy and founded a semireligious school whose members called themselves Pythagoreans. Their motto was “Everything is number”; their studies were called *mathema* (“what is learned”) and consisted of music, astronomy, geometry, and arithmetic (the subject group called the **quadriivium**, which formed the core of medieval and later higher education) “for the purification of soul.” Their research delved into the theories of proportion (in relation to music) and [†]polygonal numbers (triangular numbers, square numbers, etc.), and more generally into the theory of numbers and geometric algebra. It is said that they knew of the irrationality of $\sqrt{2}$, though no evidence of this has been found. Even after the demise of the Pythagorean school, its followers continued to promote mathematics in collaboration with the Academy of Plato.

Another significant school was the Eleatic. Among its members Zeno (c. 490–c. 430 B.C.) is especially important. Zeno's paradoxes are arguments leading to absurdity. Some see within them the origin of logical reasoning and, consequently, of theoretical mathematics [3]. It is chronologically difficult to attribute

to Zeno the consideration of the continuum and irrational numbers, but we can find in him the impetus toward atomistic reasoning. The computation of the volume of pyramids (by dividing them into “atomistic” laminae) by Democritus (fl. 430? B.C.) and the atomistic calculation of the area of circles by Antiphon (fl. 430 B.C.) came shortly after the time of Zeno.

The middle decades of the 4th century B.C. are known as the Age of Pericles, the Golden Age of Athens. The †trisection of an angle, the †duplication of a cube, and the †quadrature of a circle, known at that time as the “**three big problems**” (→ 179 Geometric Construction), were studied by the Sophists. Hippias of Elis (fl. 420 B.C.), Hippocrates of Chios (fl. 430 B.C. in Athens), Archytas of Taras (c. 430–365 B.C.), Menaechmus (fl. 350 B.C.), and his brother Dinostratus (fl. 350 B.C.) solved these problems using conic sections and the **quadratrix** (a transcendental curve whose equation is $y = x \cot(\pi x/2)$).

By 400 B.C. Athens had lost its political influence, but it remained the center of Greek culture. It was during this time that Plato’s Academy flourished, and Plato (427–347 B.C.) and his followers laid particular importance on mathematics. Archytas, Menaechmus, and Dinostratus belonged to or were closely associated with this school. During the first fifty years of the Academy, research in the following fields was pursued: methodology of mathematics or science in general (i.e., dialectics, analysis, synthesis); geometric reconstruction of Mesopotamian algebra; the theory of irrationals in relation to the geometrization of algebra (Theodorus of Cyrene (5th century B.C.), who was Plato’s teacher, as well as Theaitetus of Athens (415?–369 B.C.) contributed to this study, and the general theory of proportion by Eudoxus of Cnidos (c. 408–c. 355 B.C.) also belongs to this field); the method of exhaustion (by Eudoxus); and studies of the “three big problems” and conic sections. It was this school in which the term *mathema* came to be used in its present sense of “mathematics” rather than in the sense of disciplines in general.

The conquests of Alexander the Great accelerated the already considerable cultural influence of Athens. Later, during the Ptolemaic period, the center of culture moved to Alexandria. The Mouseion at Alexandria, the combined library and university, is said to have possessed hundreds of thousands of volumes.

At Alexandria, Euclid (c. 300 B.C.) compiled his *Elements*, which became a model for scientific works for centuries to come—Newton’s *Principia* as well as Spinoza’s *Ethics*

are modeled on it. Most historians say that Euclid’s method derives from Aristotle (384–322 B.C.), who, after studying at Plato’s Academy, founded a new school, the Peripatetics, whose doctrines are at many points opposed to those of the Academy. Others, however, see the origin of Euclid’s axiomatic method in the Eleatics [5]; we can find prototypes of some parts of the *Elements* in both Oenopides, who lived during the time of Zeno, and in Hippocrates.

The third century B.C. was the Golden Age of Greek mathematics. Archimedes of Syracuse (c. 282–212 B.C.) was the greatest mathematician, mechanic, and technician of antiquity. He did important work in mathematics, studying the exact quadrature of the parabola. According to his *epodos* (method), he would obtain a result by mechanical experiments and then prove it by the method of “exhaustion.” He also computed the value of π ; studied spirals and other curves, spheres, and circular cylinders; contributed to the development of statics and optics and their application; and had a profound influence on later mathematicians. During the same period, Apollonius of Perga (fl. 210 B.C.) wrote *Konikon biblia* (Books on Conics) in eight books, of which the last has been lost. The geometric theory of †conic sections contained in this work is not much different from the one we know today; it had a great influence on 17th-century scientists especially. Other mathematicians of this period worth noting are Eratosthenes (c. 275–195 B.C.), who conceived the †sieve method of finding prime numbers and who measured the earth, and Hipparchus (fl. 150 B.C.), called the father of astronomy, who made a table of sines.

Hellenistic influence began to decline in the first century B.C., and the influence of Alexandria decreased. The Mouseion burned in 48 B.C., but was rebuilt. Among the mathematicians of this time, we may count Heron (fl. 60? A.D.); Menelaus (fl. 100 A.D.), who wrote *Sphaerica*; Theon of Smyrna (fl. 125 A.D.); Ptolemy (fl. 150 A.D.), the author of *Almagest*; Nicomachus (50?–150? A.D.), the author of *Arithmetike eisagoge*; Diophantus (fl. 250? A.D.), whose career is not fully known but who wrote *Arithmetika*, of which six of the original thirteen books remained to influence †Fermat; and Pappus (fl. 300 A.D.), the last creative mathematician in Greece, who left eight books of the *Synagoge*, which influenced †Descartes and which still exist today.

The period following the fall of the Western Roman Empire was a difficult one for Greco-Egyptian science. The Mouseion was destroyed for the second time in 392 A.D. Theon of Alexandria (fl. 380) and his daughter, Hy-

patia (c. 370–415), were at that time working on commentaries on the classics. Among the few remaining works of the period is Proclus' (410–485) commentaries on the first book of Euclid's *Elements*. The Athenian Academy was closed in 529 by order of the Emperor Justinian; the last director was Simplicius, who commented on Aristotle. Soon afterward, Alexandria fell into the hands of the Moors, and many scholars fled as refugees to Constantinople, the capital of the Eastern Empire.

188 (XIII.28) Green's Functions

A. General Remarks

Green's functions are usually considered in connection with [†]boundary value problems for ordinary differential equations and also with [†]elliptic and [†]parabolic partial differential equations. For example, consider boundary value problems for the [†]Laplacian in 3-dimensional space: $L[u] = (\partial^2/\partial x_1^2 + \partial^2/\partial x_2^2 + \partial^2/\partial x_3^2)u$. Let D be a bounded domain with a smooth boundary S and the boundary condition B on S be either $u(x) = 0$ ($x \in S$) (the first kind) or $\partial u/\partial n + \beta u = 0$ ($x \in S$) (the third kind), where n is the outer normal of unit length, $\beta(x) \geq 0$, and $\beta(x) \neq 0$. We say that the function $g(x_1, x_2, x_3; \xi_1, \xi_2, \xi_3)$ is the **Green's function** of L (or the partial differential equation $L[u] = 0$) relative to the boundary condition B , when (i) $g(x, \xi)$ satisfies $L_x[g(x, \xi)] = 0$ except for $x = \xi$; (ii) $g(x, \xi) = -1/4\pi r + \omega(x, \xi)$, where $r = (\sum_{i=1}^3 (x_i - \xi_i)^2)^{1/2}$ and $\omega(x, \xi)$ is a regular function, i.e., of class C^v for a suitable value v ; (iii) $g(x, \xi)$ satisfies the boundary condition B , i.e., $g(x, \xi) = 0$, $x \in S$ (the first kind), or $(\partial/\partial n + \beta)g(x, \xi) = 0$, $x \in S$ (the third kind). Conditions (i) and (ii) mean that $g(x, \xi)$ is a [†]fundamental solution of L , i.e., $L_x[g(x, \xi)] = \delta(x - \xi)$, where $\delta(x - \xi)$ is [†]Dirac's measure at the point $x = \xi$. Note that if $g(x, \xi)$ is a fundamental solution, then by adding any solution u of the equation $L[u] = 0$ to g , we obtain another fundamental solution $g + u$. Thus Green's function is the fundamental solution that satisfies the given boundary condition. To be more precise, in the boundary value problem, if the boundary condition is of the first kind, $g(x, \xi)$ can be obtained by adding to a fundamental solution $-1/4\pi r$ the solution $\omega(x, \xi)$ of the following Dirichlet problem: $\Delta_x \omega(x, \xi) = 0$, $\omega(x, \xi) = 1/4\pi r$ ($x \in S$). We remark that there are slightly different definitions for Green's function. For example, there are cases where $g(x, \xi)$ is defined by $g(x, \xi) = 1/4\pi r + \omega(x, \xi)$ or by $g(x, \xi) = 1/r + \omega(x, \xi)$.

In the case in the previous paragraph, Green's functions satisfying the boundary conditions are uniquely determined. In general, if we are given a Green's function, then

for any regular function $v(x)$ the function

$$u(x) = \int_D g(x, \xi) v(\xi) d\xi$$

represents the solution of $L[u] = v$ with the boundary condition B . More precisely, if $v(x)$ satisfies the Hölder condition $|v(x) - v(x')| \leq L|x - x'|^\alpha$ ($0 < \alpha \leq 1$) (L, α positive constants), then $u(x)$ is of class C^2 . Conversely, if $u(x)$ satisfies the equation $L[u] = v$ and the boundary condition B , it is represented by the formula for $u(x)$. This means that if we denote the operator that associates u to v by G , then G is the inverse operator of the Laplacian L with the boundary condition B , and Green's function is the integral kernel of the operator G . Using this property, the boundary value problem relative to L can be reduced to a problem of integral equations. For example, the differential equation with the boundary condition B containing the complex parameter λ , $L[u] + \lambda u = f$, is equivalent to the integral equation $u + \lambda G[u] = G[f]$, which is obtained by letting G act from the left on the above differential equation. In this way, the problem can be simplified.

In the case of general boundary value problems for higher-order elliptic operators, Green's functions are defined in the same way as before (\rightarrow 189 Green's Operator). The important case is when L and the boundary condition B define a self-adjoint operator. In this case, Green's function is symmetric ($g(x, \xi) = g(\xi, x)$). To obtain Green's function is not easy in general. However, in some cases such functions can be obtained fairly easily (\rightarrow Appendix A, Table 15.VI).

B. Self-Adjoint Ordinary Differential Equations of the Second Order

Consider the operator $L[u] \equiv (p(x)u')' + q(x)u$ ($p(x) > 0$) defined in the interval $a \leq x \leq b$, with boundary conditions of the form $\alpha u' + \beta u = 0$ at the two endpoints. Then Green's function $g(x, \xi)$ is defined in the following way: (i) For $x \neq \xi$, $L[g(x, \xi)] = 0$; (ii) $[\partial g(x, \xi)/\partial x]_{x=\xi}^{\pm} = 0 = 1/p(\xi)$; (iii) for ξ fixed, $g(x, \xi)$ satisfies the homogeneous boundary conditions at $x = a$ and $x = b$.

Conditions (i) and (ii) mean that $L[g(x, \xi)] = \delta(x - \xi)$. We can construct $g(x, \xi)$ in the following way: Let $u_1(u_2)$ be the solution of $L[u] = 0$ satisfying the boundary condition at $x = a$ (at $x = b$). If u_1 and u_2 are linearly independent, we can satisfy $p(u_1' u_2 - u_1 u_2') = 1$ by choosing the constants suitably. Then Green's function $g(x, \xi)$ is defined by $g(x, \xi) = u_1(x)u_2(\xi)$ for $x \leq \xi$, and $g(x, \xi) = u_1(\xi)u_2(x)$ for $\xi \leq x$. If u_1 and u_2 are linearly dependent, there exists no

Green's function that satisfies conditions (i), (ii), and (iii). However, by modifying the definition, we can get a generalized Green's function playing a similar role [2]. This method can be applied to the case of ordinary differential equations of higher order.

C. The Laplace Operator

When the domain D is the n -dimensional sphere of radius a with center at the origin, Green's function of the Laplacian relative to the boundary condition $u = 0$ is obtained in the following way. Let $E(r)$ be the following fundamental solution of the Laplacian: $E(r) = (2\pi)^{-1} \log r$ for $n = 2$ and $E(r) = -((n-2) \cdot \omega_n r^{n-2})^{-1}$ for $n \geq 3$, where $\omega_n = 2\pi^{n/2} \Gamma(n/2)$ is the $(n-1)$ -dimensional surface area of the n -dimensional unit sphere. Then Green's function $g(x, \xi)$ is defined by

$$g(x, \xi) = E(r) - E(\rho r'/a),$$

where $\rho = (\sum_{i=1}^n \xi_i^2)^{1/2}$, $r' = (\sum_{i=1}^n (x_i - \xi_i)^2)^{1/2}$, $\xi'_i = (a/\rho)^2 \xi_i$.

D. Helmholtz's Differential Equation

Let D be an exterior domain with a smooth boundary S in \mathbf{R}^3 . In mathematical physics, the boundary value problem of finding a solution $u(x)$ of Helmholtz's differential equation $(\Delta + k^2)u(x) = f(x)$ ($k > 0$) satisfying $u(x) = 0$ ($x \in S$) is of particular interest. In this case, concerning the behavior of $u(x)$ at infinity, we usually assume Sommerfeld's radiation condition:

When $|x| \rightarrow +\infty$, $u(x) = O(|x|^{-1})$,

$$\left(\frac{\partial}{\partial r} u - iku \right) \Big|_{|x|=r} = o(|x|^{-1}),$$

where $\partial/\partial r$ is the derivative along the radial direction. It is known that this condition ensures the uniqueness of the solution (Rellich's uniqueness theorem). We can construct Green's function $G(x, \xi)$ for any $k(>0)$ so that for smooth $f(x)$ with bounded support,

$$u(x) = \int_D G(x, \xi) f(\xi) d\xi$$

represents the solution satisfying $u(x) = 0$ ($x \in S$) and Sommerfeld's radiation condition. Then, with

$$G(x, \xi) = -\frac{e^{ik|x-\xi|}}{4\pi|x-\xi|} + K_c(x, \xi),$$

where

$$|x - \xi| = \left(\sum_{i=1}^3 (x_i - \xi_i)^2 \right)^{1/2},$$

$K_c(x, \xi)$ can be obtained by solving an integral equation of \dagger Fredholm type [3, 4]. In this case, there exists no Green's operator in L_2 space, and $G(x, \xi)$ can be considered to be a generalized Green's function [4].

E. Stokes's Differential Equation

Let D be a bounded domain in \mathbf{R}^3 with smooth boundary S , and consider **Stokes's differential equation** in D

$$\mu \Delta u_i = \frac{\partial p}{\partial x_i} - \rho X_i, \quad i = 1, 2, 3, \quad \sum_{j=1}^3 \frac{\partial u_j}{\partial x_j} = 0,$$

where μ, ρ are positive constants. In hydrodynamics, we consider the boundary value problem of finding solutions $(u_1(x), u_2(x), u_3(x), p(x))$ of Stokes's equation satisfying the boundary condition $u_i(x) = 0, x \in S (i = 1, 2, 3)$. In this case, **Green's tensors** $G_{ij}(x, \xi), g_j(x, \xi)$ can be constructed, and for smooth functions $X_i(x) (i = 1, 2, 3)$ the unique solution of this boundary value problem is represented by

$$u_i(x) = \rho \sum_{j=1}^3 \int_D G_{ij}(x, \xi) X_j(\xi) d\xi,$$

$$p(x) = \rho \sum_{j=1}^3 \int_D g_j(x, \xi) X_j(\xi) d\xi$$

[5].

F. Parabolic Equations

Consider the boundary value problem (the initial boundary value problem):

$$L[u] \equiv \frac{\partial u}{\partial t} - c^2 \frac{\partial^2 u}{\partial x^2} = f(x, t), \quad t > 0, \quad a < x < b,$$

$$u(x, 0) = \varphi(x),$$

where at $x = a$ and $x = b$, $u(x, t)$ satisfies some homogeneous boundary conditions.

In this case, we can construct the function $g(x, t; \xi, \tau) (t \geq \tau)$ satisfying the following conditions: (i) $L[g] = 0$ except for $x = \xi, t = \tau$;

$$g(x, t; \xi, \tau) = \frac{\exp(-(x-\xi)^2/4c^2(t-\tau))}{2c\sqrt{\pi(t-\tau)}} + (\text{regular function})$$

in a neighborhood of $x = \xi, t = \tau$; and (iii) $g(x, t; \xi, \tau)$ satisfies the given homogeneous boundary conditions at $x = a$ and $x = b$. Then

$$u(x, t) = \int_0^t \int_a^b g(x, t; \xi, \tau) f(\xi, \tau) d\xi d\tau + \int_a^b g(x, t; \xi, 0) \varphi(\xi) d\xi$$

represents the solution of the problem stated

in this section for regular functions f, φ . The function $g(x, t; \xi, \tau)$ is called **Green's function** relative to the boundary value problem. Detailed consideration of such elementary cases is found in [6].

G. Kernel Functions

The kernel function is closely related to Green's function of Δ (the Laplacian) relative to the first boundary value problem in a domain in \mathbf{R}^2 .

First we explain the general definitions of the kernel function. Let E be a general set, and let \mathfrak{F} be a \dagger Hilbert space of complex-valued functions defined on E with a suitable inner product (f, g) . Suppose that we are given a function $K(x, y)$ defined on $E \times E$ satisfying the following conditions: (i) For any fixed y , $K(x, y)$ regarded as a function of x belongs to \mathfrak{F} ; and (ii) for any $f(x) \in \mathfrak{F}, (f(x), K(x, y))_x = f(y)$. Then $K(x, y)$ is called a **kernel function** or **reproducing kernel**. The kernel function, if it exists, is unique and is \dagger positive definite Hermitian; that is,

$$\sum_{j,k=1}^n K(y_j, y_k) \xi_j \bar{\xi}_k \geq 0. \quad (1)$$

Conversely, any positive definite function is a reproducing kernel of some Hilbert space. A necessary and sufficient condition for the existence of the kernel function is that for any $y \in E$, the linear functional $f \rightarrow f(y)$ be bounded. In this case, the minimum of $\|f\|$ under the condition $f(y) = 1 (f \in \mathfrak{F})$ is attained by the element $K(x, y)/K(y, y)$, and its value is $K(y, y)^{-1/2}$. When \mathfrak{F} is a \dagger separable space, then by an \dagger orthonormal system $\{\varphi_v(x)\}$, we can represent $K(x, y)$ as

$$K(x, y) = \sum_{v=1}^{\infty} \varphi_v(x) \overline{\varphi_v(y)}. \quad (2)$$

As an example of kernel functions, the following case is of particular importance. Let E be an n -dimensional \dagger complex manifold, φ and ψ be holomorphic \dagger differential forms of degree n on E , and let the following inner product be given:

$$(\varphi, \psi) = \int_E \varphi \wedge \bar{\psi}.$$

Now \mathfrak{F} is given by $\mathfrak{F} = \{\varphi \mid \varphi, \varphi < +\infty\}$, and the kernel function is called the **kernel differential**. When E is a domain in \mathbf{C}^n , regarding the coefficients of the differential form as functions, we call the kernel function **Bergman's kernel function**. Moreover, if E can be mapped onto a bounded domain by a one-to-one holomorphic mapping, then

$$ds^2 = \sum (\partial^2 \log K(z, \bar{z}) / \partial z_j \partial \bar{z}_k) dz_j d\bar{z}_k$$

is positive definite and gives a Kähler metric which is called the **Bergman metric**.

H. Kernel Functions for Domains in the Complex Plane

Let E be a domain D in the complex plane ($z = x + iy$). Let $K(z, \zeta)$ be Bergman's kernel function of D , and let $G(z, \zeta)$ be Green's function of Δ relative to the first boundary condition with a pole at ζ . Then we have

$$K(z, \zeta) = -(2/\pi) \partial^2 G(z, \zeta) / \partial z \partial \bar{\zeta}. \quad (3)$$

Next, let $U(z, \zeta)$ be the kernel function of the Hilbert space consisting of the holomorphic differential forms whose integrals are single-valued, and let $N(z, \zeta)$ be **Neumann's function** of Δ , i.e., the function that is harmonic in $D - \{\zeta\}$, has the same singularity as G at ζ , and whose derivative in the normal direction $\partial N / \partial n$ is constant along the boundary. Then we have

$$U(z, \zeta) = (2/\pi) \partial^2 N(z, \zeta) / \partial z \partial \bar{\zeta}. \quad (4)$$

Now the kernel $H(z, \zeta) = (N(z, \zeta) - G(z, \zeta)) / 2\pi$ is the kernel function relative to the Hilbert space consisting of all real harmonic functions whose integral mean value along the boundary Γ is 0 and having the inner product

$$(\varphi, \psi) = \iint_D \left(\frac{\partial \varphi}{\partial x} \frac{\partial \psi}{\partial x} + \frac{\partial \varphi}{\partial y} \frac{\partial \psi}{\partial y} \right) dx dy.$$

The kernel $H(z, \zeta)$ is called a **harmonic kernel function**.

Suppose that the boundary Γ is piecewise smooth, and consider the space of all holomorphic functions in D that are continuous on the boundary of D . The inner product of such functions φ and ψ is given by $(\varphi, \psi) = \int_{\Gamma} \varphi \bar{\psi} ds$ (ds is the element of the arc length of Γ). Hence we have a Hilbert space. Then the kernel function relative to this Hilbert space is called **Szegő's kernel function**, which has a close relation with bounded functions.

The kernel functions enable us to represent holomorphic mappings that map the domain D onto various canonical domains (\rightarrow 77 Conformal Mappings).

189 (XIII.29) Green's Operator

A. General Remarks

Consider the first and the third boundary value problems for the elliptic equation

$$A[u] \equiv -\Delta u + \sum_{i=1}^n a_i(x) \frac{\partial u}{\partial x_i} + c(x)u = f(x)$$

(\rightarrow 323 Partial Differential Equations of Elliptic Type). Let D be a bounded domain of \mathbf{R}^n whose boundary S consists of a finite number of smooth hypersurfaces. By the method of orthogonal projection, we take the domain $\mathscr{D}(A)$ as follows: (i) $\{u(x) | u(x) \in H^2(D) \text{ and } u(x) = 0 \text{ for } x \in S\}$ or (ii) $\{u(x) | u(x) \in H^2(D) \text{ and } \partial u / \partial n + \beta(x)u = 0 \text{ for } x \in S\}$ according as we are considering the first or third boundary value problem, where $H^2(D)$ is the Sobolev space (\rightarrow 168 Function Spaces). If the operator A is a one-to-one mapping from $\mathscr{D}(A)$ onto the function space $L_2(D)$, we call the inverse operator A^{-1} **Green's operator** relative to the boundary condition, and we denote it by G . In general, the existence of A^{-1} is not guaranteed. However, if we take real t large enough, $G_t = (A + tI)^{-1}$ exists.

Consider the general case where λ is a complex parameter: $(\lambda I - A)[u] = f(x)$, $f(x) \in L_2(D)$. Letting G_t act from the left, we have $(I - (\lambda + t)G_t)[u] = -G_t f$. Conversely, if $u \in L_2(D)$ is a solution, clearly $u(x) \in \mathscr{D}(A)$, and $u(x)$ satisfies the first partial differential equation and the boundary condition. Since G_t is a com-

compact operator in $L_2(D)$, the \dagger Riesz-Schauder theorem can be applied (\rightarrow 68 Compact and Nuclear Operators). In particular, if $\lambda + t$ is not an \dagger eigenvalue of G_t , $u(x) = (\lambda I - A)^{-1} f = -(\lambda I - (\lambda + t)G_t)^{-1} G_t f$ represents a unique solution.

In the equations in the first paragraph of this section, if $a_i(x) = 0$ and $c(x)$ and $\beta(x)$ are real, then G_t is a \dagger self-adjoint operator in $L_2(D)$, and therefore the \dagger Hilbert-Schmidt expansion theorem can be applied. Namely, let $\{\lambda_i\}$ be the eigenvalues of A such that $A\omega_i(x) = \lambda_i\omega_i(x)$, where $\{\omega_i(x)\}$ is an \dagger orthonormal system in $L_2(D)$. Then for any $f(x) \in L_2(D)$, $f(x) = \sum_{i=1}^\infty (f, \omega_i)\omega_i(x)$, where the right-hand side is taken in the sense of \dagger mean convergence. Furthermore, for $f(x) \in \mathcal{D}(A)$, we have the expansion $(Af)(x) = \sum_{i=1}^\infty \lambda_i(f, \omega_i)\omega_i(x)$ in the same sense.

When G_t is not self-adjoint, let G_t^* be the \dagger adjoint operator of G_t in $L_2(D)$. Then G_t^* represents Green's operator relative to the equation

$$\begin{aligned} (A^* + tI)[v] &= -\Delta v - \sum_{i=1}^n \frac{\partial}{\partial x_i} (\overline{a_i(x)}v) \\ &\quad + (\overline{c(x)} + t)v \\ &= g(x), \end{aligned}$$

corresponding to the boundary conditions (i) $v(x) = 0$, $x \in S$ (first boundary condition) and (ii) $(\partial/\partial n)v + \beta'(x)v = 0$, $x \in S$, where

$$\beta'(x) = \overline{\beta(x)} + \sum_{i=1}^n \overline{a_i(x)} \cos nx_i,$$

with n the outer normal (third boundary condition) [2].

B. Elliptic Equations of Higher Order

Green's operator can be defined for elliptic equations of higher order. Consider the equation

$$\begin{aligned} A(x, \partial/\partial x)u(x) &= f(x), \quad x \in D; \\ B_j(x, \partial/\partial x)u(x) &= 0, \quad x \in S, \\ j &= 1, 2, \dots, b \ (b = m/2), \quad (1) \end{aligned}$$

where A is an \dagger elliptic operator of order m and the boundary operators $\{B_j\}$ satisfy: (i) At every point x of S , the normal direction is not \dagger characteristic for any B_j ; and (ii) the order m_j of B_j is less than m , and $m_j \neq m_k$ ($j \neq k$). The domain $\mathcal{D}(A)$ of A is defined by

$$\begin{aligned} \mathcal{D}(A) &= \{u(x) | u \in H^m(D) \text{ and} \\ &\quad B_j(x, \partial/\partial x)u(x) = 0 \text{ for } x \in S, \\ &\quad j = 1, 2, \dots, b\}. \end{aligned}$$

When A is a one-to-one mapping from $\mathcal{D}(A)$ onto $L_2(D)$, the inverse $G = A^{-1}$ is called **Green's operator**.

This general boundary value problem, especially the existence theorem, was treated under some algebraic conditions on A and $\{B_j\}$ by M. Schechter [5] who showed that $G[u] \in H^m(D)$ if $u(x) \in L_2(D)$ and that $G[u]$ depends continuously on u . In particular, if $m > n/2$, then by \dagger Sobolev's theorem, G is a continuous mapping from $L_2(D)$ into $C^0(\overline{D})$, and G is represented by an \dagger integral operator of Hilbert-Schmidt type (L. Gårding [6]). Namely, for any $f(x) \in L_2(D)$,

$$\begin{aligned} (Gf)(x) &= \int_D G(x, \xi) f(\xi) d\xi, \\ \iint |G(x, \xi)|^2 dx d\xi &< +\infty. \end{aligned}$$

In general, the function $G(x, \xi)$, obtained by the **kernel representation** of Green's operator G , is called **Green's function**.

On the other hand, consider, for example, the \dagger Dirichlet problem of Δ in \mathbb{R}^3 . Then Green's function is defined in the following way (\rightarrow 188 Green's Functions): $G(x, \xi) = -(4\pi|x - \xi|)^{-1} + u(x, \xi)$, where $u(x, \xi)$ satisfies (i) $\Delta_x u(x, \xi) = 0$, and (ii) $G(x, \xi)|_{x \in S} = 0$. The function defined in this manner coincides with Green's function defined as a kernel representation of Green's operator [1, 2].

Suppose that in problem (1) the \dagger elliptic operator $A(x, \partial/\partial x)$ is independent of x , and let $E(x)$ be a \dagger fundamental solution, i.e., $E(x)$ is a distribution solution of $A(\partial/\partial x)E(x) = \delta(x)$ ($\delta(x)$ is \dagger Dirac's δ -function; \rightarrow 112 Differential Operators). Then $E(x)$ is a C^∞ -function away from the origin. Moreover, in a neighborhood of the origin the following estimates hold: For $|\alpha| < m$,

$$\left| \left(\frac{\partial}{\partial x} \right)^\alpha E(x) \right| \leq \begin{cases} c|x|^{m-n-|\alpha|}, & m-n-|\alpha| < 0, \\ c \log|x|^{-1}, & m-n-|\alpha| = 0, \\ c, & m-n-|\alpha| > 0, \end{cases}$$

where c is some positive constant. When problem (1) has Green's operator G , we can say the following, using the fundamental solution: Green's function $G(x, \xi)$ exists and can be written as $G(x, \xi) = E(x - \xi) + u(x, \xi)$, where for any fixed $\xi \in D$, $u(x, \xi)$ satisfies (i) $A(\partial/\partial x)u(x, \xi) = 0$ and (ii) $B_j(x, \partial/\partial x)G(x, \xi) = 0$, $x \in S$, $j = 1, 2, \dots, b$.

C. Hypoelliptic Operators

Let

$$\begin{aligned} A(x, \partial/\partial x) &= \sum_{|\alpha| \leq m} a_\alpha(x) \left(\frac{\partial}{\partial x} \right)^\alpha, \\ \left(\frac{\partial}{\partial x} \right)^\alpha &= \frac{\partial^{|\alpha|}}{\partial x_1^{\alpha_1} \dots \partial x_n^{\alpha_n}}, \end{aligned}$$

be a general partial differential operator with C^∞ -coefficients. If the kernel $E(x, \xi)$ satisfies $A(x, \partial/\partial x)E(x, \xi) = \delta(x - \xi)$, that is, if we have the relation $\langle E(x, \xi), {}^1A(x, \partial/\partial x)\varphi(x) \rangle_x = \varphi(\xi)$ for any $\varphi(x) \in \mathcal{D}$, then $E(x, \xi)$ is called a **fundamental solution** of A , where 1A is the **transposed operator** of A :

$${}^1A(x, \partial/\partial x)v(x) = \sum_{|\alpha| \leq m} (-1)^{|\alpha|} \left(\frac{\partial}{\partial x} \right)^\alpha (a_\alpha(x)v(x)).$$

Now if there exists a fundamental solution $E'(x, \xi)$ of ${}^1A(x, \partial/\partial x)$ such that (i) $E'(x, \xi)$ defines a kernel that gives rise to two continuous mappings, one of which maps the space \mathcal{D}_ξ into \mathcal{E}_x , and the other of which maps the space \mathcal{D}_x into \mathcal{E}_ξ (\rightarrow 168 Function Spaces), and (ii) for $x \neq \xi$, $E'(x, \xi)$ a C^∞ -function of (x, ξ) , then any distribution $u(x)$ satisfying $A(x, \partial/\partial x)u(x) = g(x)$ is a C^∞ -function, where $g(x)$ is of class C^∞ . In general, an operator A with the property that any solution $u(x)$ of $A(x, \partial/\partial x)u(x) = g(x)$ is of class C^∞ whenever $g(x)$ is of class C^∞ , is called **hypoelliptic**. Elliptic and parabolic operators are both hypoelliptic. L. Hörmander characterized the hypoelliptic differential operators with constant coefficients [8] (\rightarrow 112 Differential Operators).

A kernel $E(x, \xi)$ such that

$$A(x, \partial/\partial x)E(x, \xi) = \delta(x - \xi) + \varpi(x, \xi),$$

with $\varpi(x, \xi)$ a C^∞ -function, is called a **parametrix** of A . To prove the hypoellipticity of A , it suffices to show the existence of a parametrix $E'(x, \xi)$ of the operator 1A having the properties (i) and (ii) mentioned in the previous paragraph.

To explain the notion of the fundamental solution for the evolution equations, suppose that we are given an evolution equation

$$L[u] = \frac{\partial^m}{\partial t^m} u(x, t) + \sum_{j < m} a_{x,j}(x, t) \left(\frac{\partial}{\partial x} \right)^j \frac{\partial^j}{\partial t^j} u(x, t) = 0,$$

$x \in \mathbf{R}^n$, $t_0 \leq t \leq T$. A kernel $E(x, t; \xi, t_0)$ ($t_0 \leq t \leq T$) is called a **fundamental solution** to the evolution equation if

$$L_{x,t}(E(x, t; \xi, t_0)) = 0, \quad t > t_0,$$

and

$$\lim_{t \rightarrow t_0 + 0} \frac{\partial^i}{\partial t^i} E(x, t; \xi, t_0) = \begin{cases} 0, & 0 \leq j \leq m-2, \\ \delta(x - \xi), & j = m-1. \end{cases}$$

190 (IV.1) Groups

A. Definition

Let G be a nonempty set. Suppose that for any elements a, b of G there exists a uniquely determined element c of G , which is called the **product** of a and b , written $c = ab$. We call G a **group** or **multiplicative group** if (i) the **associative law** $a(bc) = (ab)c$ holds, and (ii) for any elements $a, b \in G$ there exist uniquely determined elements $x, y \in G$ satisfying $ax = b$, $ya = b$. Then the mapping $(a, b) \rightarrow ab$ is called **multiplication** in G . Condition (ii) is equivalent to the following two conditions: (iii) There exists an element e (called the **identity element** or **unit element** of G) such that $ae = ea = a$ for any element a of G ; and (iv) for any element a of G there exists an element x such that $ax = xa = e$.

The element x in condition (iv) is called the **inverse** (or **inverse element**) of a , denoted by a^{-1} . The uniqueness of the identity element e and the inverse a^{-1} follows readily from the axioms. The identity element of a multiplicative group is sometimes denoted by 1. If $ab = ba$, then we say that a and b **commute**. The **commutative law**, $ab = ba$ for any elements $a, b \in G$, is not assumed in general. A group satisfying the commutative law is called an **Abelian group** (or **commutative group**) in honor of N. H. Abel, who made use of commutative groups in his study of the theory of equations. The product in a commutative group is often written in the form $a + b$, and in this case the mapping $(a, b) \rightarrow a + b$ is called **addition**. The element $a + b$ is called the **sum** of a and b , and G is called an **additive group**. In an additive

group the identity element is usually denoted by 0 and called the **zero element**, and the inverse of a is denoted by $-a$ (\rightarrow 2 Abelian Groups; 277 Modules). To describe the †law of composition, we sometimes use notation different from multiplication or addition (\rightarrow 409 Structures).

B. Examples

A †linear space over a †field K is an additive group with respect to the usual addition of vectors (\rightarrow 256 Linear Spaces). A field is an additive group with respect to the addition, and the set of nonzero elements of a field forms a group with respect to the multiplication, which is called the **multiplicative group of the field** (\rightarrow 149 Fields).

All †invertible $n \times n$ matrices over a ring R form a group with respect to the usual multiplication of matrices. This group is called the †general linear group of degree n over R (\rightarrow 60 Classical Groups).

All one-to-one mappings from a set M onto itself (i.e., all **permutations** on M) form a group with respect to the composition defined by $(f \circ g)(x) = f(g(x))$ ($x \in M$). (Sometimes the product $f \circ g$ is denoted by gf and $f(x)$ by xf . Then $x(gf) = (xg)f$.) The group of all permutations on M is called the **symmetric group** on M . A group G is called a **permutation group** (on M) if every element of G is a permutation on M . For instance, the general linear group of degree n over a field K may be regarded as a permutation group on the set of n -dimensional vectors, and it is also regarded as a permutation group on a †tensor space.

All †motions in a Euclidean space form a group with respect to the usual composition of motions. All invertible $n \times n$ matrices over K leaving a given †quadratic form invariant form a group with respect to the usual multiplication of matrices. This group is called the †orthogonal group belonging to the given quadratic form. If K is the †complex number field or the real number field, then these groups are Lie groups (\rightarrow 13 Algebraic Groups; 151 Finite Groups; 161 Free Groups; 249 Lie Groups; 423 Topological Groups).

C. Fundamental Concepts

If a group G consists of a finite number of elements, then G is called a **finite group**; otherwise, G is called an **infinite group**. The number of elements of G is called the **order** of G . A nonempty subset H of G is called a **subgroup** of G if H is a group with respect to the multiplication of the group G . Hence a nonempty sub-

set H is a subgroup of G if and only if $a^{-1}b \in H$ for any $a, b \in H$. For a family $\{H_\lambda\}$ of subgroups of G , the intersection $\bigcap_\lambda H_\lambda$ is also a subgroup.

The associative law of multiplication says that elements a_1, a_2, a_3 of G determine the product $a_1 a_2 a_3$, which is the common value of $(a_1 a_2) a_3$ and $a_1 (a_2 a_3)$. This law can be generalized to say that any ordered set of n elements a_1, a_2, \dots, a_n ($n > 2$) of G determines their product $a_1 a_2 \dots a_n$ (**general associative law**).

When $a_1 = a_2 = \dots = a_n = a$, we denote the product $aa \dots a$ by a^n . If we define a^{-n} for $n \geq 0$ by $a^0 = e$ and $a^{-n} = (a^n)^{-1}$, we then have $a^n a^m = a^{n+m}$, $(a^n)^m = a^{nm}$ for any $n, m \in \mathbb{Z}$. If there exists a positive integer n such that $a^n = e$, then the smallest positive integer d with $a^d = e$ is called the **order** of the element a . If there is no such n , then a is called an element of **infinite order**. If a is of infinite order, then its powers $a^0 (= e), a^{\pm 1}, a^{\pm 2}, \dots$, are all unequal. If a is of order d , then the different powers of a are $a^0 (= e), a, a^2, \dots, a^{d-1}$. All the powers of a form a subgroup $\langle a \rangle$ of G , called a **cyclic subgroup**. The order of an element a is the same as the order of the subgroup $\langle a \rangle$. The group $\langle a \rangle$ itself is called a **cyclic group** and is an example of an Abelian group (\rightarrow 2 Abelian Groups).

Let S be a subset of a group G . Then the intersection of all subgroups of G containing S is called the subgroup **generated** by S and is denoted by $\langle S \rangle$. It is the smallest subgroup containing S , and if S is nonempty, $\langle S \rangle$ consists of all the elements of the form $a_1^{m_1} a_2^{m_2} \dots a_r^{m_r}$ ($a_i \in S, m_i \in \mathbb{Z}$). If $\langle S \rangle = G$, the elements of S are called **generators** of G . When G has a finite set of generators, G is said to be **finitely generated**. When $S = \{a\}$, then $\langle S \rangle$ coincides with $\langle a \rangle$, and the element a is the generator of the cyclic group $\langle a \rangle$. Suppose that elements a_1, \dots, a_n of G satisfy an equation of the form $a_1^{m_1} a_2^{m_2} \dots a_n^{m_n} = 1$. This equation is then called a **relation** among the elements a_1, \dots, a_n . If we have a system of generators and all relations among the generators, then they define a group (\rightarrow 161 Free Groups). It is, however, still an open problem to find a general procedure to decide whether the group determined by a given system of generators and the relations among them contains elements other than the identity (\rightarrow 161 Free Groups B).

For a subset S and an element x of a group G , the set of all elements $x^{-1}sx$ ($s \in S$) is denoted by $x^{-1}Sx$ or S^x , and S and S^x are called **conjugate**. We have $(ab)^x = a^x b^x$, $(a^{-1})^x = (a^x)^{-1}$. If H is a subgroup, then H^x is also a subgroup. For a subset S , the set of all elements x satisfying $S^x = S$ forms a subgroup $N(S)$, called the **normalizer** of S . The set of all elements that commute with every element of

S forms a subgroup $Z(S)$, called the **centralizer** of S . The centralizer Z of G is called the **center** of G . The set of all elements conjugate to a given element a of G is called a **conjugacy class**. A group G is the disjoint union of its conjugacy classes.

Let H be a subgroup of a group G and x an element of G . The set of elements of the form hx ($h \in H$) is denoted by Hx and is called a **right coset** of H . A **left coset** xH is defined similarly. G is the disjoint union of left (right) cosets of H . The cardinality of the set of left cosets of H equals that of the set of right cosets of H ; it is called the **index** of the subgroup H and is denoted by $(G:H)$. Given two subgroups H and K of G , the set $HxK = \{h x k \mid h \in H, k \in K\}$ is called the **double coset** of H and K , and G is the disjoint union of different double cosets of H and K . If the left cosets of a subgroup H are also the right cosets, i.e., if $Hx = xH$ for every $x \in G$, then H is called a **normal subgroup** (or **invariant subgroup**) of G . An equivalent condition is that $H = H^x$ for all $x \in G$. The center of G is always a normal subgroup of G . If H is a normal subgroup of G , the set of all products of an element of Ha and an element of Hb coincides with Hab . Thus if we define the product of two cosets Ha and Hb to be Hab , then the set of cosets of H forms a group. This group is denoted by G/H and is called the **factor group** (or **quotient group**) of G modulo H . (When G is an additive group, G/H is also denoted by $G - H$ and is called the **difference group**.) The group G itself and $\{e\}$ are normal subgroups of G . If G has no normal subgroup other than these two, then G is called a **simple group**. A subgroup of finite index contains a normal subgroup of finite index. If H is a subgroup of finite index, then we can find a common complete system of representatives of the left cosets and the right cosets of H . If G is finitely generated, then so is any subgroup of G of finite index.

Let R be an \dagger equivalence relation defined in a group G . If xRx' and yRy' always imply $(xy)R(x'y')$, then we say that R is **compatible** with the multiplication. The \dagger quotient set G/R is a group with respect to the induced multiplication. This group is called the **quotient group** of G with respect to R . The equivalence class H containing e is a normal subgroup, and xRx' if and only if $x^{-1}x' \in H$, i.e., x and x' are contained in the same coset of H . Thus G/R coincides with G/H .

If G is a finite group of order n , then the order and the index of any subgroup of G , the order of any element of G , the cardinal number of any conjugacy class of G , and the number of different conjugate subgroups of any subgroup of G are all divisors of n .

D. Isomorphisms and Homomorphisms

If there is a one-to-one mapping $a \leftrightarrow a'$ of the elements of a group G onto those of a group G' and if $a \leftrightarrow a'$ and $b \leftrightarrow b'$ imply $ab \leftrightarrow ab'$, then we say that G and G' are **isomorphic** and write $G \cong G'$. If we put $a' = f(a)$, then $f: G \rightarrow G'$ is a \dagger bijection satisfying $f(ab) = f(a)f(b)$ ($a, b \in G$). More generally, if a mapping $f: G \rightarrow G'$ satisfies $f(ab) = f(a)f(b)$ for all $a, b \in G$, then f is called a **homomorphism** of G to G' . An \dagger injective (\dagger surjective) homomorphism is also called a \dagger monomorphism (\dagger epimorphism). If there is a surjective homomorphism $G \rightarrow G'$, then we say that G' is **homomorphic** to G . The composite of two homomorphisms is also a homomorphism. If a homomorphism $f: G \rightarrow G'$ is a bijection, then f is called an **isomorphism**. In this case f^{-1} is also an isomorphism, and we have $G \cong G'$.

For a subgroup H of a group G , the injective homomorphism $f: H \rightarrow G$ defined by $f(a) = a$ ($a \in H$) is called the **canonical injection** (or **natural injection**). For a factor group G/R of G , the surjective homomorphism $f: G \rightarrow G/R$ such that $a \in f(a)$ ($a \in G$) is called the **canonical surjection** (or **natural surjection**).

Let $f: G \rightarrow G'$ be a homomorphism. Then the **image** $f(G)$ of f is a subgroup of G' , and the **kernel** $H = \{a \in G \mid f(a) = e' \text{ (the identity of } G')\}$ of f is a normal subgroup of G . The equivalence classes of the equivalence relation given by $f(x) = f(y)$ are just the cosets of H , and f induces an isomorphism $\bar{f}: G/H \rightarrow f(G)$. The latter proposition is called the **homomorphism theorem** of groups. This theorem is extended in the following way: For simplicity let $f: G \rightarrow G'$ be a surjective homomorphism. (i) If H' is a normal subgroup of G' , then the inverse image $H = f^{-1}(H')$ is a normal subgroup of G , and f induces the isomorphism $\bar{f}: G/H \rightarrow G'/H'$. (ii) if H is a subgroup and N is a normal subgroup of G , then $HN = \{hn \mid h \in H, n \in N\}$ is a subgroup of G , and the canonical injection $H \rightarrow HN$ induces an isomorphism $H/H \cap N \rightarrow HN/N$. (iii) If H and N are two normal subgroups of G such that $H \supset N$, then the canonical surjection $G \rightarrow G/N$ induces an isomorphism $G/H \rightarrow (G/N)/(H/N)$. Propositions (i), (ii), and (iii) are called the **isomorphism theorems** of groups.

A homomorphism of G to itself is called an **endomorphism** of G , and an isomorphism of G to itself is called an **automorphism** of G . The set of automorphisms of G forms a group with respect to the composition of mappings, called the **group of automorphisms** of G . Given an element a of G , the mapping $x \rightarrow a^{-1}xa$ ($x \in G$) yields an automorphism of G which is called an **inner automorphism** of G . The set of inner automorphisms of G forms a normal subgroup of the group of automorphisms of G , called the

group of inner automorphisms of G , which is isomorphic to the factor group of G modulo its center. The factor group of the group of automorphisms of G modulo the group of inner automorphisms of G is called the **group of outer automorphisms** of G .

If a mapping $f: G \rightarrow G'$ from a group G to another group G' satisfies $f(ab) = f(b)f(a)$ ($a, b \in G$), then f is called an **antihomomorphism**. A bijective antihomomorphism is called an **anti-isomorphism**. When $G = G'$, f is called an **anti-endomorphism** or **anti-automorphism** (e.g., $f: G \rightarrow G$ defined by $f(a) = a^{-1}$ is an anti-isomorphism).

E. Groups with Operator Domain

Let Ω be a set and G a group. Suppose that for each $\theta \in \Omega$ and $x \in G$, the product $\theta x \in G$ is defined and satisfies $\theta(xy) = \theta(x)(\theta y)$. Then Ω is called an **operator domain** of G , and G is called a group with operator domain Ω , or simply an **Ω -group**. (We sometimes write x^θ instead of θx .) The mapping $(\theta, x) \rightarrow \theta x$ from $\Omega \times G$ to G is called the \circ operation of Ω on G . If G is an Ω -group, then any element θ of Ω induces an endomorphism $\theta_G: x \rightarrow \theta x$ of G . Conversely, if we are given a mapping $\theta \rightarrow \theta_G$ of Ω to the set of endomorphisms of G , then we may regard G as an Ω -group. Any group may be regarded as an Ω -group with Ω equal to the empty set or to the set consisting of the identity automorphism of G . Thus the general theory of groups can be extended to the theory of groups with operator domain, and in some cases effective use of suitable operator domains can be fruitful in the investigation of the properties of groups themselves. (\rightarrow 2 Abelian Groups; 277 Modules).

A subgroup H of an Ω -group G is called an **Ω -subgroup** (or **admissible subgroup**) if $\theta x \in H$ for any $\theta \in \Omega$ and $x \in H$. In this case, H is also an Ω -group. If an equivalence relation R defined in G is compatible with the multiplication and also compatible with the operators, namely, if xRx' implies $(\theta x)R(\theta x')$ for any $\theta \in \Omega$, then the quotient group G/R is also an Ω -group. The equivalence class containing e is an **admissible normal subgroup**. Conversely, if H is an admissible normal subgroup, then the equivalence relation defined by H is compatible with the operators, and the factor group G/H is an Ω -group. A homomorphism $f: G \rightarrow G'$ of an Ω -group G to an Ω -group G' is called an **Ω -homomorphism** (**admissible homomorphism** or **operator homomorphism**) if $f(\theta x) = \theta f(x)$ for any $\theta \in \Omega$ and $x \in G$. If f is an isomorphism, then f is called an **Ω -isomorphism** (**admissible isomorphism** or **operator isomor-**

phism). We have the homomorphism theorem and the isomorphism theorems of Ω -groups if we consider only admissible subgroups and admissible homomorphisms.

F. Sequences of Subgroups

Let H_1, H_2, \dots be an infinite sequence of (normal) subgroups of a group G . If $H_i \subseteq H_{i+1}$ ($i = 1, 2, \dots$), then the sequence is called an **ascending chain** of (normal) subgroups. If $H_i \not\subseteq H_{i+1}$ ($i = 1, 2, \dots$), then it is called a **descending chain** of (normal) subgroups. If there is no ascending (or descending) chain of (normal) subgroups of G , we say that G satisfies the **ascending (or descending) chain condition** for (normal) subgroups. These conditions are the same as the ascending (or descending) chain condition in the ordered set of all (normal) subgroups of G (\rightarrow 311 Ordering C). A group G satisfies the ascending chain condition for subgroups if and only if every subgroup of G is finitely generated. Also, for groups with operator domain we have similar results. The structure of Abelian groups satisfying the ascending (descending) chain condition is completely determined (\rightarrow 2 Abelian Groups). It is not known whether there is an infinite group satisfying both the ascending and descending chain conditions for subgroups. A group satisfying the descending chain condition for subgroups has no element of infinite order, but the converse is not true. There is an infinite group which is finitely generated and has no element of infinite order (\rightarrow 161 Free Groups C).

G. Normal Chains

A finite sequence $G = G_0 \supset G_1 \supset G_2 \supset \dots \supset G_r = \{e\}$ of subgroups of a group G is called a **normal chain** if G_i is a normal subgroup of G_{i-1} for $i = 1, 2, \dots, r$. We call r the **length** of the chain. The sequence $G_0/G_1, G_1/G_2, \dots, G_{r-1}/G_r$ is called the **sequence of factor groups** of the normal chain. A normal chain $G = H_0 \supset H_1 \supset H_2 \supset \dots \supset H_s = \{e\}$ is called a **refinement** of the chain $G = G_0 \supset G_1 \supset \dots \supset G_r = \{e\}$ if every G_i appears in this chain. Two normal chains with the same length are called isomorphic if there is a one-to-one correspondence between their sequences of factor groups such that corresponding factor groups are isomorphic. Any two normal chains have refinements which are isomorphic to each other (Schreier's refinement theorem). A normal chain is called a **composition series** (or **Jordan-Hölder sequence**) if it consists of different subgroups of G and in

any proper refinement there appear two successive subgroups which are the same. The sequence of factor groups of a composition series is called a **composition factor series**, and the factor groups appearing in this series are called **composition factors**. Any composition factor is a simple group. As a direct consequence of the refinement theorem we see that if a group G has a composition series, then the composition factor series is unique up to isomorphism and the ordering of the factors. (This theorem is due to O. Hölder. C. Jordan proved that if G is a finite group, then the set of orders of composition factors is independent of the choice of composition series. Hence we call the theorem the **Jordan-Hölder theorem**.)

For an Ω -group G , if we consider only Ω -subgroups, we have definitions and theorems similar to those in this section. When we take the group of inner automorphisms of G as Ω , then a composition series of the Ω -group G is called a **principal series**. If we take the group of automorphisms of G as Ω , then a composition series is called a **characteristic series**. An infinite group G does not always have a composition series. Even if G has a composition series, G may have an infinite normal chain $G_1 \subset G_2 \subset \dots \subset G$ such that each G_i is a normal subgroup of G_{i+1} and $\bigcup G_i = G$. In fact, there is a simple group which has such an infinite normal chain (P. Hall). Two groups which have isomorphic composition series are not necessarily isomorphic. A subgroup of a group G is called a **subnormal subgroup** of G if it may appear in some normal chain. The intersection of two subnormal subgroups is also subnormal, but their **join** (i.e., the subgroup generated by both of them) is not necessarily subnormal in an infinite group. The set of subgroups and the set of normal subgroups of a group form \dagger lattices with respect to the inclusion relation (for the relationship between these lattices and the group structure \rightarrow [8]).

H. Commutator Subgroups

Given two elements a and b of a group G , we call $a^{-1}b^{-1}ab = [a, b]$ the **commutator** of a and b . The subgroup C generated by all commutators in G is called the **commutator subgroup** (or **derived group**) of G . The subgroup C is a normal subgroup of G , and the factor group G/C is Abelian. On the other hand, if B is a normal subgroup of G and G/B is Abelian, then B contains C . For two subsets A, B of G , the subgroup generated by the commutators $[a, b]$ ($a \in A, b \in B$) is called the **commutator group of A and B** and is denoted by $[A, B]$. If A and B are normal subgroups of G , then $C' = [A, B]$ is

also a normal subgroup of G , and A/C' commutes with B/C' elementwise in the factor group G/C' . Furthermore, $[A, B]$ is the minimal normal subgroup with the property. The subgroup $[G, G]$ is the commutator subgroup of G .

If the commutator subgroup of G is Abelian, then G is called a **meta-Abelian group**. If a group G has a normal chain $G (= G_0) \supset G_1 \supset G_2 (= \{e\})$ of length 2 and the factor groups $G/G_1, G_1/G_2$ are Abelian, then G is meta-Abelian. Meta-Abelian groups are special cases of solvable groups, discussed in Section I.

I. Solvable Groups

Suppose that we are given a series of subgroups G_i ($i = 0, 1, 2, \dots$) of G such that $G = G_0$ and $[G_i, G_i] = G_{i+1}$. Then we have a normal chain $G = G_0 \supset G_1 \supset G_2 \supset \dots$. If $G_r = \{e\}$ for some r , then G is called a **solvable group**. For the normal chain $G (= G_0) \supset G_1 \supset \dots \supset G_r (= \{e\})$ the factor groups G_i/G_{i+1} ($i = 0, 1, \dots, r-1$) are all Abelian. A finite group G is solvable if and only if G has a composition series $G = H_0 \supset H_1 \supset H_2 \supset \dots \supset H_s = \{e\}$ such that the factor groups H_i/H_{i+1} ($i = 0, 1, \dots, s-1$) are all of prime order. An \dagger irreducible algebraic equation over a field of \dagger characteristic 0 is solvable by radicals if and only if its Galois group is solvable (\rightarrow 172 Galois Theory).

J. Nilpotent Groups

The sequence of subgroups $G = G_0 \supset G_1 \supset G_2 \supset \dots$ defined inductively by setting $G_r = [G, G_{r-1}]$ ($r = 1, 2, \dots$) is called the **lower central series** of G . If $G_n = \{e\}$ for some n , then G is called a **nilpotent group**, and the least number n with $G_n = \{e\}$ is called the **class** of the nilpotent group G . A nilpotent group is solvable. Let Z_1 be the center of G , Z_2/Z_1 be the center of G/Z_1 , and so on. Then we have a sequence of subgroups $Z_0 = \{e\} \subset Z_1 \subset Z_2 \subset \dots$, called the **upper central series** of G . A group G is nilpotent if and only if $Z_m = G$ for some m , and the least number m with $Z_m = G$ is the class of G . For the subgroups G_r and Z_r ($r = 1, 2, \dots$), we have $[G_{i-1}, Z_i] = \{e\}$. If G is a \dagger Lie group, then G is nilpotent if and only if the corresponding \dagger Lie algebra \mathfrak{g} is nilpotent, i.e., $\mathfrak{g}^n = 0$.

K. Infinite Solvable Groups

The concepts of solvability and nilpotency are generalized in several ways for infinite groups. For instance, a group G is called a **generalized solvable group** if any homomorphic image of G

which is unequal to $\{e\}$ contains an Abelian normal subgroup unequal to $\{e\}$, and G is called a **generalized nilpotent group** if any homomorphic image ($\neq \{e\}$) of G has center unequal to $\{e\}$. These definitions coincide with the previous ones for finite groups but not for infinite groups [7].

L. Direct Products

Let G_1, \dots, G_n be a finite number of groups. The set G of all elements (x_1, \dots, x_n) with $x_i \in G_i$ ($i = 1, \dots, n$) is a group if we define the product of two elements $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$ to be $xy = (x_1 y_1, \dots, x_n y_n)$. We call G the **direct product** of groups G_1, \dots, G_n and write $G = G_1 \times \dots \times G_n$. If e_j is the identity element of G_j , then $e = (e_1, \dots, e_n)$ is the identity element of G . The mapping $(x_1, \dots, x_n) \rightarrow x_i$ from G to G_i is a surjective homomorphism, called the **canonical surjection**. The subgroup $H_i = \{(e_1, \dots, e_{i-1}, x_i, e_{i+1}, \dots, e_n) \mid x_i \in G_i\}$ is isomorphic to G_i . The subgroups H_i ($i = 1, \dots, n$) satisfy the following conditions: (i) H_i is a normal subgroup of G . (ii) H_i commutes with H_j elementwise if $i \neq j$. (iii) Any element of G can be written uniquely as the product of elements of H_1, \dots, H_n . Conversely, if a group G has subgroups H_1, \dots, H_n satisfying these three conditions, then G is isomorphic to $H_1 \times \dots \times H_n$. In this case we also write $G = H_1 \times \dots \times H_n$, and we call this a **direct decomposition** of G . Each H_i is called a **direct factor** of G . Conditions (i), (ii), and (iii) are equivalent to condition (i), (ii') $G = H_1 H_2 \dots H_n$, and $H_1 \dots H_{i-1} \cap H_i = \{e\}$ ($i = 2, \dots, n$).

A group G is called **indecomposable** if G cannot be decomposed into the direct product of two subgroups unequal to $\{e\}$, and **completely reducible** if G is the direct product of simple groups. If G satisfies the ascending or descending chain condition for normal subgroups, then G can be decomposed into the direct product of indecomposable groups. Such a decomposition is not unique in general, but if G has two direct product decompositions $G = G_1 \times \dots \times G_m = H_1 \times \dots \times H_n$, where G_i and H_j are indecomposable and not equal to $\{e\}$, then $m = n$ and the factors G_i are isomorphic to the factors H_j for some j ; moreover, if G_1 corresponds, say, with H_1 , then we have $G = H_1 \times G_2 \times \dots \times G_m$. This fact was first stated by J. H. M. Wedderburn, and a complete proof of the theorem was given by R. Remak and O. Schmidt. Later W. Krull extended it to more general groups (with operator domain), and we call it the **Krull-Remak-Schmidt theorem**. O. Ore formulated it as a theorem on π -modular lattices.

For an infinite number of groups G_λ ($\lambda \in \Lambda$)

we define the direct product $\prod_{\lambda \in \Lambda} G_\lambda$ of these groups similarly. The set of all elements $(\dots, x_\lambda, \dots)$ ($x_\lambda \in G_\lambda$) such that almost all x_λ (i.e., all except a finite number of λ) are identity elements is a subgroup of the direct product, called the **direct sum** (or **restricted direct product**) of $\{G_\lambda\}$.

M. Free Products

Given a family of groups $\{G_\lambda\}_{\lambda \in \Lambda}$, we define the most general group G generated by these groups, called the **free product** of $\{G_\lambda\}$, together with canonical injections $f_\lambda: G_\lambda \rightarrow G$.

Let S be the disjoint union of the sets $\{G_\lambda\}_{\lambda \in \Lambda}$, and regard G_λ as a subset of S . A **word** is either void or a finite sequence a_1, a_2, \dots, a_n of elements of S , and we denote the set of all words by W . The product of two words w and w' is defined by connecting w with w' so that the π -associative law holds. We write $w \succsim w'$ when two words w and w' satisfy one of the following two conditions: (i) The word w has successive members a, b which belong to the same group G_λ , and the word w' is obtained from w by replacing a, b by the product ab . (ii) Some member of w is an identity element, and w' is the word obtained from w by deleting this member. For two words w and w' , we write $w \equiv w'$ if there is a finite sequence of words $w = w_0, w_1, \dots, w_n = w'$ such that for each i ($1 \leq i \leq n$), either $w_{i-1} \succsim w_i$ or $w_i \succsim w_{i-1}$. This relation is an equivalence relation and is compatible with the multiplication. Thus we may define a multiplication for the quotient set G of W by this equivalence relation, and then G is a group whose identity element is the equivalence class containing the void word. Any $x \in G_\lambda$ is regarded as a word, and we have an injective homomorphism $f_\lambda: G_\lambda \rightarrow G$ by assigning the corresponding class to each element of G_λ . The group G is called the **free product** of the system of groups $\{G_\lambda\}_{\lambda \in \Lambda}$, and f_λ is called the **canonical injection**. The free product G of $\{G_\lambda\}_{\lambda \in \Lambda}$ is characterized by the following universal property: Given a group G' and homomorphisms $f'_\lambda: G_\lambda \rightarrow G'$ ($\lambda \in \Lambda$), we can find a unique homomorphism $g: G \rightarrow G'$ such that $g \circ f_\lambda = f'_\lambda$. The free product is the dual concept of direct product and is also called the π -coproduct (\rightarrow 52 Categories and Functors). If each G_λ is an infinite cyclic group generated by a_λ , then the free product of the G_λ is the π -free group generated by $\{a_\lambda\}$ (\rightarrow 161 Free Groups).

The concept of free product is generalized in the following way. Let H be a fixed group. We consider the family of pairs (G, j) , where G is a group and $j: H \rightarrow G$ is an injective homomorphism. A homomorphism of pairs $f: (G, j) \rightarrow$

(G', j') is defined to be a group homomorphism $f: G \rightarrow G'$ such that $f \circ j = j'$. For a given family of pairs $\{(G_\lambda, j_\lambda)\}$, we have the **amalgamated product** (G, j) of the family and the canonical homomorphism $f_\lambda: (G_\lambda, j_\lambda) \rightarrow (G, j)$, which is characterized by the following universal property: Given a pair (G', j') and homomorphisms $f'_\lambda: (G_\lambda, j_\lambda) \rightarrow (G', j')$, we have a unique homomorphism $g: (G, j) \rightarrow (G', j')$ such that $g \circ f_\lambda = f'_\lambda$. If $H = \{e\}$, then the amalgamated product is the same as the free product. Now f_λ is an injection. If we regard G_λ as a subgroup of G , then G is generated by the subgroups G_λ and $G_\lambda \cap G_\mu = j_\lambda(H) = j_\mu(H)$ ($\lambda \neq \mu$).

The notion of the amalgamated product is useful in constructing groups with interesting properties. For instance, we have a group whose nonidentity elements are all conjugate (B. H. Neumann and G. Higman), and a group generated by a finite number of elements such that its homomorphic image ($\neq \{e\}$) is always an infinite group (Higman) so that we have an infinite simple group generated by a finite number of elements.

N. Extensions

Let N and F be groups. A group G is called an **extension** of F by N if G has a normal subgroup \bar{N} isomorphic to N and $G/\bar{N} \cong F$. The problem of finding all extensions was solved by Schreier (*Monatsh. Math. Phys.*, 34 (1926); *Abh. Math. Sem. Univ. Hamburg*, 4 (1928)). Suppose that (1) to each $\sigma \in F$ there corresponds an automorphism s_σ of N ; (2) there exist elements $c_{\sigma, \tau}$ ($\sigma, \tau \in F$) of N such that $s_\sigma(s_\tau(a)) = c_{\sigma, \tau}(s_{\sigma\tau}(a))c_{\sigma, \tau}^{-1}$ ($a \in N$); and (3) $c_{\sigma, \tau}c_{\sigma\tau, \rho} = s_\sigma(c_{\tau, \rho})c_{\sigma, \tau\rho}$. Then the set G of all symbols as_σ ($a \in N, \sigma \in F$) is an extension of F by N if we define multiplication by $as_\sigma \cdot bs_\tau = (as_\sigma(b)c_{\sigma, \tau})s_{\sigma\tau}$. In fact, the set of all elements $\bar{a} = ac_{1,1}^{-1}s_1$ ($a \in N$) is a normal subgroup \bar{N} of G such that $G/\bar{N} \cong F$. Any extension can be obtained in this way. A system $(s_\sigma, c_{\sigma, \tau})$ satisfying (1), (2), and (3) above is called a **factor set** belonging to F . Two factor sets $(s_\sigma, c_{\sigma, \tau})$ and $(t_\sigma, d_{\sigma, \tau})$ are said to be **associated** if there exist elements a_σ ($\sigma \in F$) of N such that $t_\sigma(a) = s_\sigma(a_\sigma a a_\sigma^{-1})$ and $d_{\sigma, \tau} = a_\sigma(s_\sigma(a_\tau))c_{\sigma, \tau}a_{\sigma\tau}^{-1}$. In this case, two extensions determined by these factor sets are isomorphic. If $(s_\sigma, c_{\sigma, \tau})$ is associated with $(t_\sigma, d_{\sigma, \tau})$ ($d_{\sigma, \tau} = 1$ for any $\sigma, \tau \in F$), then we say that the corresponding extension is a **split extension**. In this case, the extension G contains a subgroup \bar{F} isomorphic to F , and $G = \bar{F}\bar{N}$, $\bar{F} \cap \bar{N} = \{e\}$. We call such an extension a **semidirect product** of N and F .

If N is Abelian, then condition (2) is simply $s_\sigma(s_\tau(a)) = s_{\sigma\tau}(a)$, since the only inner automorphism of N is the identity mapping. The con-

ditions of associated factor sets and split extension are also simplified. If N is contained in the center of G , then G is called a **central extension** of N .

O. Transfers

Let H be a subgroup of finite index in G and g_i ($i = 1, \dots, h$) be representatives of the right cosets of H . For $b \in Hg_i$ we write $g_i = \bar{b}$. Then for $x \in G$ an element $\bar{x} = H' \prod_{i=1}^h g_i x (g_i x)^{-1}$ of H/H' is determined uniquely (independent of the choice of representatives), where H' is the commutator subgroup of H . The correspondence $G'x \rightarrow \bar{x}$ yields a homomorphism of G/G' to H/H' , which is called the **transfer** from G/G' to H/H' .

P. Generalizations

The concept of group can be generalized in several ways. A set S in which a multiplication $(a, b) \rightarrow ab$ satisfying $(ab)c = a(bc)$ (the associative law) is defined is called a **semigroup**. If S is a commutative semigroup in which $ax = bx$ implies $a = b$ (the **cancellation law**), then S can be embedded in a group G so that the multiplication in S is preserved in G and any $x \in G$ is the quotient of two elements of S : $x = a^{-1}b = ba^{-1}$ ($a, b \in S$). Such a group G is determined uniquely by S . We call it the **group of quotients** of S .

The notion of semigroup is obtained by taking only associativity from the group axioms. On the other hand, if Q is a set with a law of composition $(a, b) \rightarrow ab$ which is not necessarily associative but satisfies the condition that any two among a, b, c in the equation $ab = c$ determine the third uniquely, then Q is called a **quasigroup**. A quasigroup with an identity element e such that $ea = ae = a$ for every element a is called a **loop**. For loops, we have an analog of the structure theory of groups (R. H. Bruck, *Trans. Amer. Math. Soc.*, 60 (1946)).

If we give up the possibility of forming products for all pairs of elements or the uniqueness of the product in the axioms for groups, then we have the following generalizations of groups. A set M with multiplication under which to any elements $a, b \in M$ there corresponds a nonempty subset ab of M is called a **hypergroupoid**. Moreover, if the associative law $(ab)c = a(bc)$ holds and for any elements $a, b \in M$ there exist $x, y \in M$ such that $b \in xa, b \in ay$, then M is called a **hypergroup**.

A set M is called a **mixed group** if (1) M can be partitioned into disjoint subsets M_0, M_1, M_2, \dots ; (2) for $a \in M_0, b \in M_i$ ($i = 0, 1, 2, \dots$),

elements $ab, a \setminus b$ of M_i are defined such that $a(a \setminus b) = b$; (3) for $b, c \in M_i$, an element b/c of M_0 is defined such that $(b/c) \cdot c = b$; and (4) the associative law $(ab)c = a(bc)$ ($a, b \in M_0, c \in M$) holds (A. Loewy, 1927).

A set M is called a **groupoid** if (1) M can be partitioned into disjoint subsets M_{ij} ($i, j = 1, 2, \dots$); (2) for $a \in M_{ij}$ and $b \in M_{jk}$, an element $ab \in M_{ik}$ is defined; (3) for $a \in M_{ij}$ and $b \in M_{ik}$, an element $a \setminus b \in M_{jk}$ is defined such that $a(a \setminus b) = b$; (4) for $a \in M_{ij}$ and $b \in M_{kj}$, an element $a/b \in M_{ik}$ is defined such that $(a/b)b = a$; and (5) for $a \in M_{ij}$, $b \in M_{jk}$, and $c \in M_{kl}$, the associative law $a(bc) = (ab)c$ holds (H. Brandt, 1926). These generalized concepts also have some practical applications (\rightarrow 2 Abelian Groups; 13 Algebraic Groups; 60 Classical Groups; 69 Compact Groups; 92 Crystallographic Groups; 122 Discontinuous Groups; 151 Finite Groups; 161 Free Groups; 243 Lattices; 249 Lie Groups; 277 Modules; 362 Representations; 422 Topological Abelian Groups; 423 Topological Groups; 437 Unitary Representations).

Q. History

The concept of the group was first introduced in the early 19th century, but its rudiments can be found in antiquity; in fact, it was virtually contained in the concept of motion or transformation used in ancient geometry. From the time it took explicit form in the late 19th century, it has played a fundamental role in all fields of mathematics.

In their study of algebraic equations in the late 18th century, J. L. †Lagrange, A. T. Vandermonde, and P. Ruffini saw the importance of the group of permutations of roots; using this idea N. H. Abel showed that a general equation of degree ≥ 5 cannot be solved algebraically. A. L. †Cauchy studied the group of permutations of roots for its own interest, but a complete description of the relationship between groups and algebraic equations was first given by E. †Galois. C. Jordan developed a detailed exposition of the theory given by Abel and Galois in his *Traité des substitutions* (1870) [1]. Up to that time, a group meant a permutation group; the axiomatic definition of a group was given by A. Cayley (1854) and L. Kronecker (1870). F. †Klein emphasized the significance of group theory in geometry in his †Erlangen program (1872), and M. S. †Lie developed the theory of †Lie groups in the 1880s. In 1897, W. Burnside published his *Theory of groups* [3], whose second edition (1911) is one of the classics in group theory and is still valuable. Since 1896, G. Frobenius [2] and others have developed the theory of

representation of groups by matrices (\rightarrow 362 Representations). By that time, the theory of finite groups had acquired all its essential features. Among the branches of abstract algebra, the theory of groups was the first to develop; it led to the progress of abstract algebra in the 1930s. Since the latter half of that decade, the theory of finite groups has been developed further; there has been increased interest in the theory, and many significant results have been obtained, especially since 1955 (\rightarrow 151 Finite Groups).

191 (VII.8) G-Structures

Differential geometry studies differentiable manifolds and geometric objects or structures

on them. Among the geometric structures, the Riemannian and complex structures, with their contacts with other fields of mathematics and with their richness in results, occupy a central position in differential geometry. Perhaps it is impossible to say precisely what a differential geometric structure is or should be. However, the notion of **G-structure** allows a unified description of many of the interesting known geometric structures, such as Riemannian and complex structures.

A. The Notion of G-Structures

Let M be an m -dimensional C^∞ -manifold, and let $\tau: T(M) \rightarrow M$ be its \dagger tangent bundle. For $x \in M$, $T_x(M) = \tau^{-1}(x)$ is the vector space of tangent vectors at x . Let $\pi: F(M) \rightarrow M$ denote the \dagger frame bundle of M . It is a $GL(m; \mathbf{R})$ -principal bundle on M and $F_x(M) = \pi^{-1}(x)$ is the set of linear isomorphisms (called **frames** at x) of \mathbf{R}^m onto $T_x(M)$. Here $GL(m; \mathbf{R})$ is the general linear group of \mathbf{R}^m . Hence $F_x(M)$ can be naturally identified with the set of ordered bases of $T_x(M)$. Write $\theta = (\theta^1, \dots, \theta^m)$ for the **canonical form** of $F(M)$, which is the \mathbf{R}^m -valued 1-form on $F(M)$ defined by $\theta(v) = p^{-1}(\pi_*(v))$ for any $v \in T_p(F(M))$. Given a diffeomorphism $f: M \cong N$ of M onto another C^∞ -manifold N , we can naturally define the bundle isomorphism $f^{(1)}: F(M) \cong F(N)$ by $f^{(1)}(p) = f_* \circ p$.

Let G be a \dagger Lie subgroup of $GL(m; \mathbf{R})$. A principal G -subbundle $\pi_p: P \rightarrow M$ of the frame bundle $\pi: F(M) \rightarrow M$ is called a **G-structure** over M . Thus P is a regular submanifold of $F(M)$ satisfying the following three conditions:

(A1) $\pi(P) = M$.

(A2) for $p \in P$ and $\sigma \in GL(m; \mathbf{R})$, $p\sigma \in P$ if and only if $\sigma \in G$.

(A3) for any $x \in M$, there exist an open neighborhood U of x and a C^∞ -mapping $s: U \rightarrow P$ such that $\pi(s(y)) = y$ for any $y \in U$. Conversely, if a regular submanifold P of $F(M)$ satisfies the above three conditions (A1), (A2), and (A3), then $\pi_p = \pi|_P: P \rightarrow M$ is a G -structure over M . When G is closed, then condition (A3) is automatically satisfied. The restriction of θ onto P is called the **canonical form** of P and is also denoted by θ . For an open subset U of M , the restriction $P|_U = \pi_p^{-1}(U)$ is a G -structure over U .

Let $\pi_p: P \rightarrow M$ and $\pi_q: Q \rightarrow N$ be G -structures over M and N , respectively. A diffeomorphism $f: M \cong N$ is called a **G-isomorphism** of P onto Q if $f^{(1)}(P) = Q$. When such an f exists, we say that the G -structures P and Q are **equivalent**. A G -isomorphism of P onto itself is called a G -automorphism of P . Write $\text{Aut}(M, P)$ for the group of G -automorphisms of P .

Let \mathfrak{g} be the Lie algebra of G . Since G acts on P from the right, we have the natural Lie algebra homomorphism $\iota: \mathfrak{g} \rightarrow \Gamma(P, T(P))$. Here $\Gamma(P, T(P))$ is the Lie algebra of C^∞ -vector fields on P . Actually ι is injective, and we write A^* for $\iota(A)$ ($A \in \mathfrak{g}$). We call A^* the **fundamental vector field** corresponding to A .

For $x \in \mathbf{R}^m$, define $p_0(x) \in F_x(\mathbf{R}^m)$ by $p_0(x)((v^j)) = \sum_{j=1}^m v^j (\partial/\partial x^j)_x$, where x^1, \dots, x^m are the natural coordinates of \mathbf{R}^m . Any open subset D of \mathbf{R}^m has the natural G -structure $P(D, G)$ defined by $P(D, G) = \{p_0(x) \cdot \sigma \in F_x(\mathbf{R}^m); x \in D, \sigma \in G\}$. We say that a G -structure $\pi_p: P \rightarrow M$ over M is **integrable** if for each $x \in M$, there exists a local coordinate system (U, φ, D) around x such that φ is a G -isomorphism of $P|_U$ onto $P(D, G)$. Equivalently, if we set $\varphi = (x^1, \dots, x^m)$, then the frame $\{(\partial/\partial x^1)_y, \dots, (\partial/\partial x^m)_y\}$ belongs to P for each $y \in U$.

B. Examples

The following examples (B1)–(B7) show that some classical geometric structures can be treated uniformly from the viewpoint of G -structures.

(B1) An **absolute parallelism** on M is, by definition, a system $\{X_1, \dots, X_m\}$ of C^∞ -vector fields on M such that at each point $x \in M$ $\{X_1(x), \dots, X_m(x)\}$ is a basis of $T(M)_x$. Clearly this is equivalent to giving an $\{e\}$ -structure $\pi_p: P \rightarrow M$, where e stands for the identity matrix of $GL(m; \mathbf{R})$. Then P is integrable if and only if $[X_i, X_j] = 0$, $1 \leq i, j \leq m$. In this case, $\text{Aut}(M, P)$ is a finite-dimensional \dagger Lie transformation group on M .

(B2) Let E be a k -dimensional \dagger distribution, namely, E is a k -dimensional vector subbundle of $T(M)$. Write $\mathbf{R}^m = \mathbf{R}^k \oplus \mathbf{R}^{m-k}$. Set $GL(k, m; \mathbf{R}) = \{\sigma \in GL(m; \mathbf{R}); \sigma(\mathbf{R}^k) \subset \mathbf{R}^k\}$ and $P = \{p \in F(M); p(\mathbf{R}^k) \subset E\}$. Then P is a $GL(k, m; \mathbf{R})$ -structure over M . This gives a bijective correspondence between the k -dimensional distributions on M and the $GL(k, m; \mathbf{R})$ -structures on M . Moreover, P is integrable if and only if E is \dagger involutive (Frobenius theorem).

(B3) Let g be a Riemannian metric on M . Set $O(m) = \{\sigma \in GL(m; \mathbf{R}); {}^t\sigma\sigma = e\}$. Define $P(g)$ by $P(g) = \{(v_1, \dots, v_m) \in F(M); g(v_i, v_j) = \delta_{ij}\}$. Then $P(g)$ is an $O(m)$ -structure on M . This gives a bijective correspondence between the Riemannian metrics on M and the $O(m)$ -structures over M . Then $\text{Aut}(M, P(g))$ is the group of \dagger isometries of g , and a finite-dimensional Lie transformation group on M . Moreover, $P(g)$ is integrable if and only if g is flat in the sense that the Riemannian curvature tensor of g is zero.

(B4) Two Riemannian metrics g_1 and g_2 are

called **conformally equivalent** if there exists a C^∞ -function $\rho > 0$ with $g_1 = \rho g_2$. This is an equivalence relation among the Riemannian metrics on M . An equivalence class $\{g\}$ is called a **conformal structure** on M . Set $CO(m) = \{aA; A \in O(m), a \in \mathbf{R} - \{0\}\}$. Define $P(\{g\})$ by $P(\{g\}) = \{(v_1, \dots, v_m) \in F(M); g(v_i, v_j) = a\delta_{ij}, a \in \mathbf{R} - \{0\}\}$. Then $P(\{g\})$ is a $CO(m)$ -structure on M . This gives a bijective correspondence between the conformal structures on M and the $CO(m)$ -structures over M . Then $\text{Aut}(M, P(\{g\}))$ is the group of conformal transformations of $\{g\}$ and is a finite-dimensional Lie transformation group. Moreover $P(\{g\})$ is integrable if and only if the conformal structure $\{g\}$ is **conformally flat** in the sense that at each point $x \in M$, there exists a local coordinate system (x^1, \dots, x^m) around x such that $g(\partial/\partial x^i, \partial/\partial x^j) = \rho \delta_{ij}$, where ρ is a positive function.

(B5) Assume that m is even, say $m = 2l$. By an **almost symplectic structure** on M , we mean a differential 2-form Ω of maximal rank, i.e., $\Omega \wedge \dots \wedge \Omega$ (l times) never vanishes. Let A be the standard skew-symmetric bilinear form on \mathbf{R}^{2l} defined by $A((u^i), (v^j)) = (u^1 v^2 - u^2 v^1) + \dots + (u^{2l-1} v^{2l} - u^{2l} v^{2l-1})$. The symplectic group $Sp(l; \mathbf{R})$ is defined by $Sp(l; \mathbf{R}) = \{\sigma \in GL(2l; \mathbf{R}); A(\sigma u, \sigma v) = A(u, v), u, v \in \mathbf{R}^{2l}\}$. Set $P(\Omega) = \{p \in F(M); p^* A = \Omega_x, x = \pi_P(p)\}$. Then $P(\Omega)$ is an $Sp(l; \mathbf{R})$ -structure over M . This gives a bijective correspondence between the almost symplectic structures on M and the $Sp(l; \mathbf{R})$ -structures over M . Then $\text{Aut}(M, P(\Omega))$ is the group of symplectic transformations of Ω , which is never a finite-dimensional Lie transformation group. Moreover $P(\Omega)$ is integrable if and only if Ω is a symplectic structure, i.e., $d\Omega = 0$.

(B6) Assume that m is even, say $m = 2l$. We identify \mathbf{C}^l with \mathbf{R}^{2l} as a real vector space. Then $GL(m; \mathbf{C})$ is a Lie subgroup of $GL(2l; \mathbf{R})$. Let J be an almost complex structure on M . Set $P(J) = \{p \in F(M); Jp(u) = p(iu), u \in \mathbf{R}^{2l} = \mathbf{C}^l\}$. Then $P(J)$ is a $GL(l; \mathbf{C})$ -structure on M . This gives a bijective correspondence between the almost complex structures on M and the $GL(l; \mathbf{C})$ -structures over M . Then $\text{Aut}(M, P(J))$ is the group of J -analytic transformations on M . Furthermore, $\text{Aut}(M, P(J))$ is a finite-dimensional Lie transformation group when M is compact. Moreover $P(J)$ is integrable if and only if J is a complex structure.

(B7) It is easy to see that there is a bijective correspondence between the $SL(m; \mathbf{R})$ -structures over M and the set of volume elements on M . Any $SL(m; \mathbf{R})$ -structure over M is always integrable and $\text{Aut}(M, P)$ is the group of diffeomorphisms preserving Ω , which is never a finite-dimensional Lie transformation group.

C. Structure Functions

Let G be a Lie subgroup of $GL(m; \mathbf{R})$ and \mathfrak{g} the Lie algebra of G . For convenience, we write V for \mathbf{R}^m and V^* for the dual space of V . Then $V \otimes \wedge^2 V^*$ can be considered as the space of skew-symmetric bilinear mappings from $V \times V$ into V , and $\mathfrak{g} \otimes V^*$ can be identified with the space of linear mappings from V into \mathfrak{g} . Define a linear mapping $\partial: \mathfrak{g} \otimes V^* \rightarrow V \otimes \wedge^2 V^*$ by

$$(\partial T)(u, v) = -T(u)v + T(v)u$$

$$\text{for } T \in \mathfrak{g} \otimes V^*, u, v \in V.$$

Put

$$H^{2,1}(\mathfrak{g}) = V \otimes \wedge^2 V^* / \partial(\mathfrak{g} \otimes V^*).$$

Let $\pi_P: P \rightarrow M$ be a G -structure over M and θ the canonical form of P . Take any frame p in P . An m -dimensional linear subspace H of $T_p(P)$ is said to be a **horizontal subspace** of P at p if $\theta_p: H \rightarrow V (= \mathbf{R}^m)$ is a linear isomorphism. Then we write f_H for $\theta_p^{-1}: V \rightarrow H$. Write $\mathfrak{H}(T_p(P))$ for the set of horizontal subspaces of P at p . For $H \in \mathfrak{H}(T_p(P))$, define $c(p, H) \in V \otimes \wedge^2 V^*$ by

$$c(p, H)(u, v) = d\theta(f_H(u), f_H(v)) \quad \text{for } u, v \in V.$$

Then we have

$$c(p, H_1) - c(p, H_2) \in \partial(\mathfrak{g} \otimes V^*)$$

$$\text{for } H_1, H_2 \in \mathfrak{H}(T_p(P)).$$

Therefore we have a well-defined element $c(p) \in H^{2,1}(\mathfrak{g})$ by $c(p) = \{c(p, H)\}$. We call the mapping $c: P \rightarrow H^{2,1}(\mathfrak{g})$ the **structure function** of the G -structure $\pi_P: P \rightarrow M$.

Let $Q \rightarrow N$ be another G -structure over N and $f: M \simeq N$ be a G -isomorphism of P onto Q . Then we have $c(f^{(1)}(p)) = c(p)$ for $p \in P$. In particular, it is easily seen that if P is integrable, then $c \equiv 0$. However, the converse is not true in general.

D. Prolongation of Linear Lie Algebras and Groups

Let \mathbf{K} denote either \mathbf{R} or \mathbf{C} . Let \mathfrak{g} be a Lie subalgebra of $\mathfrak{gl}(m; \mathbf{K})$. For $k = 0, 1, 2, \dots$, let \mathfrak{g}_k be the space of \mathbf{K} -symmetric multilinear mappings

$$t: \underbrace{\mathbf{K}^m \times \dots \times \mathbf{K}^m}_{(k+1) \text{ times}} \rightarrow \mathbf{K}^m$$

such that for each fixed $u_1, \dots, u_k \in \mathbf{K}^m$, the linear transformation

$$v \in \mathbf{K}^m \mapsto t(v, u_1, \dots, u_k) \in \mathbf{K}^m$$

belongs to \mathfrak{g} . In particular, $\mathfrak{g}_0 = \mathfrak{g}$. We call \mathfrak{g}_k

the k th prolongation of \mathfrak{g} . If $\mathfrak{g}_k = 0$, then $\mathfrak{g}_{k+1} = \mathfrak{g}_{k+2} = \dots = 0$. The first integer k such that $\mathfrak{g}_k = 0$ is called the **order** of \mathfrak{g} . If $\mathfrak{g}_k \neq 0$ for all k , then \mathfrak{g} is said to be of **infinite type**. When \mathfrak{g} contains a matrix of rank 1 as an element, then \mathfrak{g} is of infinite type. When $\mathbf{K} = \mathbf{C}$, the converse is also true [3]. However, when $\mathbf{K} = \mathbf{R}$, the converse is not true in general. In fact, if we consider $\mathfrak{gl}(l; \mathbf{C})$ as a real Lie subalgebra of $\mathfrak{gl}(2l; \mathbf{R})$ (example (B6)), then $\mathfrak{gl}(l; \mathbf{C})$ is of infinite type, having no matrix of rank 1 in it. In general, a Lie subalgebra \mathfrak{g} of $\mathfrak{gl}(m; \mathbf{R})$ is said to be of **elliptic type** if \mathfrak{g} contains no matrix of rank 1 as an element. We consider \mathfrak{g}_1 as an Abelian Lie subalgebra of $\mathfrak{gl}(\mathbf{K}^m \oplus \mathfrak{g})$ by the correspondence $t \in \mathfrak{g}_1 \mapsto \bar{t} \in \mathfrak{gl}(\mathbf{K}^m \oplus \mathfrak{g})$, where \bar{t} is defined by

$$\begin{aligned}\bar{t}(u) &= t(\cdot, u) \quad \text{for } u \in \mathbf{K}^m, \\ \bar{t}(A) &= 0 \quad \text{for } A \in \mathfrak{g}.\end{aligned}$$

More generally, we consider \mathfrak{g}_{k+1} to be an Abelian Lie subalgebra of $\mathfrak{gl}(\mathbf{K}^m \oplus \mathfrak{g}_0 \oplus \dots \oplus \mathfrak{g}_k)$ by virtue of the correspondence $t \in \mathfrak{g}_{k+1} \mapsto \bar{t} \in \mathfrak{gl}(\mathbf{K}^m \oplus \mathfrak{g}_0 \oplus \dots \oplus \mathfrak{g}_k)$, where \bar{t} is defined by

$$\begin{aligned}\bar{t}(u) &= t(\cdot, \dots, \cdot, u) \in \mathfrak{g}_k \quad \text{for } u \in \mathbf{K}^m, \\ \bar{t}(A) &= 0 \quad \text{for } A \in \mathfrak{g}_0 \oplus \dots \oplus \mathfrak{g}_k.\end{aligned}$$

Identifying $\mathfrak{gl}(\mathbf{K}^m \oplus \mathfrak{g}_0 \oplus \dots \oplus \mathfrak{g}_{k-1}) \oplus \mathfrak{g}_k$ with $\mathfrak{gl}(\mathbf{K}^m \oplus \mathfrak{g}_0 \oplus \dots \oplus \mathfrak{g}_k)$, we have the important identity

$$(D1) \quad (\mathfrak{g}_k)_1 = \mathfrak{g}_{k+1}, \quad k=0, 1, 2, \dots$$

Let G be a Lie subgroup of $GL(m; \mathbf{R})$ and \mathfrak{g} the Lie subalgebra of $\mathfrak{gl}(m; \mathbf{R})$ corresponding to G . For $k=1, 2, \dots$, let G_k be the connected Abelian Lie subgroup of $GL(\mathbf{R}^m \oplus \mathfrak{g}_0 \oplus \dots \oplus \mathfrak{g}_{k-1})$ corresponding to the Abelian Lie subalgebra \mathfrak{g}_k ; namely, G_k consists of the linear mappings $\sigma(\bar{t})$ ($t \in \mathfrak{g}_k$) defined by

$$\begin{aligned}\sigma(\bar{t})(u) &= u + t(\cdot, \dots, \cdot, u) \quad \text{for } u \in \mathbf{R}^m, \\ \sigma(\bar{t})(A) &= A \quad \text{for } A \in \mathfrak{g}_0 \oplus \dots \oplus \mathfrak{g}_{k-1}.\end{aligned}$$

We call G_k the k th prolongation of G . We say that G is of finite (resp. infinite) type if \mathfrak{g} is of finite (resp. infinite) type. We say that G is of elliptic type if \mathfrak{g} is. From (D1), we have

$$(D2) \quad (G_k)_1 = G_{k+1}.$$

We know all irreducible Lie subalgebras \mathfrak{g} of $\mathfrak{gl}(m; \mathbf{K})$ with order ≥ 2 [3, 6].

(D3) An irreducible Lie subalgebra \mathfrak{g} of $\mathfrak{gl}(m; \mathbf{C})$ is of infinite type if and only if \mathfrak{g} is one of

$$\mathfrak{gl}(m; \mathbf{C}), \quad \mathfrak{sl}(m; \mathbf{C}), \quad \mathfrak{csp}\left(\frac{m}{2}; \mathbf{C}\right), \quad \mathfrak{sp}\left(\frac{m}{2}; \mathbf{C}\right),$$

where $\mathfrak{csp}(m/2; \mathbf{C}) = \mathbf{C} \oplus \mathfrak{sp}(m/2, \mathbf{C})$.

(D4) An irreducible Lie algebra \mathfrak{g} of $\mathfrak{gl}(m; \mathbf{R})$ is of infinite type if and only if \mathfrak{g} is one of

$$\begin{aligned}\mathfrak{gl}\left(\frac{m}{2}; \mathbf{C}\right), \quad \mathfrak{sl}\left(\frac{m}{2}; \mathbf{C}\right), \quad \mathfrak{csp}\left(\frac{m}{4}; \mathbf{C}\right), \\ \mathfrak{sp}\left(\frac{m}{4}; \mathbf{C}\right), \\ \mathfrak{gl}(m; \mathbf{R}), \quad \mathfrak{sl}(m; \mathbf{R}), \quad \mathfrak{csp}\left(\frac{m}{2}; \mathbf{R}\right), \quad \mathfrak{sp}\left(\frac{m}{2}; \mathbf{R}\right),\end{aligned}$$

where $\mathfrak{csp}(m/2; \mathbf{R}) = \mathbf{R} \oplus \mathfrak{sp}(m/2; \mathbf{R})$.

(D5) Let S be an m -dimensional irreducible Hermitian symmetric space of compact type, which is different from the complex projective space. Let $L(S)$ be the identity connected component of the group of biholomorphic transformations of S . Take any point $o \in S$ and set $L_o(S) = \{\sigma \in L(S); \sigma(o) = o\}$. Let $\mathfrak{g}(S)$ be the linear isotropy Lie subalgebra of $\mathfrak{gl}(m; \mathbf{C})$ corresponding to $L(S)$. Then $\mathfrak{g}(S)$ is an irreducible Lie subalgebra of $\mathfrak{gl}(m; \mathbf{C})$ of order 2. Conversely, every irreducible Lie subalgebra \mathfrak{g} of $\mathfrak{gl}(m; \mathbf{C})$ of finite type with order ≥ 2 is equal to $\mathfrak{g}(S)$ as given above.

(D6) Let S be an m -dimensional irreducible symmetric space of compact type. Assume that S admits a finite-dimensional connected Lie transformation group $L(S)$ which strictly contains the connected component of the group of isometries of S . Take any point $o \in S$, and set $L_o(S) = \{\sigma \in L(S); \sigma(o) = o\}$. Let $\mathfrak{g}(S)$ be the linear isotropy Lie subalgebra of $\mathfrak{gl}(m; \mathbf{R})$ corresponding to $L_o(S)$. If $(S, L(S)) \neq (\text{sphere, projective transformation group})$ or $(S, L(S)) \neq (\text{complex projective space, complex projective transformation group})$, then $\mathfrak{g}(S)$ is an irreducible Lie subalgebra of $\mathfrak{gl}(m; \mathbf{R})$ of order 2. Conversely, every irreducible Lie subalgebra \mathfrak{g} of $\mathfrak{gl}(m; \mathbf{R})$ of finite type with order ≥ 2 is equal to $\mathfrak{g}(S)$ as given above. For example, if we take an m -dimensional sphere as S and the group of conformal transformations of S as $L(S)$, then $\mathfrak{g}(S) = \mathfrak{co}(m)$.

E. Prolongation of G-Structures

Let G be a Lie subgroup of $GL(m; \mathbf{R})$ and let \mathfrak{g} be the Lie subalgebra of $\mathfrak{gl}(m; \mathbf{R})$ corresponding to G . We choose once and for all a linear subspace C of $V \otimes \wedge^2 V^*$ such that

$$V \otimes \wedge^2 V^* = \partial(\mathfrak{g} \otimes V^*) \oplus C.$$

In general there is no natural way of choosing such a C .

Let $\pi_p: P \rightarrow M$ be a G -structure on M . For each horizontal subspace H of P at p (i.e., $H \in \Theta(T_p(P))$), we define the frame $(p, H) \in F_p(P)$

to be a linear isomorphism $(p, H): \mathbf{R}^m \oplus \mathfrak{g} \rightarrow T_p(P)$ given by

$$(p, H)(v \oplus A) = f_H(v) \oplus A_p^* \quad \text{for } v \in \mathbf{R}^m, A \in \mathfrak{g},$$

where A^* is the fundamental vector field on P induced from $A \in \mathfrak{g}$. Let $P_1 = \{(p, H) \in F(P); H \in \mathcal{H}(T_p(P)), c(p, H) \in C\}$. Then $P_1 \rightarrow P$ is a G_1 -structure over P . We call $P_1 \rightarrow P$ the **first prolongation** of P . The k th **prolongation** P_k of P is defined inductively by $P_k = (P_{k-1})_1$ = the first prolongation of P_{k-1} . From (D2), P_k is a G_k -structure over P_{k-1} .

Take any $f \in \text{Aut}(M, P)$. It can be proved that $f^{(1)} \in \text{Aut}(P, P_1)$. Since $P_k = (P_{k-1})_1$, we can define $f^{(k)} \in \text{Aut}(P_{k-1}, P_k)$ inductively by $f^{(k)} = (f^{(k-1)})^{(1)}$. By the correspondence $f \mapsto f^{(k)}$, we can consider $\text{Aut}(M, P)$ as a subgroup of $\text{Aut}(P_{k-1}, P_k)$.

If G is connected, then

$$(E1) \quad \text{Aut}(M, P) = \text{Aut}(P_{k-1}, P_k), \quad k = 1, 2, \dots$$

Let $Q \rightarrow N$ be another G -structure. By a similar argument to that above, we see that $P \rightarrow M$ and $Q \rightarrow N$ are equivalent if and only if $P_k \rightarrow P_{k-1}$ and $Q_k \rightarrow Q_{k-1}$ are equivalent. In [1], E. Cartan studied general equivalence problems of two G -structures. In that problem the above prolongation procedure plays an important role.

F. Automorphisms of G -Structures of Finite Type

S. Kobayashi proved the following:

(F1) Theorem [4]. Let $P \rightarrow M$ be an $\{e\}$ -structure over M . Then $\text{Aut}(M, P)$ is a finite-dimensional Lie transformation group on M such that $\dim \text{Aut}(M, P) \leq \dim M$. More precisely, for any point $x \in M$, the mapping $\sigma \in \text{Aut}(M, P) \mapsto \sigma(x) \in M$ is injective, and its image $\{\sigma(x); \sigma \in \text{Aut}(M, P)\}$ is a closed submanifold of M . The submanifold structure on this image makes $\text{Aut}(M, P)$ into a finite-dimensional Lie transformation group on M .

Now let G be a Lie subgroup of $GL(m; \mathbf{R})$ of finite type, say $G_k = \{e\}$. Then $P_k \rightarrow P_{k-1}$ is an $\{e\}$ -structure. From theorem (F1) above, it follows that $\text{Aut}(P_{k-1}, P_k)$ is a finite-dimensional Lie transformation group. As explained in Section E, $\text{Aut}(M, P)$ is a subgroup of $\text{Aut}(P_{k-1}, P_k)$. Clearly $\text{Aut}(M, P)$ is closed in $\text{Aut}(P_{k-1}, P_k)$. Since every closed subgroup of a Lie group is again a Lie group, we have the following:

(F2) Theorem. Let $P \rightarrow M$ be a G -structure over M . If G is of finite type, then $\text{Aut}(M, P)$ is a Lie transformation group of dimension $\leq \dim(\mathbf{R}^m \oplus \mathfrak{g} \oplus \mathfrak{g}_1 \oplus \dots \oplus \mathfrak{g}_{k-1})$.

G. Automorphisms of G -Structures of Elliptic Type

The following theorem of R. Palais allows us to prove that the automorphism groups of many general geometric structures are finite-dimensional Lie transformation groups.

(G1) Theorem [5]. Let L be a group of C^∞ -transformations of a C^∞ -manifold M . Let \mathcal{L} be the set of all vector fields X on M which generate global 1-parameter groups $\varphi_t = \exp tX$ of transformations of M such that $\varphi_t \in L$. If the set \mathcal{L} generates a finite-dimensional Lie algebra of vector fields on M , then L is a finite-dimensional Lie transformation group, and \mathcal{L} is the Lie algebra of L .

Let $P \rightarrow M$ be a G -structure over M . For any representation $\rho: G \rightarrow GL(V)$, we write $E(\rho)$ for the associated vector bundle of P with respect to ρ . Let $\rho_1: G \rightarrow GL(\mathfrak{gl}(m; \mathbf{R}))$ be the representation defined by $\rho_1(\sigma)A = \sigma A \sigma^{-1}$ for $\sigma \in G$, $A \in \mathfrak{gl}(m; \mathbf{R})$. Let $\rho_2: G \rightarrow GL(\mathfrak{g})$ be the representation defined by $\rho_2(\sigma)A = \sigma A \sigma^{-1}$ for $\sigma \in G$, $A \in \mathfrak{g}$. Then ρ_2 is a subrepresentation of ρ_1 , since $\rho_1(\sigma)A = \rho_2(\sigma)A$ for $\sigma \in G$, $A \in \mathfrak{g}$. We remark that $E(\rho_1) = \text{Hom}(T(M), T(M))$. We write $\mathfrak{g}(M)$ for $E(\rho_2)$. Then $\mathfrak{g}(M)$ is a vector subbundle of $\text{Hom}(T(M), T(M))$. We write F for the quotient vector bundle $\text{Hom}(T(M), T(M))/\mathfrak{g}(M)$. Let $\Phi: \text{Hom}(T(M), T(M)) \rightarrow F$ be the natural projection. We fix an affine connection ∇ on M which preserves P . We write T for the torsion tensor field of ∇ . For each vector field $X \in \Gamma(M, T(M))$, we define a C^∞ -section $\nabla X + T(X, \cdot)$ in $\Gamma(M, \text{Hom}(T(M), T(M)))$ by

$$u \in T(M)_x \mapsto \nabla_u X + T(X(x), u) \in T_x(M).$$

Then define a first-order linear differential operator

$$D: \Gamma(M, T(M)) \rightarrow \Gamma(M, F)$$

by $D(X) = \Phi(\nabla X + T(X, \cdot))$. It is easy to see that

$$(G2) \quad \mathcal{L}(M, P) \subset \ker D,$$

where $\mathcal{L}(M, P)$ is the Lie algebra of all vector fields $X \in \Gamma(M, T(M))$ which generate global 1-parameter groups $\varphi_t = \exp tX$ of transformations of M such that $\varphi_t \in \text{Aut}(M, P)$. Then we can show:

(G3) D is an elliptic operator if and only if G is of elliptic type.

Now suppose M is compact. Then from the standard fact on linear elliptic operators on compact manifolds, we know the dimension of $\ker D$ is finite if D is elliptic. Thus from (G2), (G3), and theorem (G1), we have the following:

(G4) Theorem [7]. Let $P \rightarrow M$ be a G -structure on an m -dimensional compact mani-

fold M . If G is of elliptic type, then $\text{Aut}(M, P)$ is a finite-dimensional Lie transformation group.

H. Local Equivalence Problem

Let $\pi_P: P \rightarrow M$ and $\pi_Q: Q \rightarrow N$ be two G -structures. We say that $P \rightarrow M$ and $Q \rightarrow N$ are **locally equivalent** if the following holds:

(H1) For arbitrarily given $(p, q) \in P \times Q$, there exists a local G -isomorphism $f: U \cong V$ of $P|U$ onto $Q|V$ such that $f^{(1)}(p) = q$, where U (resp. V) is an open neighborhood of $\pi_P(p)$ (resp. $\pi_Q(q)$).

From now on, we assume that the structure function c_P (resp. c_Q) of P (resp. Q) is constant. If such an f as in (H1) exists, we must have $c_Q(f^{(1)}(p')) = c_P(p')$ for $p' \in P|U$. Therefore c_P and c_Q must be the same constant. Cartan reduced the local equivalence problem between P and Q to that of certain differential systems on $P \times Q$. In fact, let $\theta_P = (\theta^1, \dots, \theta^m)$ and $\theta_Q = (\psi^1, \dots, \psi^m)$ be the canonical forms of P and Q respectively. Let $\alpha: P \times Q \rightarrow P$, $\beta: P \times Q \rightarrow Q$ be the canonical projections such that $\alpha(p, q) = p$, $\beta(p, q) = q$. Let Σ be the differential system on $P \times Q$ generated by $\{\alpha * \theta^1 - \beta * \psi^1, \dots, \alpha * \theta^m - \beta * \psi^m\}$. If X is the m -dimensional regular submanifold of $P \times Q$ given by the graph of $f^{(1)}$ in (H1), i.e., $X = \{(p', f^{(1)}(p')) \in P \times Q; p' \in P|U\}$, then X is an m -dimensional integral submanifold of Σ satisfying the following conditions:

$$(H2) \quad (p, q) \in X,$$

$$(H3) \quad \alpha * \theta^1, \dots, \alpha * \theta^m \text{ are linearly independent on } T_{(p,q)}(X).$$

Conversely any m -dimensional integral submanifold of Σ satisfying (H2) and (H3) is the graph of a local G -isomorphism f required in (H1). Therefore the local equivalence problem between P and Q is equivalent to the problem of finding an m -dimensional integral submanifold X of Σ satisfying (H2) and (H3) for any $(p, q) \in P \times Q$.

We say that G is **involutive** if there exist linear subspaces $0 = V_0 \subset V_1 \subset \dots \subset V_m = \mathbf{R}^m$ such that

$$(H4) \quad \dim V_k = k \quad (k = 0, \dots, m),$$

$$(H5) \quad \dim \mathfrak{g}_1 = \sum_{k=0}^m \dim \mathfrak{g}(V_k),$$

where \mathfrak{g} is the Lie algebra of G and $\mathfrak{g}(V_k) = \{A \in \mathfrak{g}; A(u) = 0 \text{ for } u \in V_k\}$. Now we have:

(H6) Proposition. Let $P \rightarrow M$ and $Q \rightarrow N$ be two G -structures such that their structure functions are constant and equal. The differential system Σ on $P \times Q$ defined as above is involutive at any m -dimensional integral

element E of Σ on which $\alpha * \theta^1, \dots, \alpha * \theta^m$ are linearly independent if and only if G is involutive.

Combining proposition (H6) above with the classical \dagger Cartan-Kähler theorem, we obtain the following theorems:

(H7) Theorem ([1], also see [8]). Let $P \rightarrow M$ and $Q \rightarrow N$ be two real analytic G -structures over M and N , respectively, such that their structure functions are constant and equal. Suppose G is involutive. Then $P \rightarrow M$ and $Q \rightarrow N$ are locally equivalent.

(H8) Theorem. Let $P \rightarrow M$ be a real analytic G -structure over M . Suppose G is involutive. Then P is integrable if and only if the structure function of P is zero everywhere.

Finally, we remark that for a general Lie subgroup $G \subset GL(m, \mathbf{R})$, G_k is involutive for $k \geq k_0$ [8].

I. Cartan-Kähler Theorem on Differential Systems

Let U be an open subset of \mathbf{R}^m . We write $A^k(U)$ for the space of real analytic differential k -forms on U . Put $A^*(U) = A^0(U) \oplus \dots \oplus A^m(U)$. Then $A^*(U)$ is a graded \mathbf{R} -algebra with respect to the usual exterior product. By a **differential system** on U we mean an ideal Σ of $A^*(U)$ such that

$$(I1) \quad \Sigma = A^0(U) \cap \Sigma \oplus A^1(U) \cap \Sigma \oplus \dots \oplus \Sigma \cap A^m(U),$$

$$(I2) \quad d(\Sigma) \subset \Sigma,$$

$$(I3) \quad \Sigma \text{ is finitely generated as an ideal.}$$

For convenience we write $\Sigma^{(k)} = \Sigma \cap A^k(U)$. When $\Sigma^{(0)} = \{0\}$, we call Σ a **restricted differential system**.

Let Σ be a differential system on $U \subset \mathbf{R}^m$. By a **k -dimensional integral manifold** of Σ , we mean a k -dimensional regular real analytic submanifold of U such that for any $\alpha \in \Sigma$, we have $\alpha|X \equiv 0$. In the above definition, it is sufficient to know that $\alpha|X \equiv 0$ for any $\alpha \in \Sigma^{(k)}$.

For $x \in U$, we write $G_k(T_x(U))$ for the set of all k -dimensional linear subspaces of $T_x(U)$. Set $G_k(T(U)) = \bigcup_{x \in U} G_k(T_x(U))$ (disjoint union); then $G_k(T(U))$ is naturally a real analytic manifold of dimension $m + m(m - k)$. Let Σ be a differential system on U . A k -plane $E \in G_k(T_x(U))$ is called a **k -dimensional integral element** of Σ at x if for any $\alpha \in \Sigma^{(k)}$, we have $\alpha|E = 0$. Thus X is a k -dimensional integral submanifold if and only if $T_x(X)$ is a k -dimensional integral element of Σ for each $x \in X$. We write $I_k(\Sigma)$ for the set of k -dimensional integral elements of Σ . In general $I_k(\Sigma)$ is a real analytic subset of $G_k(T(U))$. For any k -dimensional

integral element E at $x \in U$, we define the **polar space** $H(E)$ by

$$H(E) = \{u \in T_x(U); \alpha(u, v_1, \dots, v_k) = 0 \\ \text{for } \alpha \in \Sigma^{(k+1)}, v_1, \dots, v_k \in E\}.$$

Then $E \subset H(E)$. Moreover $F \in G_{k+1}(T_x(U))$ with $F \supset E$ is in $I_{k+1}(\Sigma)$ if and only if $F \subset H(E)$. Let E be a k -dimensional integral element of Σ . We choose $\varphi^1, \dots, \varphi^k \in A^1(U)$ such that $\varphi^1|E, \dots, \varphi^k|E$ are linearly independent. Define $\mathcal{U}(\varphi^1, \dots, \varphi^k)$ by

$$\mathcal{U}(\varphi^1, \dots, \varphi^k) = \{F \in G_k(T(U)); \varphi^1|F, \dots, \varphi^k|F \\ \text{linearly independent}\}.$$

Then $\mathcal{U}(\varphi^1, \dots, \varphi^k)$ is an open neighborhood of E in $G_k(T(U))$. For any element $F \in \mathcal{U}(\varphi^1, \dots, \varphi^k)$, define $F_1, \dots, F_k \in F$ by $\varphi^i(F_k) = \delta_k^i$. Thus $\{F_1, \dots, F_k\}$ is the dual basis of $\varphi^1|F, \dots, \varphi^k|F$. Any element $\alpha \in \Sigma^{(k)}$ defines a real analytic function α_* on $\mathcal{U}(\varphi^1, \dots, \varphi^k)$ by $\alpha_*(F) = \alpha(F_1, \dots, F_k)$. We call E **regular** if there exist $\alpha^1, \dots, \alpha^l \in \Sigma^{(k)}$ and an open neighborhood \mathcal{V} of E in $\mathcal{U}(\varphi^1, \dots, \varphi^k)$ such that

$$(I4) \quad I_k(\Sigma) \cap \mathcal{V} = \{F \in \mathcal{V}; \alpha_*^1(F) = \dots = \alpha_*^l(F) = 0\},$$

$$(I5) \quad d\alpha_*^1, \dots, d\alpha_*^l \text{ are linearly independent on } \mathcal{V},$$

$$(I6) \quad \dim H(F) \text{ is constant for any } F \in \mathcal{V}.$$

We say that $E \in I_k(\Sigma)$ is an **ordinary element** if E contains a $(k-1)$ -dimensional regular integral element.

The following is the well-known theorem due to Cartan and Kähler [7].

(17) Theorem. Let Σ be a restricted differential system on $U \subset \mathbf{R}^m$. Let X be a k -dimensional integral submanifold of Σ . Suppose that $T_x(X)$ is regular for a point $x \in X$ and that there exists a $(k+1)$ -dimensional integral element F at x with $F \supset T_x(X)$. Then there exists a $(k+1)$ -dimensional integral submanifold Y of Σ such that $x \in Y$, $T_x(Y) = F$, and $X \subset Y$ in a neighborhood of x .

We say that Σ is **involutive** at $E \in I_k(\Sigma)$ if there exist $0 = E^0 \subset E^1 \subset \dots \subset E^{k-1} \subset E$ such that E^j is a j -dimensional regular integral element of Σ ($j=0, 1, \dots, k-1$). Applying theorem (G7) inductively, we obtain:

Corollary. Let Σ be a restricted differential system on $U \subset \mathbf{R}^m$. If E is a k -dimensional involutive integral element of Σ at x , there exists a k -dimensional integral submanifold of Σ such that $x \in X$ and $T_x(X) = E$.

In view of this corollary, it is important to know when Σ is involutive at $E \in I_k(\Sigma)$.

(18) Lemma [9]. Let Σ be a restricted differential system on $U \subset \mathbf{R}^m$, and E be a k -dimensional integral element of Σ . Then Σ is

involutive at E if and only if there exist $0 = E^0 \subset E^1 \subset \dots \subset E^{k-1} \subset E$ such that $I_k(\Sigma)$ is a submanifold of $G_k(T(U))$ near E with dimension $m + k(m-k) - \sum_{j=0}^{k-1} t_j$, where $t_j = m - \dim H(E^j)$.

192 (X.24) Harmonic Analysis

A. Fourier Transforms

Let $f(x)$ be an element of the \dagger function space $L_1(-\infty, \infty)$ and t a real number. Then the integral

$$\hat{f}(t) = (2\pi)^{-1/2} \int_{-\infty}^{\infty} f(x) e^{-itx} dx \quad (1)$$

converges, and the function $\hat{f}(t)$ is continuous in $(-\infty, \infty)$. We call \hat{f} the \dagger Fourier transform of f . If $f(x) \in L_2(-\infty, \infty)$, then $f(x) \in L_1(-a, a)$ for any finite interval $(-a, a)$, and if we set

$$\hat{f}_a(t) = (2\pi)^{-1/2} \int_{-a}^a f(x) e^{-itx} dx,$$

then \hat{f}_a \dagger converges in the mean of order 2 as $a \rightarrow \infty$ to a function \hat{f} in L_2 . In this case, we define \hat{f} to be the \dagger Fourier transform of f ($\in L_2$). Furthermore, in this case, if we set

$$f_a(x) = (2\pi)^{-1/2} \int_{-a}^a \hat{f}(t) e^{itx} dt,$$

then $\lim_{a \rightarrow \infty} f_a(x) = f(x)$ (**Plancherel theorem**). Moreover, we have \dagger Parseval's identity: $\int_{-\infty}^{\infty} |f(x)|^2 dx = \int_{-\infty}^{\infty} |\hat{f}(t)|^2 dt$ (\rightarrow 160 Fourier Transform).

Suppose that $f(x)$ is periodic with period 2π and $f \in L_2(-\pi, \pi)$. We set

$$a_n = (2\pi)^{-1} \int_{-\pi}^{\pi} f(x) e^{-inx} dx$$

(\dagger Fourier coefficients). The n th partial sum of the \dagger Fourier series $s_n(x) = \sum_{v=-n}^n a_v e^{ivx}$ converges in the mean of order 2 to $f(x)$, and Parseval's identity

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} |f(x)|^2 dx = \sum_{n=-\infty}^{\infty} |a_n|^2$$

holds. On the other hand, if $\{a_n\}$ is a given sequence such that $\sum_{n=-\infty}^{\infty} |a_n|^2 < \infty$, then $\sum_{v=-n}^n a_v e^{ivx}$ converges in the mean of order 2 to a function $f(x)$, the Fourier coefficients of $f(x)$ are $\{a_n\}$, and Parseval's identity holds (\rightarrow 159 Fourier Series).

B. Bochner's Theorem and Herglotz's Theorem

A complex-valued function $f(x)$ defined on $(-\infty, \infty)$ is said to be of **positive type** (or **positive definite**) if $\sum_{j,k=1}^n f(x_j - x_k) \xi_j \bar{\xi}_k \geq 0$ for any finite number of reals x_1, x_2, \dots, x_n and complex numbers $\xi_1, \xi_2, \dots, \xi_n$. If $f(x)$ is measurable on $(-\infty, \infty)$ and of positive type, then there exists a \dagger monotone increasing real-

valued bounded function $\alpha(t)$ such that

$$f(x) = \int_{-\infty}^{\infty} e^{itx} d\alpha(t) \quad (2)$$

for almost all x . If $\alpha(-\infty) = 0$ and $\alpha(t)$ is right continuous, then $\alpha(t)$ is unique (**Bochner's theorem**). Conversely, if $\alpha(t)$ is nondecreasing and bounded and $f(x)$ is defined by (2), then $f(x)$ (called the **Fourier-Stieltjes transform** of $\alpha(t)$) is continuous and of positive type.

A sequence $\{a_n\}$ ($-\infty < n < \infty$) is said to be **positive definite** (or of **positive type**) if $\sum_{j,k=1}^n a_{j-k} \xi_j \bar{\xi}_k \geq 0$ for finitely many arbitrarily chosen complex numbers $\xi_1, \xi_2, \dots, \xi_n$. If $\{a_n\}$ is of positive type, then there exists a monotone increasing bounded function $\alpha(t)$ on $[-\pi, \pi]$ such that

$$a_n = \int_{-\pi}^{\pi} e^{int} d\alpha(t)$$

(**Herglotz's theorem**). Conversely, if $\alpha(t)$ is monotone increasing and bounded and a_n is defined by the above integral, then the sequence $\{a_n\}$ is of positive type.

C. Poisson's Summation Formula

If $f(x) \in L_1(-\infty, \infty)$ is of \dagger bounded variation and continuous and if $\hat{f}(t)$ is its Fourier transform, then we have

$$\sqrt{a} \sum_{k=-\infty}^{\infty} f(ak) = \sqrt{b} \sum_{k=-\infty}^{\infty} \hat{f}(bk),$$

where $ab = 2\pi$ ($a > 0$). This is called **Poisson's summation formula**.

D. Generalized Tauberian Theorems of Wiener

Suppose that we are given a function $f(x) \in L_1(-\infty, \infty)$ whose Fourier transform $\hat{f}(t)$ is never zero. Then the set of functions given by

$$h(x) = \int_{-\infty}^{\infty} f(x-y)g(y)dy,$$

where $g \in L_1(-\infty, \infty)$, is dense in $L_1(-\infty, \infty)$. Hence we can deduce the \dagger generalized Tauberian theorem of Wiener: If the Fourier transform $\hat{k}_1(t)$ of $k_1(x) \in L_1(-\infty, \infty)$ does not vanish for any real t and

$$\lim_{x \rightarrow \infty} \int_{-\infty}^{\infty} k_1(x-y)f(y)dy = C \int_{-\infty}^{\infty} k_1(y)dy$$

for a function $f(x)$ that is bounded and measurable on $(-\infty, \infty)$, then for any $k_2 \in L_1(-\infty, \infty)$,

$$\lim_{x \rightarrow \infty} \int_{-\infty}^{\infty} k_2(x-y)f(y)dy = C \int_{-\infty}^{\infty} k_2(y)dy$$

(→ 160 Fourier Transform G). Hence we can deduce †Tauberian theorems of the Littlewood type [3].

E. Harmonic Analysis

Let $\alpha(\lambda)$ be a complex-valued function on $(-\infty, \infty)$ that is of bounded variation and right continuous. If we have the expression

$$f(t) = \int_{-\infty}^{\infty} e^{i\lambda t} d\alpha(\lambda), \quad (2')$$

then we say that the function $f(t)$ is represented by the superposition of harmonic oscillations $e^{i\lambda t}$. Conversely, when $f(t)$ is given, we have the problem of finding a function $\alpha(\lambda)$ as above such that $f(t)$ can be expressed in the form of (2'). When such a function $\alpha(\lambda)$ exists, it is also an important problem (in harmonic analysis) to find the amplitude $\alpha(\lambda) - \alpha(\lambda - 0)$ of the component of a proper oscillation. Concerning this problem, we have the following three theorems:

(I) A necessary and sufficient condition for $f(x)$ to be representable in the form (2') is

$$\sup_{1 \leq n} \int_{-\infty}^{\infty} \left| \int_{-\infty}^{\infty} \left(\frac{\sin(t/n)}{t/n} \right)^2 f(t) e^{-i\lambda t} dt \right| d\lambda < \infty.$$

(II) For a function $f(t)$ expressed in the form (2'), we have: (i) for any λ_0 ,

$$\alpha(\lambda_0) - \alpha(\lambda_0 - 0) = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T f(t) e^{-i\lambda_0 t} dt,$$

and (ii) if $\alpha(\lambda)$ is continuous at $\lambda = \lambda_0 - \sigma$ and $\lambda = \lambda_0 + \sigma$ ($\sigma > 0$), then

$$\begin{aligned} & \alpha(\lambda_0 + \sigma) - \alpha(\lambda_0 - \sigma) \\ &= \lim_{T \rightarrow \infty} \sqrt{\frac{2}{\pi}} \int_{-T}^T \frac{\sin \sigma t}{t} f(t) e^{-i\lambda_0 t} dt. \end{aligned}$$

(III) In (2'), suppose that the discontinuity points of $\alpha(\lambda)$ are $\lambda_1, \lambda_2, \dots$, and set $a_n = \alpha(\lambda_n) - \alpha(\lambda_n - 0)$ ($n = 1, 2, \dots$); then

$$\lim_{S \rightarrow \infty} \frac{1}{S} \int_0^S f(t+s) f(\bar{s}) ds = \sum_{n=1}^{\infty} |a_n|^2 e^{i\lambda_n t}.$$

F. The Paley-Wiener Theorem

In formula (1), if we change the variable from t to a complex variable $\zeta = t + i\sigma$, then we have

$$F(\zeta) = (2\pi)^{-1/2} \int_{-\infty}^{\infty} f(x) e^{-i\zeta x} dx, \quad (3)$$

which is called the **Fourier-Laplace transform** of $f(x)$. In particular, if $f(x)$ has bounded †support, then $F(\zeta)$ is an †entire function. Concerning Fourier-Laplace transforms, Paley and Wiener proved the following theorems:

(I) A necessary and sufficient condition for an entire function $F(\zeta)$ to be the Fourier-Laplace transform of a †function of class C^∞ having its support in a finite interval $[-B, B]$ is that for any N , there exists a constant $C_N > 0$ such that $|F(\zeta)| \leq C_N (1 + |\zeta|)^{-N} e^{B|\sigma|}$ for all $\zeta = t + i\sigma$.

(II) If $g(t) \in L_2(0, \infty)$, then its one-sided †Laplace transform

$$f(z) = (2\pi)^{-1/2} \int_0^\infty g(t) e^{-tz} dt$$

satisfies: (i) $f(z)$ is holomorphic in the right half-plane $\operatorname{Re} z > 0$, and (ii)

$$\sup_{x>0} \int_{-\infty}^{\infty} |f(x+iy)|^2 dy < \infty.$$

Conversely, if $f(z) = f(x+iy)$ ($x > 0$) satisfies (i) and (ii), then the boundary function $f(iy) \in L_2(-\infty, \infty)$ exists and is such that

$$\lim_{x \downarrow 0} \int_{-\infty}^{\infty} |f(iy) - f(x+iy)|^2 dy = 0,$$

its Fourier transform in L_2

$$g(t) = \text{l.i.m.}_{N \rightarrow \infty} (2\pi)^{-1/2} \int_{-N}^N f(iy) e^{ity} dy$$

vanishes at almost all negative t , and $f(z)$ is the one-sided Laplace transform of $g(t)$.

G. Harmonic Analysis on Locally Compact Abelian Groups

The general theory of harmonic analysis on the real line was extended to a theory on locally compact Abelian groups by A. Weil, I. M. Gel'fand, D. A. Raikov, and others. The theory of normed rings was utilized for the development of the theory (→ 36 Banach Algebras). This theory is called **harmonic analysis on locally compact Abelian groups**, and it has been developed as described in the following sections.

H. Group Rings

Let $L_1 = L_1(G)$ be the set of all integrable functions with respect to a †Haar measure on a locally compact Abelian group G . If we define the norm and multiplication in $L_1(G)$ by

$$\|f\| = \int_G |f(x)| dx,$$

$$f \cdot g(x) = \int_G f(xy^{-1}) g(y) dy,$$

respectively, then L_1 has the structure of a commutative †Banach algebra. (We call $f \cdot g$ the **convolution** (or **composition product**) of f

and g .) If the topology of G is not † discrete, $L_1(G)$ does not have a unity for multiplication. Hence, adjoining a formal unity $\mathbf{1}$ to $L_1(G)$, we set $R = \{\alpha\mathbf{1} + f \mid \alpha \text{ is a complex number, } f \in L_1(G)\}$, and

$$\|\alpha\mathbf{1} + f\| = |\alpha| + \|f\|,$$

$$(\alpha\mathbf{1} + f) + (\beta\mathbf{1} + g) = (\alpha + \beta)\mathbf{1} + (f + g),$$

$$(\alpha\mathbf{1} + f) \cdot (\beta\mathbf{1} + g) = (\alpha\beta)\mathbf{1} + (\beta f + \alpha g + f \cdot g).$$

Then R is a commutative Banach algebra with unity. When G is discrete, $R = L_1(G)$. The Banach algebra R is called the **group algebra** of G . The group algebra R of G is † semisimple. R is algebraically isomorphic to a subalgebra of $C(\mathfrak{M})$, which is the associative algebra of all continuous functions on the compact Hausdorff space \mathfrak{M} consisting of all maximal ideals in R (\rightarrow 36 Banach Algebras). By this correspondence, if $\varphi \in R$ corresponds to $\varphi(M)$, which is a function on \mathfrak{M} , then $\sup_{M \in \mathfrak{M}} |\varphi(M)| \leq \|\varphi\|$. $L_1(G)$ belongs to \mathfrak{M} if and only if the group G is not discrete.

I. Fourier Transforms

According as the group G is discrete or not, we set $\mathfrak{R} = \mathfrak{M}$ or $\mathfrak{R} = \mathfrak{M} - \{L_1(G)\}$. Then there exists a one-to-one correspondence between the elements $M \in \mathfrak{R}$ and the elements χ of the † character group \hat{G} of G such that the following formulas are valid:

$$f(M) = \int_G \chi(x) f(x) dx, \quad f \in L_1, \quad (4)$$

$$\chi(y) = f_y(M) / f(M), \quad (5)$$

where $f_y(x) = f(xy^{-1})$ and f is a function such that $f(M) \neq 0$. This correspondence $M \leftrightarrow \chi$ gives a homeomorphism between the locally compact space \mathfrak{R} and \hat{G} . Hence if we identify M with χ and set $f(M) = \hat{f}(\chi)$, then \hat{f} is a continuous function on \hat{G} , called the **Fourier transform** of $f(x)$. Since $f \rightarrow f(M)$ is an algebraic isomorphism, $(fg)^{\wedge}(\chi) = \hat{f}(\chi)\hat{g}(\chi)$. If $\hat{f}(\chi) \equiv \hat{g}(\chi)$, then f is equal to g in $L_1(G)$. This is the **uniqueness theorem** of Fourier transforms. From it we can deduce the † maximal almost periodicity of locally compact Abelian groups.

If G is not discrete, then $L_1(G) \in \mathfrak{M}$, and $f(L_1(G)) = 0$ for $f \in L_1(G)$. Hence $\{\chi \mid |\hat{f}(\chi)| \geq \varepsilon\}$ is a compact subset of \hat{G} . This means that \hat{f} is a continuous function vanishing at infinity on \hat{G} . (This is a generalization of the † Riemann-Lebesgue theorem concerning the cases $G = \mathbf{R}^1$ or $\mathbf{T}^1 = \mathbf{R}/\mathbf{Z}$.) Any continuous function $u(\chi)$ on \hat{G} vanishing at infinity is approximated uniformly by $\hat{f}(\chi)$, which is the Fourier transform of $f \in L_1(G)$.

J. Positive Definite Functions

A function $\varphi(x)$ defined on G is said to be **positive definite** (or of **positive type**) if the inequality $\sum_{j,k=1}^n \varphi(x_j x_k^{-1}) \alpha_j \bar{\alpha}_k \geq 0$ holds for arbitrary elements x_1, \dots, x_n in G and arbitrary complex numbers $\alpha_1, \dots, \alpha_n$. We denote by P_G the set of all positive definite functions on G . If $\varphi \in P_G$, then $\varphi(e) > 0$ (e is the identity of G), $|\varphi(x)| \leq \varphi(e)$, and $\varphi(x^{-1}) = \overline{\varphi(x)}$. If G is locally compact, we further assume that $\varphi \in P_G$ is measurable with respect to the Haar measure of G . Then for any $f \in L_1(G)$,

$$\iint \varphi(xy^{-1}) f(y) \overline{f(y)} dx dy \geq 0.$$

Any $\varphi \in P_G$ is equal almost everywhere to a continuous $\varphi_1 \in P_G$. (Concerning positive definite functions on locally compact groups and their relation with unitary representations \rightarrow 437 Unitary Representations B.)

K. Harmonic Analysis and the Duality Theorem

If G is a locally compact Abelian group, then a function $\varphi(x)$ on G belongs to P_G if and only if there exists a nonnegative measure $\mu(\hat{G}) < \infty$ on \hat{G} such that $\varphi(x) = \int_G \chi(x) d\mu(\chi)$. (When $G = \mathbf{R}^1$, this theorem is † Bochner's theorem, whereas when $G = \mathbf{Z}$, it is Herglotz's theorem.) Hence we can prove a spectral resolution of unitary representations of G : $U(x) = \int_G \chi(x) dE(\chi)$ (a generalization of † Stone's theorem). If $f \in L_1(G) \cap P_G$, then $\hat{f}(\chi) \geq 0$, $\hat{f} \in L_1(\hat{G})$, and the **inversion formula** of Fourier transforms $f(x) = \int_G \bar{\chi}(x) \hat{f}(\chi) d\chi$ holds, provided that the Haar measure on G is suitably chosen. If $f \in L_1(G) \cap L_2(G)$, then $\hat{f} \in L_2(\hat{G})$, and **Parseval's identity** $\int_G |f(x)|^2 dx = \int_G |\hat{f}(\chi)|^2 d\chi$ holds. If we put $Uf = \hat{f}$ and $V\hat{f} = f$, then U is extendable uniquely to an isometry of $L_2(G)$ onto $L_2(\hat{G})$ and V is extendable uniquely to its inverse transformation, respectively (**Plancherel's theorem** on locally compact Abelian groups). By the inversion formula and Plancherel's theorem, we can prove that the character group $\hat{\hat{G}}$ of \hat{G} is isomorphic to G as a topological group. This is called the **Pontryagin duality theorem** of locally compact Abelian groups (\rightarrow 422 Topological Abelian Groups). In particular, if G is compact, \hat{G} is a discrete Abelian group. Then we can normalize the Haar measure of G and \hat{G} so that the measure of G and the measure of each element of \hat{G} are 1. Plancherel's theorem implies that the set of characters of G is a † complete † orthonormal set in $L_2(G)$.

L. Poisson's Summation Formula

Suppose that G is a locally compact Abelian group, H is its discrete subgroup, and G/H is compact. Then the * annihilator Γ of H is a discrete subgroup of \hat{G} . For any continuous function $f(x)$ on G , if $\sum_{y \in H} f(xy)$ is convergent absolutely and uniformly (hence $f \in L_1(G)$) and $\sum_{\xi \in \Gamma} \hat{f}(\xi)$ is convergent absolutely, then $\sum_{y \in H} f(y) = c \sum_{\xi \in \Gamma} \hat{f}(\xi)$, where c is a constant depending on the Haar measures of G and \hat{G} . This is called **Poisson's summation formula** on a locally compact Abelian group (a generalization of * Poisson's summation formula on $G = \mathbf{R}$).

M. Closed Ideals in $L_1(G)$

In the following, the group operations in G and \hat{G} are denoted by $+$, and the value of the character $\gamma(x)$ ($x \in G, \gamma \in \hat{G}$) is written as (x, γ) .

For a function f defined on G and any $y \in G$, the translation operator τ_y is defined by $\tau_y f(x) = f(x - y)$. A closed subspace of $L_1(G)$ is an ideal in $L_1(G)$ if and only if it is invariant under all translations (N. Wiener). A closed ideal I coincides with $L_1(G)$ if and only if the set of zeros of I , i.e., $Z(I) = \bigcap_{f \in I} \hat{f}^{-1}(0)$, is empty (Wiener's Tauberian theorem). A closed ideal I is maximal if and only if $Z(I)$ consists of a single point. If the dual \hat{G} of G is discrete, then the closed ideals in $L_1(G)$ are completely characterized by the zeros; that is, * spectral synthesis is possible, but this situation does not hold generally. P. Malliavin's theorem states that if \hat{G} is not discrete, then there exists a set E in \hat{G} and two different closed ideals I and J such that $Z(I) = Z(J) = E$. Such a set E is called a non-S-set. For example, if $\hat{G} = \mathbf{R}^3$, the unit sphere is a non-S-set (L. Schwartz).

N. Operating Functions

Denote by $A(\hat{G})$ the set of all Fourier transforms of the functions in $L_1(G)$. Let $\hat{f} \in A(\hat{G})$ and Φ an analytic function in a neighborhood of the range of \hat{f} . Furthermore, assume that $\Phi(0) = 0$ if G is not discrete. Then there exists a $\hat{g} \in A(\hat{G})$ such that $\hat{g}(\gamma) = \Phi(\hat{f}(\gamma))$ for $\gamma \in \hat{G}$ (Wiener-Lévy theorem). In general a function Φ defined on a set D in the complex plane is said to **operate** in a function algebra R or to be an **operating function** on R if $\Phi(f) \in R$ for all $f \in R$ whose range lies in D . The converse of the Wiener-Lévy theorem holds in the following form. Let G be an infinite Abelian group and Φ a function on the interval $[-1, 1]$. If Φ operates in $A(G)$, then Φ is analytic in a neighborhood of the origin if G is compact, and

analytic in a neighborhood of $[-1, 1]$ if G is not compact [14, 15]. Let E be a subset of \hat{G} , and I_E the set of all $\hat{f} \in A(\hat{G})$ such that $\hat{f} = 0$ on E . Let $A(E) = A(\hat{G})/I_E$ be the quotient algebra. The set E is called a **set of analyticity** if every operating function on $A(E)$ is analytic. For a characterization of such a set \rightarrow [11].

O. Measure Algebras

For a locally compact Abelian group G , let $M(G)$ be the set of all * regular bounded complex measures. For λ and μ in $M(G)$, the convolution $\lambda * \mu$ is defined by $(\lambda * \mu)(E) = \int_G \lambda(E - y) \cdot d\mu(y)$, where E is a Borel set in G . Then $M(G)$ is a semisimple commutative Banach algebra whose product is defined to be the convolution. The Fourier-Stieltjes transform of $\mu \in M(G)$ is defined by

$$\hat{\mu}(\gamma) = \int_G (x, \gamma) d\mu(x), \quad \gamma \in \hat{G}.$$

A continuous function on \hat{G} is positive definite if and only if it is the Fourier-Stieltjes transform of a positive measure in $M(G)$ (Bochner's theorem). Assume that G is not discrete. A function on the interval $[-1, 1]$ that operates in the Fourier-Stieltjes transforms of measures in $M(G)$ can be extended to an entire function, and a function on the whole complex plane that operates in the * Gelfand representation of $M(G)$ is an entire function [15]. From this fact, it follows that $M(G)$ is asymmetric and nonregular. Furthermore, there exists a measure $\mu \in M(G)$ such that $\hat{\mu}(\gamma) \geq 1$ but $1/\hat{\mu}$ is not a Fourier-Stieltjes transform of $M(G)$. (See also Wiener and Pitt [16], Shreider [17], and Hewitt and Kakutani [18]; for the general description of measure algebra, see Rudin [11] and Hewitt and Ross [12].)

P. Idempotent Measures

A measure $\mu \in M(G)$ is called **idempotent** if $\mu * \mu = \mu$, that is, $\hat{\mu}(\gamma) = 0$ or 1 for all $\gamma \in \hat{G}$. Then $\hat{\mu}$ is the characteristic function of the set $\{\gamma \in \hat{G} | \hat{\mu}(\gamma) = 1\}$. The smallest ring of subsets of \hat{G} that contains all open cosets of subgroups of \hat{G} is called the coset ring of \hat{G} . The characteristic function of a set E in \hat{G} is the Fourier-Stieltjes transform of an idempotent measure in $M(G)$ if and only if E belongs to the coset ring of \hat{G} [19]. A simple proof of this theorem is given by T. Ito and I. Amemiya (*Bull. Amer. Math. Soc.*, 70 (1964)). When G is the unit circle, the coset ring consists of sequences periodic except at a finite number of points, and for this case the theorem was obtained by H. Helson. Let

n_1, n_2, \dots, n_k be distinct integers and $d\mu(x) = \sum_{j=1}^k e^{in_j x} \cdot dx$. Then μ is an idempotent measure on the unit circle. J. E. Littlewood conjectured that the norm of μ exceeds $c \log k$, where c is a positive constant not depending on the choice of $\{n_j\}$. A partial answer was given by P. J. Cohen [19] for compact connected Abelian groups and was improved by H. Davenport (*Mathematika*, 7 (1960)) and E. Hewitt and H. S. Zuckerman (*Proc. Amer. Math. Soc.*, 14 (1963)).

Q. Mappings of Group Algebras

Let G and H be two locally compact Abelian groups and φ a nontrivial homomorphism of $L_1(G)$ into $M(H)$. Associated with φ there is a mapping φ^* of a subset Y of \hat{H} into \hat{G} such that $\varphi(f)(\gamma) = \hat{f}(\varphi^*(\gamma))$ for $\gamma \in Y$ and $= 0$ for $\gamma \notin Y$, or symbolically $\varphi(f) = \hat{f}(\varphi^*)$. A continuous mapping α of Y into \hat{G} is said to be piecewise affine if there exist a finite number of mutually disjoint sets S_j , $j = 1, \dots, n$, in the coset ring of \hat{H} and mappings α_j such that (i) $Y = \bigcup_{j=1}^n S_j$; (ii) α_j is defined on an open coset K_j of \hat{H} , where $K_j \supset S_j$; (iii) $\alpha_j = \alpha$ on S_j ; and (iv) $\alpha_j(\gamma + \gamma' - \gamma'') = \alpha_j(\gamma) + \alpha_j(\gamma') - \alpha_j(\gamma'')$ for all $\gamma, \gamma', \gamma'' \in K_j$, $j = 1, \dots, n$. P. J. Cohen's theorem is: If φ is a homomorphism of $L_1(G)$ into $M(H)$, then Y belongs to the coset ring of \hat{H} and φ^* is a piecewise affine mapping of Y into \hat{G} . Conversely, for any piecewise affine mapping α , there is a homomorphism φ of $L_1(G)$ into $M(H)$ such that $\varphi^* = \alpha$. Related theorems have been studied by A. Beurling, H. Helson, J.-P. Kahane, Z. L. Leibenson, and W. Rudin [11].

R. Exceptional Sets

Let G be a locally compact Abelian group. A subset E is said to be independent if $n_1 x_1 + \dots + n_k x_k = 0$, where the n_j are integers and $x_j \in E$ implies $n_j x_j = 0$, $j = 1, \dots, k$. A set E in G is called a **Kronecker set** if for every continuous function φ on E of absolute value 1 and $\varepsilon > 0$ there exists a $\gamma \in \hat{G}$ such that $|\varphi(x) - (x, \gamma)| < \varepsilon$, $x \in E$. Every Kronecker set is independent and of infinite order, but independent sets are not necessarily Kronecker sets. For a group G whose elements are of finite order p , a set E is called of type K_p if for every continuous function φ on E with values $\exp(2\pi i k/p)$, $k = 0, \dots, p-1$, there is a $\gamma \in \hat{G}$ such that $\varphi = \gamma$ on E . If E is a compact Kronecker set in G and μ is a measure with support in E , i.e., $\mu \in M(E)$, then $\|\mu\| = \|\hat{\mu}\|_\infty$. A compact set E is called a **Helson set** if there is a constant C such that $\|\mu\| \leq C \|\hat{\mu}\|_\infty$ for $\mu \in M(E)$. Every K_p set is also a Helson set. For a Helson set E , $C(E) = A(E)$. A discrete

analog of a Helson set is a Sidon set. A subset F of a discrete group \hat{G} is called a **Sidon set** if there is a constant C such that $\sum_{\gamma \in F} |a_\gamma| \leq C \sup_x |\sum_{\gamma \in F} a_\gamma(x, \gamma)|$ for every polynomial $\sum a_\gamma(x, \gamma)$. For example, a lacunary sequence $\{n_k\}$, $n_{k+1}/n_k > q > 1$, of integers is a Sidon set. These sets are deeply connected with harmonic analysis on groups, and measures concentrated on these sets have some unexpected pathological properties (\rightarrow e.g., [11, 13]).

S. Tensor Algebras and Group Algebras

Let X and Y be compact Hausdorff spaces, and denote by $V(X, Y)$ the projective tensor product $C(X) \hat{\otimes} C(Y)$ of continuous function spaces $C(X)$ and $C(Y)$. The norm of $\varphi(x, y) = \sum_{j=1}^\infty f_j(x)g_j(y)$ is defined by $\|\varphi\| = \inf \sum_{j=1}^\infty \|f_j\|_\infty \|g_j\|_\infty$, where the infimum is taken for all expressions of φ . If \hat{G} is an infinite compact group, then there exist two subsets K_1 and K_2 such that (i) K_1 and K_2 are homeomorphic to the Cantor ternary set; (ii) the expression $\gamma_1 + \gamma_2$ of an element of $E = K_1 + K_2$ is unique, where $\gamma_1 \in K_1$ and $\gamma_2 \in K_2$; (iii) $K_1 \cap K_2 \neq \emptyset$; and (iv) $K_1 \cup K_2$ is a Kronecker set or a set of type K_p for some p . Varopoulos' theorem states that the algebra $V(K_1, K_2)$ is isomorphic to $A(E)$ which denotes the algebra of restriction of functions in $A(\hat{G})$ on the set E . By this theorem, the problems of spectral synthesis and operating functions of group algebras are transformed into problems of tensor algebras. For a more precise discussion \rightarrow [20].

Harmonic Functions and Subharmonic Functions

A. General Remarks

A real-valued function u of \dagger class C^2 defined in a domain D in the n -dimensional Euclidean space \mathbf{R}^n is called **harmonic** if it satisfies the Laplace equation

$$\Delta u(P) = \frac{\partial^2 u}{\partial x_1^2} + \dots + \frac{\partial^2 u}{\partial x_n^2} = 0 \quad (P = (x_1, \dots, x_n))$$

in D . A harmonic function is, by definition, twice continuously differentiable, but turns out to be real analytic. It is not true, however, that the solutions of the Laplace equation are real analytic. For example, for the function $u(x, y) = \operatorname{Re} \exp(-z^{-4})$ ($z = x + iy \neq 0$), $u(0, 0) = 0$, u_{xx} and u_{yy} exist everywhere, and u satisfies the

Laplace equation, but is not continuous at the origin.

The fundamental properties of harmonic functions do not depend essentially on n .

A real-valued function u of class C^2 satisfying the inequality $\Delta u \geq 0$ is called **subharmonic**. For a more general definition of subharmonic functions and their properties — Sections P–U.

B. Invariance of Harmonicity

Harmonicity in \mathbf{R}^2 is invariant under any \dagger conformal transformation. Namely, when there exists a conformal bijection sending a domain D in the xy -plane onto a domain D' in the $\xi\eta$ -plane, every harmonic function $u(x, y)$ on D is transformed into a harmonic function of (ξ, η) on D' . In \mathbf{R}^n for $n \geq 3$, harmonicity is not generally preserved under conformal transformations. However, harmonicity is preserved in the following special case: Let D be a domain in \mathbf{R}^n ($n \geq 3$), and consider the **inversion** $f: D \rightarrow D'$ defined by $f(x_1, \dots, x_n) = (x'_1, \dots, x'_n) = (a^2 x_1 / r^2, \dots, a^2 x_n / r^2)$, $r = (x_1^2 + \dots + x_n^2)^{1/2}$. Let $u(x_1, \dots, x_n)$ be a harmonic function on D , and let $v(x'_1, \dots, x'_n)$ be the function on D' obtained by applying the **Kelvin transformation** to u . Namely, $v(x'_1, \dots, x'_n) = (a/r')^{n-2} u(a^2 x'_1 / r'^2, \dots, a^2 x'_n / r'^2)$, where $r'^2 = x_1'^2 + \dots + x_n'^2$. Then the function v is harmonic on D' . A function u that is harmonic outside a compact set is called **regular at the point at infinity** if any Kelvin transform of u is harmonic in a neighborhood of the origin, in which case $u(P) \rightarrow 0$ as $\overline{OP} \rightarrow \infty$. Now let $T: x_k = x_k(x'_1, \dots, x'_n)$, $1 \leq k \leq n$, be a one-to-one analytic transformation of a domain D' onto another domain D . If there exists a positive function $\varphi(x'_1, \dots, x'_n)$ in D' such that $\varphi(x'_1, \dots, x'_n) u(x_1(x'_1, \dots, x'_n), \dots, x_n(x'_1, \dots, x'_n))$ is harmonic for any harmonic function $u(x_1, \dots, x_n)$ in D , then T is conformal. A conformal transformation as it is known in differential geometry is either (i) a \dagger similarity transformation, (ii) an inversion with respect to a sphere or a plane, or (iii) a finite combination of transformations of types (i) and (ii).

C. Examples of Harmonic Functions

(1) If u is a polynomial in x_1, \dots, x_n and harmonic in \mathbf{R}^n , then the terms of degree k in u form a harmonic function for each $k \geq 0$. A harmonic homogeneous polynomial is said to be a **spherical harmonic**. (2) $\log r$ in \mathbf{R}^2 and r^{2-n} in \mathbf{R}^n ($n \geq 3$) are harmonic except at $r = 0$. (3) Every \dagger logarithmic potential in \mathbf{R}^2 and every \dagger Newtonian potential in \mathbf{R}^n ($n \geq 3$) is harmonic outside the \dagger support of the measure. Con-

Harmonic Functions and Subharmonic Functions

versely, any harmonic function defined on a domain D is represented in an arbitrary relatively compact domain D' in D as the sum of a logarithmic ($n=2$) or Newtonian ($n \geq 3$) potential of a measure on $\partial D'$ and the potential of a \dagger double layer. (4) Both the real part u and the imaginary part v of an analytic function of a complex variable are harmonic. We call v a **conjugate harmonic function** of u . If u is harmonic on a \dagger simply connected domain D , then the conjugate v of u is given by

$$v(x, y) = \int_{(a, b)}^{(x, y)} \left(-\frac{\partial u}{\partial y} dx + \frac{\partial u}{\partial x} dy \right) + \text{constant},$$

where (a, b) is a fixed point in D and the path of integration is contained in D . When D is a \dagger multiply connected domain, v may take many values in accordance with the \dagger homology classes of the paths of integration.

D. Green's Formulas

In the following one should substitute "curve" for the term "surface" when $n=2$. Let D be a bounded domain whose boundary S consists of a finite number of closed surfaces that are piecewise of class C^1 . Let u and v be harmonic in D , and suppose that all the first-order partial derivatives of u and v have finite limits at every boundary point. We call D the inside of S . Let n be a normal on S toward the outside of D . Then the relation

$$\int_S \left(u \frac{\partial v}{\partial n} - v \frac{\partial u}{\partial n} \right) d\sigma = 0 \quad (1)$$

follows immediately from \dagger Gauss's formula, where $d\sigma$ is the \dagger surface element on S . In particular, when v is identically equal to 1, formula (1) gives

$$\int_S \frac{\partial u}{\partial n} d\sigma = 0. \quad (2)$$

Equations (1) and (2) are called **Green's and Gauss's formulas**, respectively. Conversely, u is harmonic in D if u is a function of class C^2 in D and at every point $p \in D$, there is a sequence $\{r_k\}$ decreasing to zero and such that $\int_{S(P, r_k)} (\partial u / \partial n) d\sigma = 0$ ($k = 1, 2, \dots$), where $S(P, r_k)$ is the spherical surface with center at P and radius r_k . Another sufficient condition for u to be harmonic is that u is of class C^1 and, at every point $P \in D$, there be an $r_p > 0$ such that $\int_{S(P, r)} (\partial u / \partial n) d\sigma = 0$ for every r , $0 < r < r_p$ (Koebe, Bocher).

E. Mean Value Theorems

We assume that u is a harmonic function, D the domain of definition of u , and S the bound-

ary of D . The mean value of u on the surface or the interior of any ball in D is equal to the value of u at the center of the ball. Namely,

$$u(P) = \frac{1}{\tau_n r^n} \int_{B(P, r)} u d\tau = \frac{1}{\sigma_n r^{n-1}} \int_{S(P, r)} u d\sigma,$$

where τ_n and σ_n are the volume and surface area of a unit ball in \mathbf{R}^n , respectively, $B(P, r)$ is the open ball with center at P and radius r , and $d\tau$ is the volume element. These relations are called **mean value theorems**. Conversely, if v is continuous in D and at every point $P \in D$, there is a sequence $\{r_k\}$ decreasing to zero and such that the mean value of v over $B(P, r_k)$ or $S(P, r_k)$ is equal to $v(P)$ for each k , then v is harmonic in D . This result is called **Koebe's theorem**. From the mean value theorems the **maximum principle** for harmonic functions follows: Any nonconstant u assumes neither maximum nor minimum in D . If both u and v are harmonic in D and have the same finite boundary value at every point on S , then $u \equiv v$ in D by the maximum principle. This is called the **uniqueness theorem**.

F. Boundary Value Problems

The **first boundary value problem** (or **Dirichlet problem**) is the problem of finding a harmonic function defined on D that assumes boundary values prescribed on S (\rightarrow 120 Dirichlet Problem). The **second boundary value problem** (or **Neumann problem**) is the problem of finding a harmonic function u whose normal derivative $\partial u / \partial n$ is equal to a function f prescribed on the piecewise smooth boundary S . The solution, if it exists, is uniquely determined up to an additive constant. In order for the solution to exist, f should satisfy the condition $\int_S f d\sigma = 0$. The **third boundary value problem** is the problem of finding a harmonic function u on D that satisfies $\partial u / \partial n = hu + f$ on S , where h and f are functions prescribed on S . All these problems can be reduced to certain \dagger Fredholm integral equations. There is also the boundary value problem of mixed type, in which the boundary values are prescribed in a part of S and the normal derivatives are prescribed on the rest.

G. The Poisson Integral

Let D be a bounded domain with smooth boundary S and u a function harmonic in D and continuous on $D \cup S$. Let $G(P, Q)$ be Green's function in D . Then (1) yields

$$u(P) = -\frac{1}{\sigma_n} \int_S u(Q) \frac{\partial G(P, Q)}{\partial n_Q} d\sigma(Q).$$

In particular, if $D = B(0, r)$, then

$$u(P) = \frac{r^2 - \overline{OP}^2}{\sigma_n r} \int_{S(0, r)} \frac{u(Q)}{PQ^n} d\sigma(Q).$$

Conversely, given an integrable function f on $S(0, r)$, we set

$$u(P) = \frac{r^2 - \overline{OP}^2}{\sigma_n r} \int_{S(0, r)} \frac{f(Q)}{PQ^n} d\sigma(Q).$$

Then $u(p)$ is harmonic in $B(0, r)$ and converges to $f(Q)$ as P tends to any point Q on $S(0, r)$ where f is continuous. We call u a **Poisson integral**. Sometimes it is possible to represent a harmonic function u in $B(0, r)$ in the following form, which is more general than the Poisson integral:

$$u(P) = \frac{r^2 - \overline{OP}^2}{\sigma_n r} \int_{S(0, r)} \frac{1}{PQ^n} d\alpha(Q), \quad (3)$$

where α is a signed \dagger Radon measure on $S(0, r)$. In order for u to admit such a representation, it is necessary and sufficient that $\int_{S(0, r)} |u| d\sigma$ be a bounded function of r' for $0 < r' < r$, or equivalently, that the \dagger subharmonic function $|u|$ have a \dagger harmonic majorant. Furthermore, if α is absolutely continuous, then the Poisson integral representation of u is possible, and vice versa. A necessary and sufficient condition for the function u to admit the Poisson integral representation is that there exist a positive convex function $\varphi(t)$ on $t > 0$ such that $\varphi(t)/t \rightarrow \infty$ as $t \rightarrow \infty$ and $\varphi(|u|)$ has a harmonic majorant.

When D is a general domain in which Green's function exists, every positive harmonic function $u(P)$ is represented uniquely as the integral $\int K(P, Q) d\mu(Q)$, where $K(P, Q)$ is a \dagger Martin kernel and μ is a Radon measure on the Martin boundary B whose support is contained in a certain essential part of B , each point of which is called a minimal point. A similar integral representation appears in the theory of Markov processes (\rightarrow 260 Markov Chains I). The representation $\int K(P, Q) d\mu(Q)$ is a generalization of (3). In terms of a function similar to $\varphi(t)$, we can give a necessary and sufficient condition for $u(P)$ to be represented in the form $\int K(P, Q) f(Q) dv(Q)$, which corresponds to the Poisson integral representation and in which v is determined by $1 = \int K(P, Q) dv(Q)$. This condition is equivalent to the condition that $u(P)$ be **quasibounded**, i.e., that there exist an increasing sequence of bounded harmonic functions that converges to u [7].

A positive harmonic function u is said to be **singular** if any nonnegative harmonic minorant of u vanishes identically. Every positive harmonic function can be expressed as the sum of a quasibounded harmonic function and a singular one.

H. Expansion

Let $P_0 = (x_1^0, \dots, x_n^0)$ be a point in D , and denote the distance from P_0 to S by r . Then a harmonic function u is expanded uniquely into a power series

$$\sum a_{k_1, \dots, k_n} (x_1 - x_1^0)^{k_1} \dots (x_n - x_n^0)^{k_n}, \quad k_1, \dots, k_n \geq 0,$$

in $B(P_0, (\sqrt{2} - 1)r)$. Thus u is (real) analytic in D . If u vanishes on an open set in D , then $u \equiv 0$ in D . If the power series is written as $\sum_k h_k$ with spherical harmonics h_k of degree $k = 1, 2, \dots$, then this series converges over all of $B(P_0, r)$.

I. Sequences of Harmonic Functions

In this section, $\{u_m\}$ is a sequence of harmonic functions in a bounded domain D . First, if each u_m is bounded and continuous on $D \cup S$ and $\{u_m\}$ converges uniformly on S , then $\{u_m\}$ converges uniformly in D , and the limiting function u is harmonic in D . Moreover, $\partial^{k_1 + \dots + k_n} u_m / \partial x_1^{k_1} \dots \partial x_n^{k_n}$ converges to $\partial^{k_1 + \dots + k_n} u / \partial x_1^{k_1} \dots \partial x_n^{k_n}$ uniformly on any compact subset of D (**Harnack's first theorem**). Second, if $u_1 \leq u_2 \leq \dots$ in D and there is a point of D at which $\{u_m\}$ is bounded, then $\{u_m\}$ converges uniformly on any compact subset of D (**Harnack's second theorem**). The following **Harnack's lemma** is useful: If u is positive harmonic in D , P_0 is a point of D , and K is a compact subset of D , then there exist positive constants c and c' , depending only on P_0 and K , such that $cu(P_0) \leq u(P) \leq c'u(P_0)$ on K .

Any family of (locally) uniformly bounded harmonic functions is \dagger normal. A family of positive harmonic functions that is bounded at a point is also normal by Harnack's lemma. If $\int_D |u_k - u_m|^p d\tau \rightarrow 0$ as $k, m \rightarrow \infty$ for $p \geq 1$, then \dagger Hölder's inequality implies that $\{u_m\}$ converges uniformly on any compact subset of D . It follows that if $\int_D |\text{grad}(u_k - u_m)|^p d\tau \rightarrow 0$ as $k, m \rightarrow \infty$ and $\{u_n\}$ converges at a point in D , then there exists a harmonic function u in D such that $\int_D |\text{grad}(u_m - u)|^p d\tau \rightarrow 0$ as $m \rightarrow \infty$ and u_m converges to u uniformly on any compact subset of D , where P_0 is any point in D . Finally, if $\int_D |u_n|^p d\tau$ ($p \geq 1$) are bounded, then $\{u_n\}$ forms a normal family.

J. Level Surfaces and Orthogonal Trajectories

The set $\{P | u(P) = \text{constant}\}$ is called a **level surface (niveau or equipotential surface)**. When a is given as the constant, the level surface is called the a -level surface. Assume that u is not a constant. A point where $\text{grad } u$ vanishes is called **critical**. The set of critical points consists of at most countably many \dagger real analytic

manifolds of dimension $\leq n-2$ ($n = \dim D$, and a manifold of dimension 0 is understood to be a point). Any compact subset of D intersects only a finite number of such manifolds; we express this fact by saying that the manifolds do not cluster in D . Each of these manifolds is contained in a certain level surface. The complement of the critical points with respect to any level surface consists of real analytic manifolds of dimension $n-1$ that do not cluster in D .

For each noncritical point there exists an analytic curve passing through it such that $\text{grad } u$ is parallel to the tangent to the curve at each point on the curve. A maximal curve with this property is called an **orthogonal trajectory** (or **line of force**). Along every orthogonal trajectory, u increases strictly in one direction and hence decreases in the other, so that none of the orthogonal trajectories is a closed curve. There is exactly one orthogonal trajectory passing through any noncritical point. Therefore no two orthogonal trajectories intersect, and no orthogonal trajectory terminates at a noncritical point. Moreover, the set of limit points of any orthogonal trajectory in each direction does not contain any noncritical point. When u is a Green's function $G(P, Q)$, every orthogonal trajectory is called a **Green line**, and a Green line that originates at the pole Q and along which u decreases to 0 is called **regular**. For any sufficiently large a , the a -level surface Σ_a is an analytic closed surface homeomorphic to a spherical surface. Let E be a family of orthogonal trajectories originating at the pole. If the intersection A of E and a closed level surface Σ_a is an $(n-1)$ -dimensional measurable set, then the harmonic measure of A at Q with respect to the interior of Σ_a is called the **Green measure** of E . M. Brelot and G. Choquet proved that all orthogonal trajectories originating at the pole except those belonging to a family of Green measure zero are regular. Consider a domain D bounded by two compact sets, and denote by u the harmonic measure of one compact set with respect to D . Assume that u is not a constant. Then u changes from 0 to 1 along all orthogonal trajectories except those belonging to a family that is small with respect to a measure similar to the Green measure (see "flux" defined in Section K).

K. Harmonic Flows

Denote by Σ_a the a -level surface for a harmonic function u , and by Σ_a^0 the complement of the set of critical points with respect to Σ_a . Let σ be an $(n-1)$ -dimensional domain in Σ_a^0 such that the $(n-2)$ -dimensional boundary of σ is piecewise of class C^2 . Suppose that u assumes

the value b ($> a$) on each orthogonal trajectory passing through σ . Consider the union of orthogonal trajectories that pass through σ . The subset of this union on which u assumes values between a and b forms a set called a **regular tube**. The parts of the boundary corresponding to a and b are called the lower and upper bases of the tube; accordingly, σ is the lower base. The integral $\int (\partial u / \partial n) d\sigma$ on any section (i.e., the part of a level surface in the tube) is constant and is called the **flux** of the tube. The family of orthogonal trajectories passing through an $(n-1)$ -dimensional domain (not necessarily bounded by a smooth boundary) in Σ_a^0 is called a **harmonic flow**, and a subfamily is called a harmonic subflow if its intersection A with Σ_a^0 is measurable (in the $(n-1)$ -dimensional sense). The flux of a harmonic subflow is defined to be $\int_A (\partial u / \partial n) d\sigma$. Then the Green measure of family E of Green lines originating at the pole is equal to the flux of E divided by σ_n . We can compute the exact value of the extremal length of any harmonic subflow.

L. Isolated Singularities

Let u be harmonic in an open ball except at the center O . It is expressed as the sum of a function $h(P)$ harmonic in the entire ball and $\sum_{m=0}^{\infty} H_m(P) / \overline{OP}^{2m+1}$, where H_m is a spherical harmonic of degree m . If $\overline{OP}^\alpha u(P) \rightarrow 0$ as $P \rightarrow O$ for $\alpha > 0$, then $u(P)$ is equal to $h(P) + c / \overline{OP} + \dots + H_m(P) / \overline{OP}^{2m+1}$ with $m < \alpha - 1$. In particular, if u is bounded in a neighborhood of O , then O is a **removable singularity** for u . If u is bounded above (below), then $u(P) = h(P) + c / \overline{OP}^{n-2}$, where $c \leq 0$ ($c \geq 0$). (When $n = 2$, we have $u(p) = h(p) + c \log 1 / \overline{OP}$. For the removability of a set of capacity zero \rightarrow 169 Function-Theoretic Null Sets).

If u is harmonic near the point at infinity, i.e., outside some closed ball, then

$$u(P) = \sum_{m=0}^{\infty} \frac{H_m(P)}{\overline{OP}^{2m+1}} + \sum_{m=0}^{\infty} U_m(P),$$

where the first sum is regular at the point at infinity and U_m is a spherical harmonic of degree m . If $\overline{OP}^{-\alpha} u(P) \rightarrow 0$ as $\overline{OP} \rightarrow \infty$ with $\alpha \geq 0$, then $U_m \equiv 0$ for all $m > \alpha$. If u is bounded above or below, then $U_m \equiv 0$ for all $m \geq 1$. If u is harmonic in \mathbf{R}^n and $\overline{OP}^{-\alpha} u(P) \rightarrow 0$ as $\overline{OP} \rightarrow \infty$ with $\alpha \geq 0$, then u is a polynomial of degree m ($< \alpha$). If u is harmonic and bounded above or below in \mathbf{R}^n , then u is constant. Brelot called a function u harmonic at the point at infinity if

$$u(P) = \text{constant} + \sum_{m=1}^{\infty} \frac{H_m(P)}{\overline{OP}^{2m+1}}$$

(note that $m \geq 1$) near the point at infinity [1].

M. Harmonic Continuation

If u vanishes in a subdomain of D , then $u \equiv 0$ in D . If u_k is harmonic in D_k ($k = 1, 2$), $D_1 \cap D_2 \neq \emptyset$, and $u_1 \equiv u_2$ in $D_1 \cap D_2$, then u_1 and u_2 define a harmonic function in $D_1 \cup D_2$. If the boundaries of mutually disjoint domains D_1 and D_2 have a surface S_0 of class C^1 in common, u_k is harmonic in D_k ($k = 1, 2$), $u_1 = u_2$ on S_0 , and $\partial u_1 / \partial n$ and $-\partial u_2 / \partial n$ exist and coincide on S_0 , then u_1 and u_2 define a harmonic function in the domain $D_1 \cup S_0 \cup D_2$. We express this fact by saying that one of u_1 and u_2 is a **harmonic continuation** of the other. It follows that $u \equiv 0$ in D if the boundary of D contains a surface S_0 of class C^1 and $u = \partial u / \partial n = 0$ on S_0 . Consider the case $n = 2$. If the boundary of a Jordan domain contains an analytic arc C and u (or $\partial u / \partial n$) vanishes on C , then a harmonic continuation of u into a certain domain beyond C is possible. If $n = 3$, however, nothing is known except in the case where S_0 is a part of a spherical surface or a plane and $u = 0$ (or $\partial u / \partial n = 0$) on S_0 .

Boundary values of u do not always exist, but in some special cases, u has limits. For instance, a positive harmonic function in a ball has a finite limit at almost every boundary point Q if the variable is restricted to any angular domain with vertex at Q .

N. Green Spaces

As a generalization of Riemann surfaces, Brelot and Choquet introduced \mathcal{E} -spaces [3]. It is required that \mathcal{E} be a separable connected topological space and satisfy the following two conditions: (i) At each point P there exists a neighborhood V_P of P and a homeomorphism between V_P and an open set V'_P in the Alexandrov compactification $\mathbf{R}^n \cup \{\infty\}$; (ii) if $A = V_{P_1} \cap V_{P_2} \neq \emptyset$ and A'_k is the part of V'_{P_k} that corresponds to A ($k = 1, 2$), then the correspondence between A'_1 and A'_2 via A is a conformal (possibly with the sense of angles reversed) transformation when $n = 2$ and an isometric transformation (which keeps ∞ invariant) when $n \geq 3$. If a Green's function exists on \mathcal{E} , then \mathcal{E} is called a **Green space**. Harmonic functions and the Dirichlet problem on a Green space have been discussed from various points of view.

O. Biharmonic Functions

A function v is called **polyharmonic** if $\Delta^k v = 0$ ($k \geq 2$) and **biharmonic** if $\Delta \Delta v = 0$; sometimes, polyharmonic functions are also called biharmonic. A biharmonic function in a plane domain D is written as $\operatorname{Re}(\bar{z}f(z) + g(z))$, where f

and g are complex analytic in D (Goursat's representation). Biharmonic functions are used in the theory of elasticity and hydrodynamics.

P. Subharmonic Functions

Let D be a domain in the n -dimensional Euclidean space \mathbf{R}^n ($n \geq 2$). A real-valued function $u(P)$ in D is called **subharmonic** if (1) $-\infty \leq u < +\infty$, $u \neq -\infty$; (2) u is upper semicontinuous; and (3) at every point P_0 of D , the mean value of u over the surface of any closed ball in D with center at P_0 is not smaller than $u(P_0)$, i.e.,

$$u(P_0) \leq \frac{1}{\sigma_n r^{n-1}} \int u d\sigma \equiv L(P_0, r),$$

where σ_n is the area of the surface of a unit ball in \mathbf{R}^n . Condition (3) can be replaced by: (3') The mean value $A(P_0, r)$ of u over the closed ball is $\geq u(P_0)$. In order that an upper semicontinuous function u be subharmonic it is necessary and sufficient that, for any subdomain D' of D and for any harmonic function h in D' , the maximum principle hold for $u - h$.

We call $-u$ **superharmonic** when u is subharmonic. A harmonic function is subharmonic and superharmonic. The converse is also true (\rightarrow Section E).

When u is of class C^2 , then u is subharmonic if and only if

$$\Delta u = \frac{\partial^2 u}{\partial x_1^2} + \dots + \frac{\partial^2 u}{\partial x_n^2} \geq 0 \quad (P = (x_1, \dots, x_n)).$$

When u is an upper semicontinuous function that is not necessarily differentiable, u is subharmonic if and only if Δu interpreted as a distribution is a positive measure.

If u_1, \dots, u_k are subharmonic and a_1, \dots, a_k are positive constants, then $a_1 u_1 + \dots + a_k u_k$ and $\max(u_1(P), u_2(P), \dots, u_k(P))$ are subharmonic. If a subharmonic function u is replaced by the Poisson integral for the boundary function u inside a closed ball in D , then the resulting function in D is subharmonic. If $f(t)$ is a monotone increasing convex function, then $f(u)$ is subharmonic. If $v \geq 0$ and $\log v$ is subharmonic, then v is subharmonic. If $f(z)$ is a holomorphic function of the complex variable z and $\lambda > 0$, then $\lambda \log |f(z)|$ and hence $|f(z)|^\lambda$ are subharmonic. If h is harmonic, then $|h|$ is subharmonic. Any logarithmic potential ($n = 2$) or Newtonian potential ($n \geq 3$) is superharmonic in \mathbf{R}^n .

Q. Properties of Mean Values

Condition (3) (resp. (3')) can be replaced by the condition that there exists an $r(P_0) > 0$ at any

Harmonic Functions and Subharmonic Functions

P_0 such that $u(P_0) \leq L(P_0, r)$ ($u(P_0) \leq A(P_0, r)$) for every r , $0 < r < r(P_0)$. The relation $-\infty < A(P_0, r) \leq L(P_0, r)$ always holds, and both $A(P_0, r)$ and $L(P_0, r)$ decrease to $u(P_0)$ as $r \downarrow 0$. On any \dagger compact subset of D , u is \dagger integrable. Both $A(P_0, r)$ and $L(P_0, r)$ increase with r and are convex functions of $-\log r$ ($n=2$) and r^{2-n} ($n \geq 3$); hence they are continuous functions of r . If D' is relatively compact in D and r_0 is the distance between $\partial D'$ and ∂D , then $A(P, r)$ is a continuous subharmonic function of P in D' , where r is fixed in the interval $(0, r_0)$. By taking the average of $A(P, r)$ k times, a subharmonic function of class C^k is obtained that decreases to u as $r \downarrow 0$. If $\varphi_r((x_1^2 + \dots + x_n^2)^{1/2})$ is suitably chosen, then the \dagger convolution $u * \varphi_r$ is a subharmonic function of class C^∞ and decreases to u as $r \downarrow 0$.

R. Sequences of Subharmonic Functions

The limit of a decreasing sequence or a downward-directed net of subharmonic functions is subharmonic or equal constantly to $-\infty$. The limit of a uniformly convergent sequence of subharmonic functions is subharmonic. If u_1, u_2, \dots are subharmonic, then $\max(u_1, \dots, u_k)$ is subharmonic for every k , but $\sup(u_1, u_2, \dots)$ may not be subharmonic. Let U be a family of subharmonic functions in D that are uniformly bounded above on every compact subset of D . Then the **upper envelope** of U , i.e., the function defined by $\sup_{u \in U} u$ in D , coincides with a subharmonic function except on a set of \dagger capacity zero.

S. Harmonic Majorants and Riesz Decompositions

Suppose that we are given a subharmonic function u in D . If there is a harmonic function h satisfying $h \geq u$ in D , then h is called a **harmonic majorant** of u . When there is a harmonic majorant of u , there exists a least one among them, denoted by h_D . For any relatively compact subdomain D' of D , $h_{D'}$ always exists and equals the \dagger Perron-Brelot solution in D' for the boundary function u . As D' increases to D , $h_{D'}$ increases to a function h that is either harmonic or equal constantly to ∞ . If h_D exists, it coincides with h , and hence h is harmonic. Conversely, if h is harmonic, then h_D exists and equals h . Generally, there is a unique \dagger Radon measure μ in D with the following property: Let δ be any subdomain of D such that h_δ and the \dagger Green's function G_δ exist in δ (δ may coincide with D). Then $h_\delta - u$ is equal to the potential $\int_\delta G_\delta d\mu$, and $u = h_\delta - \int_\delta G_\delta d\mu$. In general, a representation of a superharmonic (subharmonic) function as the sum (difference)

of a harmonic function and a potential is called a **Riesz decomposition**.

T. Boundary Values

Let D be a domain in which a Green's function exists, and consider the \dagger fine topology on the \dagger Martin compactification of D . Any negative subharmonic function u in D has a finite limit with respect to the fine topology at every point of the \dagger Martin boundary Δ except at the points of a subset of Δ of harmonic measure zero (J. L. Doob). When D is a ball, u has a limit in the ordinary sense along almost every radius. However, it may happen that even if u is bounded there exists no angular limit at any point of the boundary. If the mean value of $|u|$ on every concentric smaller ball in D is bounded, then u can be decomposed into the sum of a nonnegative harmonic function and a negative subharmonic function by the Riesz decomposition, and hence u has a limit both radially and with respect to the fine topology.

Let D be a domain and K be a compact subset of D of \dagger capacity zero. If a function u is subharmonic and bounded above in $D - K$, then u can be extended to be a subharmonic function in D . A function that is equal to a subharmonic function almost everywhere is called **almost subharmonic**, and an almost subharmonic function satisfying condition (3') is called **submedian**.

Subharmonic functions can be discussed in a space more general than \mathbf{R}^n , e.g., a \dagger Riemann surface ($n=2$), or more generally, an $\dagger\mathcal{E}$ -space of dimension n (≥ 2) in the sense of Brelot and Choquet.

U. The Axiomatic Treatment

\dagger Newtonian potentials were the main object of interest in the early stages of \dagger potential theory. A major part of potential theory can be discussed on the basis of the theory of superharmonic functions [8]. For example, a \dagger polar set is defined as a set on which some superharmonic function assumes the value ∞ , and a set X is \dagger thin at a point $P_0 \notin X$ if and only if P_0 has a positive distance from X or there exists a superharmonic function $v(P)$ in a neighborhood of P_0 such that $\limsup v(P) > v(P_0)$ as $P \in X$ tends to P_0 . Moreover, we can discuss \dagger balayage, define potentials, and obtain Riesz decompositions. Generalizing results of Doob (1954) and starting from a family of harmonic functions defined axiomatically in a locally compact Hausdorff space, M. Brelot defined superharmonic functions and potentials and discussed balayage, Riesz decompositions, and

the \dagger Dirichlet problem (1957). Further progress in axiomatic potential theory has been made by Brelot, H. Bauer, C. Constantinescu, A. Cornea, and others [11, 14].

194 (VII.11) Harmonic Integrals

A. Introduction

\dagger De Rham's theorem shows that the cohomology group with real coefficients of a \dagger differentiable manifold of class C^∞ is isomorphic to the cohomology group of the cochain com-

plex of \dagger differential forms with respect to the exterior derivative d . Thus every element of the cohomology group can be represented by a class of \dagger closed differential forms. Harmonic forms enable us to choose one definite differential form in each cohomology class. The theory of harmonic forms, called the theory of **harmonic integrals**, is modeled after the theory of holomorphic differentials and their integrals (Abelian integrals) in function theory [2, 4, 5, 8].

B. Definitions

Let X be an oriented n -dimensional differentiable manifold of class C^∞ with a \dagger Riemannian metric ds^2 of class C^∞ (→ 105 Differentiable Manifolds, 364 Riemannian Manifolds A). For every (C^∞) p -form φ on X we define an $(n-p)$ -form $*\varphi$ on X as follows: First denote the \dagger volume element of X by dv . If we choose a basis $\{\omega_1, \dots, \omega_n\}$ of the space of 1-forms on an open set U of X such that $ds^2 = \sum_i \omega_i^2$ and $dv = \omega_1 \wedge \dots \wedge \omega_n$, then φ can be expressed on U in the form $\varphi = (1/p!) \sum \varphi_{i_1, \dots, i_p} \omega_{i_1} \wedge \dots \wedge \omega_{i_p}$. If we let $*\varphi = (1/(n-p)!) \sum (*\varphi)_{j_1, \dots, j_{n-p}} \omega_{j_1} \wedge \dots \wedge \omega_{j_{n-p}}$, where $(*\varphi)_{j_1, \dots, j_{n-p}} = (1/p!) \sum \delta_{i_1, \dots, i_p}^{j_1, \dots, j_{n-p}} \varphi_{i_1, \dots, i_p}$, then $*\varphi$ is an $(n-p)$ -form on U that does not depend on the choice of $(\omega_1, \dots, \omega_n)$ and is determined only by φ . Since X is covered by open sets as above, $*$ defines a linear mapping that transforms p -forms to $(n-p)$ -forms. If we let $ds^2 = \sum g_{jk} dx^j dx^k$ in terms of the local coordinate system (x^1, \dots, x^n) and $\varphi = (1/p!) \varphi_{i_1, \dots, i_p} dx^{i_1} \wedge \dots \wedge dx^{i_p}$, then, in the notation of tensor calculus, we have

$$*\varphi = (1/(n-p)!)(*\varphi)_{j_1, \dots, j_{n-p}} dx^{j_1} \wedge \dots \wedge dx^{j_{n-p}},$$

$$(*\varphi)_{j_1, \dots, j_{n-p}} = \sqrt{g} \cdot \delta_{k_1, \dots, k_p}^{j_1, \dots, j_{n-p}} \varphi^{k_1, \dots, k_p}$$

$$(g = \det(g_{ij})).$$

For two p -forms φ and ψ , we define the inner product by $(\varphi, \psi) = \int_X \varphi \wedge *\psi$ if the right-hand side converges. In order for the inner product (φ, ψ) to be defined, it suffices that either φ or ψ has compact \dagger support. Then (φ, ψ) is a symmetric, positive definite bilinear form.

If we let $\delta = (-1)^{np+n+1} *d*$ operate on p -forms, where d is the \dagger exterior derivative, then d and δ are **adjoint** to each other with respect to the inner product. That is, if either φ or ψ has compact support, we have $(d\varphi, \psi) = (\varphi, \delta\psi)$ (\dagger Stokes's theorem). We call $\Delta = d\delta + \delta d$ the **Laplace-Beltrami operator**, which is a self-adjoint \dagger elliptic differential operator. These operators satisfy relations such as $** = (-1)^{p(n-p)}$, $dd = 0$, $\delta\delta = 0$, $*\Delta = \Delta*$,

$\ast \delta = (-1)^p d \ast$, and $\delta \ast = (-1)^{n-p+1} \ast d$ (when they operate on p -forms).

A differential form φ is said to be **harmonic** if $d\varphi = 0$ and $\delta\varphi = 0$. Then $\Delta\varphi = 0$. Since Δ is an elliptic operator, a \dagger weak solution φ of the equation $\Delta\varphi = \mu$ is an ordinary solution of class C^∞ on the domain where μ is of class C^∞ . Therefore, if φ is harmonic (as a weak solution), φ is of class C^∞ .

C. Harmonic Forms on Compact Manifolds

On a compact manifold X , any φ with $\Delta\varphi = 0$ is harmonic, since $(\varphi, \Delta\varphi) = (d\varphi, d\varphi) + (\delta\varphi, \delta\varphi)$. Let $L_p(X)$ be the linear space of p -forms of class C^∞ on X , and denote by $\mathfrak{L}_p(X)$ the completion of $L_p(X)$ with respect to the inner product (φ, ψ) . Then $\mathfrak{L}_p(X)$ is the Hilbert space of square integrable measurable p -forms. Then $\mathfrak{H}_p(X) = \{\varphi \in \mathfrak{L}_p(X) | \Delta\varphi = 0 \text{ (in the weak sense)}\}$ is a finite-dimensional subspace of $\mathfrak{L}_p(X)$ and is contained in $L_p(X)$, as we have seen before. Also, $\mathfrak{H}_p(X)$ is closed in $\mathfrak{L}_p(X)$, and the \dagger projection operator $H: \mathfrak{L}_p(X) \rightarrow \mathfrak{H}_p(X)$ is an \dagger integral operator with kernel of class C^∞ . The orthogonal complement of $\mathfrak{H}_p(X)$ in $\mathfrak{L}_p(X)$ is mapped onto itself by Δ and has the inverse operator G of Δ , which is a continuous operator of the Hilbert space. By letting $G = 0$ on $\mathfrak{H}_p(X)$, we can extend G to an operator from $\mathfrak{L}_p(X)$ to $\mathfrak{L}_p(X)$ that is called **Green's operator**. It is also denoted by G , maps L_p into itself, commutes with d and δ , and satisfies $GH = HG = 0$, $H + \Delta G = 1$ (= identity mapping). Therefore, for $\varphi \in L_p(X)$ we have $\varphi = H\varphi + G\delta d\varphi + d\delta G\varphi$, which shows that H is \dagger homotopic to the identity mapping of the \dagger cochain complex $(\sum_p L_p(X), d)$. From this we infer that every cohomology class of de Rham cohomology contains a unique harmonic form that represents the cohomology class. However, since products of harmonic forms are not always harmonic, it is not appropriate to use harmonic forms to study the ring structure of cohomology. G is also an integral operator with kernel of class C^∞ outside the diagonal subset in $X \times X$.

D. Harmonic Forms on Noncompact Manifolds

If X is a noncompact manifold, let $L_p(X)$ be the space of p -forms of class C^∞ with compact support, and let $\mathfrak{L}_p(X)$ be its completion. Let $\mathfrak{B}_p(X)$ and $\mathfrak{B}_p^\ast(X)$ be the respective closures of $dL_{p-1}(X)$ and $\delta L_{p+1}(X)$ in $\mathfrak{L}_p(X)$, and let $\mathfrak{Z}_p(X)$ and $\mathfrak{Z}_p^\ast(X)$ be the respective orthogonal complements of $\mathfrak{B}_p(X)$ and $\mathfrak{B}_p^\ast(X)$ in $\mathfrak{L}_p(X)$. Then $\mathfrak{Z}_p(X) \cap \mathfrak{Z}_p^\ast(X) = \mathfrak{H}_p(X)$ is a subspace of the square integrable harmonic forms, and we

have the direct sum decomposition $\mathfrak{L}_p(X) = \mathfrak{B}_p(X) + \mathfrak{B}_p^\ast(X) + \mathfrak{H}_p(X)$. In this decomposition any component of a form of class C^∞ is also of class C^∞ .

If X is an open submanifold of another manifold Y , \bar{X} is compact, and $\partial X = \bar{X} - X$ is a closed submanifold of Y , then the theory in this section is just a generalized potential theory with boundary condition $\varphi = 0$ on ∂X . We sometimes treat decompositions of other Hilbert spaces that correspond to other boundary conditions.

E. Generalization to Complex Manifolds

If X is a complex manifold, we consider complex-valued differential forms (\rightarrow 72 Complex Manifolds C). Then the space $L_p(X)$ of p -forms is the direct sum of the spaces $L_{r,s}(X)$ of forms of type (r, s) , and the exterior derivative d has the expression $d = d' + d''$, where d' is of type $(1, 0)$ (i.e., $L_{r,s}(X) \rightarrow L_{r+1,s}(X)$) and d'' is of type $(0, 1)$. If we are given a holomorphic vector bundle E on X , we can define an operator d'' on differential forms with values in E , and we have the generalized \dagger Dolbeault theorem. If X is compact and has a \dagger Hermitian metric, we can define a Hermitian inner product on E as follows: There is an open covering $\{U_j\}$ such that over each U_j the vector bundle E is isomorphic to $U_j \times C^q$. A point of E over U_j is represented by (x, ξ_j) , where $x \in U_j$ and $\xi_j \in C^q$. For $x \in U_j \cap U_k$ we have $(x, \xi_j) = (x, \xi_k)$ (the sides are the respective expressions over U_j and U_k) if and only if $\xi_j = g_{jk}(x)\xi_k$, where $g_{jk}(x)$ is a holomorphic mapping from $U_j \cap U_k$ to $GL(q, C)$ satisfying $g_{jk}g_{kl} = g_{jl}$ on $U_j \cap U_k \cap U_l$. A differential form φ with values in E is expressed as a family $\{\varphi_j\}$ of differential forms on U_j with values in C^q such that $\varphi_j(x) = g_{jk}(x)\varphi_k(x)$ on $U_j \cap U_k$. If we take a positive definite Hermitian matrix h_j whose components are C^∞ -functions on U_j such that ${}^t g_{jk} h_j \bar{g}_{jk} = h_k$ on $U_j \cap U_k$, then $\{\xi_j h_j \bar{\xi}_j\}$ determines a Hermitian inner product on each fiber of E . We can also endow the space $L_{r,s}(E, X)$ (of forms of type (r, s) of class C^∞ with values in E) with a Hermitian inner product by setting $(\varphi, \psi) = \int_X \sum_{\alpha, \beta} h_{j\alpha\beta} \varphi_j^\alpha \wedge \bar{\psi}_j^\beta$ for $\varphi, \psi \in L_{r,s}(E, X)$ (where the φ_j^α ($\alpha = 1, \dots, q$) are the components of φ_j). If we denote by \bar{d} the adjoint operator of d'' with respect to this inner product and let $A = d''\bar{d} + \bar{d}d''$, then A is a self-adjoint elliptic differential operator, and results similar to those for Δ mentioned above hold for A . For example, the space $\mathfrak{H}_{r,s}(E, X)$ of harmonic forms of type (r, s) is of finite dimension, and there is a continuous linear operator G on $\mathfrak{L}_{r,s}(E, X)$, the completion of $L_{r,s}(E, X)$, that satisfies $1 = H + AG$, $HG = GH = 0$, $d''G = Gd''$, and $\bar{d}G = G\bar{d}$. Here H

denotes the projection $\mathfrak{L} \rightarrow \mathfrak{H}$, which is an integral operator with kernel of class C^∞ . Also, G maps $L_{r,s}(E, X)$ into itself. Therefore H is homotopic to the identity on the cochain complex $(\sum_s L_{r,s}(E, X), d'')$, and any element of ${}^{\dagger}\text{Dolbeault's cohomology groups } (d''\text{-cohomology groups})$ is represented by a unique harmonic form (\rightarrow 232 Kähler Manifolds B).

F. Other Generalizations

Even if a manifold X is not of class C^∞ , if X is a manifold of class C^1_1 , we can develop the theory of harmonic forms [6]. We say that X is of class C^1_1 if it is of class C^1 and has a set of local coordinate systems whose transition functions have derivatives satisfying the ${}^{\dagger}\text{Lip-schitz condition}$.

If X is a real analytic manifold with a real analytic Riemannian metric, then harmonic forms are also real analytic. Using this fact, we can embed real analytically a compact manifold with a real analytic Riemannian metric into a Euclidean space (P. Bidal and G. de Rham; this result is now included in the theorems of C. B. Morrey and H. Grauert).

We can consider the theory of harmonic forms with singularities [4, 5], a generalization of the theory of differential forms of the second and third kinds. Here the notion of ${}^{\dagger}\text{current}$ is very useful.

G. Cohomology Vanishing Theorems

Since the operator Δ is closely related to the Riemannian metric, some metrics may admit no harmonic forms of certain degrees except zero. This is important since it means that the corresponding cohomology group of the manifold vanishes. The condition for this phenomenon to occur can be described in terms of the curvature of the metric. This study has its origin in S. Bochner's results [2].

Here is an example of a **vanishing theorem**: Let B be a holomorphic line bundle on a compact complex manifold X of dimension n . If the ${}^{\dagger}\text{Chern class of } B$ is expressed by a real closed differential form of type $(1, 1)$ as $\omega = \sqrt{-1} \sum a_{\alpha\beta} dz^\alpha \wedge d\bar{z}^\beta$, where the Hermitian matrix $(a_{\alpha\beta})$ is positive definite at every point of X , then $H^q(X, \Omega^p(B)) = 0$ for $p + q > n$. In this case, $ds^2 = 2 \sum a_{\alpha\beta} dz^\alpha \wedge d\bar{z}^\beta$ is a ${}^{\dagger}\text{Hodge metric on } X$ (\rightarrow 232 Kähler Manifolds D).

195 (VII.15)
Harmonic Mappings

A. General Remarks

The theory of harmonic mappings between Riemannian manifolds has its origin in the study of ${}^{\dagger}\text{Plateau's problem}$. The basic problem in the theory is to deform a given mapping into a harmonic one, which is a problem of the ${}^{\dagger}\text{calculus of variations and } {}^{\dagger}\text{global analysis}$ (\rightarrow 46 Calculus of Variations, 183 Global Analysis). Recently, the theory of harmonic mappings has been applied to problems in various branches of geometry [7–9, 11].

B. Definitions and Examples

Let (M, g) and (N, h) be ${}^{\dagger}\text{Riemannian manifolds with metrics } g = \sum g_{ij} dx^i dx^j$ and $h = \sum h_{\alpha\beta} dy^\alpha dy^\beta$, respectively. We define the **energy** of a C^1 -mapping $f: M \rightarrow N$ by

$$E(f) = \frac{1}{2} \int_M |df(x)|^2 dx,$$

where $|df(x)|$ is the ${}^{\dagger}\text{Hilbert-Schmidt norm of the differential } df_x: T_x(M) \rightarrow T_{f(x)}(N)$ of f at $x \in M$ and dx is the canonical Lebesgue measure defined by g on M (assumed compact). Thus $E(f)$ can be considered to be a generalization of the classical ${}^{\dagger}\text{Dirichlet integral for functions}$. The integrand $e(f)(x) = |df(x)|^2$ is called the **energy density** of f ; it measures the sum of the squares of elements of length stretched on a complete set of mutually perpendicular directions.

The \dagger Euler-Lagrange differential equations of the energy functional $E(f)$ yield a vector field $\tau(f)$ along f , i.e., a section of the bundle $f^*T(N)$ induced from the tangent bundle $T(N)$ of N by f . In fact, given a family f_t of mappings depending differentiably on t with $f_0 = f$, we have

$$\frac{d}{dt}E(f_t)|_{t=0} = - \int_M \left\langle \tau(f), \frac{\partial f_t}{\partial t} \Big|_{t=0} \right\rangle dx,$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product of tangent vectors along f . The vector field $\tau(f)$ is called the **tension field** of the mapping f ; it indicates the direction in which the energy of f decreases most rapidly.

The Euler-Lagrange differential equations $\tau(f) = 0$ are a system of \dagger quasilinear elliptic partial differential equations of the second order. In local coordinates, these can be written in the form

$$\Delta f^\alpha + \sum g^{ij} \Gamma_{\beta\gamma}^\alpha(f) \frac{\partial f^\beta}{\partial x^i} \frac{\partial f^\gamma}{\partial x^j} = 0,$$

where Δ is the \dagger Laplace-Beltrami operator on M and the $\Gamma_{\beta\gamma}^\alpha(f)(x)$ are the \dagger Christoffel symbols on N at $f(x)$. (The f^α are local coordinates of the point $f(x)$, and (g^{ij}) is the inverse matrix of (g_{ij}) .) A C^2 -mapping $f: M \rightarrow N$ is said to be **harmonic** if its tension field $\tau(f)$ vanishes. Thus, if M is compact, a C^2 -mapping $f: M \rightarrow N$ is harmonic if and only if it is an extremal of the energy functional $E(f)$.

Examples of harmonic mappings appear in various contexts of differential geometry. For instance:

- (1) If $N = \mathbf{R}$, then the harmonic mappings $M \rightarrow \mathbf{R}$ are the \dagger harmonic functions on M .
- (2) If M is the circle S^1 , then a harmonic mapping $S^1 \rightarrow N$ is a closed \dagger geodesic of N parametrized by arc length.
- (3) Let $f: M \rightarrow N$ be an \dagger isometric immersion of M into N . Then f is harmonic if and only if it is a \dagger minimal immersion.
- (4) If M and N are \dagger Kähler manifolds, then every \dagger holomorphic or **antiholomorphic** mapping $M \rightarrow N$ is harmonic, where by an antiholomorphic mapping is meant a mapping whose differential mapping carries a differential form of type $(1, 0)$ into that of type $(0, 1)$. We note that each (anti-)holomorphic mapping is an absolute minimum for the energy in its homotopy class. There are also examples of nonholomorphic (and nonantiholomorphic) harmonic mappings between Kähler manifolds (\rightarrow Section D).

C. Fundamental Properties

- (1) **Regularity.** Since a harmonic mapping is a solution of a second-order quasilinear elliptic

system of partial differential equations $\tau(f) = 0$ (\rightarrow Section B), it is a smooth (i.e., of class C^∞) mapping. More generally, it is known that a continuous mapping that satisfies $\tau(f) = 0$ in a weak sense is smooth [4, 6].

(2) **Unique continuation property.** The following unique continuation theorem is valid for harmonic mappings: If two harmonic mappings of M into N agree up to infinitely high order at some point of M , then they are identical (M being assumed connected). In particular, a harmonic mapping that is constant on an open set is a constant mapping.

The global natures of harmonic mappings are closely related to the curvatures of the manifolds under consideration. For instance, suppose that M and N are compact and that the sectional curvatures of N are nonpositive everywhere. Then we have:

(3) **Uniqueness.** Let $f: M \rightarrow N$ be a harmonic mapping, and assume that there is a point of $f(M)$ where the sectional curvatures of N are negative. Then f is unique in its homotopy class unless $f(M)$ is a closed geodesic γ of N ; and in this case we have uniqueness up to rotation of γ , i.e., an isometry of γ which moves each point of γ a fixed oriented distance along γ .

(4) **Degeneracy.** Suppose further that the \dagger Ricci tensor (R_{ij}) of M is positive semidefinite everywhere. Then the energy density $e(f)$ is a \dagger subharmonic function for every harmonic mapping. This implies that any harmonic mapping $f: M \rightarrow N$ is \dagger totally geodesic. Moreover, if N is of negative sectional curvature, then f is either constant or maps M onto a closed geodesic of N ; if (R_{ij}) is positive definite at some point, then f is constant.

(5) **Finiteness.** Assume now that N is of negative sectional curvature. Then, for each $K \geq 1$, there are only finitely many nonconstant harmonic mappings $f: M \rightarrow N$ of dilatation bounded by K . Here, we say that the dilatation of f is bounded by K if and only if at each point of M we have $df = 0$ or $(\lambda_1/\lambda_2)^{1/2} \leq K$, $\lambda_1 \geq \lambda_2 \geq \dots > 0$ being the positive eigenvalues of the pullback quadratic form $f^*h(x)$ on $T_x(M)$ induced from the metric h of N by f .

D. Harmonic Mappings of a Surface

Let M be a compact surface. Then the energy of a mapping $M \rightarrow N$ is the \dagger Dirichlet-Douglas functional, and harmonic mappings are closely connected with solutions of Plateau's problem (\rightarrow 334 Plateau's Problem). In fact, if a \dagger conformal mapping $M \rightarrow N$ minimizes the \dagger area functional, then it also minimizes the energy functional.

Now let M and N be compact orientable

surfaces whose genera are denoted by p and q , respectively. Then the problem of existence (or nonexistence) of harmonic mappings is well understood. In fact:

(1) When $q \neq 0$, for any metrics g and h on M and N , every homotopy class of mappings $M \rightarrow N$ contains a harmonic mapping.

(2) When $q = 0$ (i.e., N is the 2-sphere S^2), every harmonic mapping whose \dagger degree d satisfies $|d| \geq p$ is holomorphic or antiholomorphic with respect to the complex structures associated with g and h . For example, consider the homotopy classes of mappings from the 2-torus T^2 to S^2 with any metrics. Then all classes with degree $|d| \geq 2$ have harmonic representatives, and any such is holomorphic or antiholomorphic; and the classes with $d = \pm 1$ have no harmonic representatives.

(3) When $q = 0$ and $|d| \leq p - 1$, we have, for every such p and d , a surface M of genus p and a metric h on S^2 such that there exists a harmonic nonholomorphic (and nonantiholomorphic) mapping of degree d from M to S^2 .

E. Existence Theorems

The basic problem in the study of harmonic mappings is to prove their existence in general geometric contexts.

(1) In regard to this problem, translating the problem of the elliptic system $\tau(f) = 0$ into the \dagger initial value problem of the corresponding nonlinear \dagger parabolic system $\partial f / \partial t = \tau(f)$, J. Eells and J. H. Sampson [1] proved that if M and N are compact and if N has nonpositive sectional curvature everywhere, then every homotopy class of mappings $M \rightarrow N$ contains a harmonic mapping that minimizes the energy in that class. Subsequently, the uniqueness of these harmonic mappings was established by P. Hartman [2] in the form stated in Section C.

(2) For harmonic mappings of surfaces, more general existence results have been known.

First, by the \dagger direct method of the calculus of variations, L. Lemaire (1977) and others proved that if M and N are compact and if M is 2-dimensional, then every conjugacy class of homomorphisms $\pi_1(M) \rightarrow \pi_1(N)$ of the fundamental groups is induced by a minimizing harmonic mapping. It follows that if, in particular, the second homotopy group $\pi_2(N)$ of N is zero, then every homotopy class of mappings of a compact surface M to N contains a harmonic representative realizing the minimum of the energy in that class.

On the other hand, by making use of the generalized \dagger Morse theory for a perturbed energy functional, J. Sacks and K. Uhlen-

beck [5] succeeded in giving a satisfactory answer to the structure of $\pi_2(N)$, which is a $\pi_1(N)$ -module, in terms of harmonic mappings. They proved that there exists a generating set for $\pi_2(N)$ consisting of harmonic mappings of spheres that minimize energy and area in their homotopy classes. We note that these harmonic mappings are minimal immersions with \dagger branch points.

(3) Next, we mention the case of harmonic mappings of manifolds with boundary. In this case, we can naturally formulate the \dagger Dirichlet and the \dagger Neumann boundary value problem for harmonic mappings.

In his study of Plateau's problem on Riemannian manifolds, C. Morrey (1948) discussed the Dirichlet problem for harmonic surfaces with boundary.

The problem in arbitrary dimensions has been studied by R. S. Hamilton [3], who extended the result of Eells and Sampson mentioned above to the case where M and N have boundaries. In fact, let M and N be compact Riemannian manifolds with boundary, and assume that N has nonpositive sectional curvature and that the boundary ∂N of N is \dagger convex (or empty). Then there exists a unique minimizing harmonic mapping in each \dagger relative homotopy class determined by the prescribed Dirichlet boundary value. We note that if ∂N is not convex, then it is easy to formulate Dirichlet problems with no solutions. Hamilton also treated the Neumann problem.

Subsequently, S. Hildebrandt, H. Kaul, and K.-O. Widman [4] gave another existence proof of solutions of the Dirichlet problem that covers the case where N admits positive sectional curvature.

196 (XXI.28) Hilbert, David

David Hilbert (January 23, 1862–February 14, 1943) was born in Königsberg, Germany. He attended the University of Königsberg from 1882 to 1885, when he received his doctoral degree with a thesis on the theory of invariants. It was there that he established a life-long friendship with H. Minkowski. In 1892 he became a professor at the University, and in 1895 he was appointed to a professorship at the University of Göttingen, a position he held until his death. He obtained his basic theorem on invariants between 1890 and 1893, and next began research on the foundations of geometry (→ 155 Foundations of Geometry) and the theory of †algebraic number fields. Concerning the former, he published *Grundlagen der Geometrie* (first edition, 1899), in which he gave the complete axioms of Euclidean geometry and a logical examination of them. Concerning the latter, he systematized all the important known results of algebraic number theory in his monumental *Zahlbericht* (1897). In number theory, he enunciated his significant conjecture on †class field theory. At the international congress of mathematicians held in Paris in 1900, he put forth 23 problems as targets for mathematics of the 20th century (Table 1). Between 1904 and 1906 he conducted research on the †Dirichlet principle of †potential theory and on the direct method in the †calculus of variations. Around 1909 he established the foundations of the theory of †Hilbert spaces. After 1910 he was chiefly involved in research on the †foundations of mathematics, and he advocated the standpoint of †formalism. He is one of the greatest mathematicians of the first half of the 20th century.

Table 1. The 23 Problems of Hilbert

- (1) To prove the continuum hypothesis (→ 33 Axiomatic Set Theory D).
- (2) To investigate the consistency of the axioms of arithmetic (→ 156 Foundations of Mathematics E).
- (3) To show that it is impossible to prove the following fact utilizing only congruence axioms: Two tetrahedra having the same altitude and base area have the same volume. Solved by M. Dehn (1900).
- (4) To investigate geometries in which the line segment between any pair of points gives the shortest path between the pair (→ 155 Foundations of Geometry).
- (5) To obtain the conditions under which a topological group has the structure of a Lie group (→ 423 Topological Groups M). Solved by A. M. Gleason and D. Montgomery and L. Zippin (1952) and H. Yamabe (1953).
- (6) To axiomatize those physical sciences in which mathematics plays an important role.
- (7) To establish the transcendence of certain numbers (→ 430 Transcendental Numbers B). The transcendence of $2\sqrt{2}$, which was one of the numbers put forth by Hilbert, was shown by A. Gel'fond (1934) and T. Schneider (1935).
- (8) To investigate problems concerning the distribution of prime numbers; in particular, to show the correctness of the Riemann hypothesis (→ 450 Zeta Functions). Unsolved.
- (9) To establish a general law of reciprocity (→ 59 Class Field Theory A). Solved by T. Takagi (1921) and E. Artin (1927).
- (10) To establish effective methods to determine the solvability of Diophantine equations (→ 97 Decision Problem; 182 Geometry of Numbers). Solved affirmatively for equations of two unknowns by A. Baker, *Philos. Trans. Roy. Soc. London*, (A) 263 (1968); solved negatively for the general case by Yu. V. Matiyasevich (1970).
- (11) To investigate the theory of quadratic forms over an arbitrary algebraic number field of finite degree (→ 348 Quadratic Forms).
- (12) To construct class fields of algebraic number fields (→ 73 Complex Multiplication).
- (13) To show the impossibility of the solution of the general algebraic equation of the seventh degree by compositions of continuous functions of two variables. Solved negatively. In general, V. I. Arnold proved that every real, continuous function $f(x_1, x_2, x_3)$ on $[0, 1]$ can be represented in the form $\sum_{i=1}^9 h_i(g_i(x_1, x_2, x_3))$, where h_i and g_i are real, continuous functions, and A. N. Kolmogorov proved that $f(x_1, x_2, x_3)$ can be represented

in the form $\sum_{i=1}^7 h_i(g_{i1}(x_1) + g_{i2}(x_2) + g_{i3}(x_3))$, where h_i and g_{ij} are real, continuous functions and g_{ij} can be chosen once for all independently of f (*Dokl. Akad. Nauk SSSR*, 114 (1957), *Amer. Math. Soc. Transl.*, 28 (1963)).

(14) Let k be a field, x_1, \dots, x_n be variables, and $f_i(x_1, \dots, x_n)$ be given polynomials in $k[x_1, \dots, x_n]$ ($i = 1, \dots, m$). Furthermore, let R be the ring formed by rational functions $F(X_1, \dots, X_m)$ in $k(X_1, \dots, X_m)$ such that $F(f_1, \dots, f_m) \in k[x_1, \dots, x_n]$. The problem is to determine whether the ring R has a finite set of generators. Solved negatively by M. Nagata, *Amer. J. Math.*, 81 (1959).

(15) To establish the foundations of algebraic geometry (\rightarrow 12 Algebraic Geometry). Solved by B. L. van der Waerden (1938–1940), A. Weil (1950), and others.

(16) To conduct topological studies of algebraic curves and surfaces.

(17) Let $f(x_1, \dots, x_n)$ be a rational function with real coefficients that takes a positive value for any real n -tuple (x_1, \dots, x_n) . The problem is to determine whether the function f can be written as the sum of squares of rational functions (\rightarrow 149 Fields O). Solved in the affirmative by E. Artin (1927).

(18) To express Euclidean n -space as a disjoint union $\bigcup_{\lambda} P_{\lambda}$, where each P_{λ} is congruent to one of a set of given polyhedra.

(19) To determine whether the solutions of regular problems in the calculus of variations are necessarily analytic (\rightarrow 323 Partial Differential Equations of Elliptic Type). Solved by S. N. Bernshtein, I. G. Petrovskii, and others.

(20) To investigate the general boundary value problem (\rightarrow 120 Dirichlet Problem; 323 Partial Differential Equations of Elliptic Type).

(21) To show that there always exists a linear differential equation of the Fuchsian class with given singular points and monodromic group (\rightarrow 253 Linear Ordinary Differential Equations (Global Theory)). Solved by H. Röhrl and others (1957).

(22) To uniformize complex analytic functions by means of automorphic functions (\rightarrow 367 Riemann Surfaces). Solved for the case of one variable by P. Koebe (1907).

(23) To develop the methodology of the calculus of variations (\rightarrow 46 Calculus of Variations).

197 (XII.2) Hilbert Spaces

A. General Remarks

The theory of Hilbert spaces arose from problems in the theory of * integral equations. D. Hilbert noticed that a linear integral equation can be transformed into an infinite system of linear equations for the * Fourier coefficients of the unknown function. He considered the linear space l_2 consisting of all sequences of numbers $\{x_n\}$ for which $\sum_{n=1}^{\infty} |x_n|^2$ is finite, and defined for each pair of elements $x = \{x_n\}$, $y = \{y_n\} \in l_2$ their inner product as $(x, y) = \sum_{n=1}^{\infty} x_n \bar{y}_n$. The space l_2 can be regarded as an infinite-dimensional extension of the notion of a Euclidean space. F. Riesz considered the space of functions now termed L_2 -space and succeeded in giving a satisfactory answer to the Fourier expansion problem. In his book [3], J. von Neumann established a rigorous foundation of quantum mechanics employing Hilbert spaces and the spectral expansion of self-adjoint operators. The following axiomatic definition (\rightarrow Section B) of Hilbert spaces is due to von Neumann. H. Weyl later justified the * Dirichlet principle of Riemann by the method of orthogonal projection in a Hilbert space, and thus paved the way for the function-analytic study of differential equations.

B. Definition

Let K be the field of complex or real numbers, the elements of which we denote by α, β, \dots

Let H be a †linear space over K , and to any pair of elements $x, y \in H$ let there correspond a number $(x, y) \in K$ satisfying the following five conditions: (i) $(x_1 + x_2, y) = (x_1, y) + (x_2, y)$; (ii) $(\alpha x, y) = \alpha(x, y)$; (iii) $(x, y) = \overline{(y, x)}$; (iv) $(x, x) \geq 0$; and (v) $(x, x) = 0 \Leftrightarrow x = 0$. Then we call H a **pre-Hilbert space** and (x, y) the **inner product** of x and y .

With the norm $\|x\| = \sqrt{(x, x)}$, H is a †normed linear space. If H is †complete with respect to the distance $\|x - y\|$ (i.e., $\|x_n - x_m\| \rightarrow 0$ ($m, n \rightarrow \infty$)) implies the existence of $\lim x_n = x$), then we call H a **Hilbert space**. According as K is complex or real, we call H a **complex** or **real Hilbert space**. A Hilbert space is a †Banach space.

A normed linear space with norm $\|x\|$ can be made a pre-Hilbert space, by defining an inner product (x, y) so that $\|x\| = \sqrt{(x, x)}$, if and only if the equality $\|x + y\|^2 + \|x - y\|^2 = 2(\|x\|^2 + \|y\|^2)$ holds for any x, y .

C. Orthonormal Sets

Two elements $x, y \in H$ are said to be mutually **orthogonal** if $(x, y) = 0$. A subset Σ of H is called an **orthogonal set** (or **system**) if $0 \notin \Sigma$ and every distinct pair $x, y \in \Sigma$ is mutually orthogonal. If every element of an orthogonal set Σ is of norm 1, then Σ is called an **orthonormal set**. Any orthogonal set $\Sigma = \{x_i\}$ can be **normalized** into an orthonormal set $\{x_i/\|x_i\|\}$. A maximal orthonormal set is called a **complete orthonormal set** or an **orthonormal basis**. All the complete orthonormal sets of a given H have the same cardinal number, which we call the **dimension** of H . Two Hilbert spaces are isomorphic if and only if they have the same dimension.

Let $\Sigma = \{x_i\}$ be an orthonormal set. Then for every $x \in H$, its **Fourier coefficients** (x, x_i) vanish for all but a countable number of i , and the **Bessel inequality** $\|x\|^2 \geq \sum_i |(x, x_i)|^2$ holds. The following three statements are equivalent in a Hilbert space: (i) Σ is complete; (ii) **Parseval's equality** $\|x\|^2 = \sum_i |(x, x_i)|^2$ holds for every x ; (iii) every x can be expanded in a **Fourier series** $x = \sum_i (x, x_i)x_i$ (\rightarrow 317 Orthogonal Functions).

D. Examples of Hilbert Spaces

The space l_2 (\rightarrow Section A) is a Hilbert space of dimension \aleph_0 . The †function space L_2 on a measure space (X, μ) is a Hilbert space if the inner product of $f, g \in L_2$ is defined by $(f, g) = \int_X f \bar{g} d\mu$. In the case of the †Lebesgue measure in a Euclidean space, L_2 is of dimension \aleph_0 , so that it is a Hilbert space isomorphic to l_2 . Further examples of Hilbert spaces are

$A_2(\Omega)$, $W_2^1(\Omega)$ ($= H^1(\Omega)$), and $H_0^1(\Omega)$ (\rightarrow 168 Function Spaces).

E. Closed Linear Subspaces and Projections

Let M be a **closed linear subspace** of a Hilbert space H , i.e., a linear subspace that is closed in the norm topology of H . It is a Hilbert space with respect to the restriction of the inner product in H . For a given M the set of all $x \in H$ such that $(x, y) = 0$ for every $y \in M$ forms a closed linear subspace M^\perp called the **orthogonal complement** of M . The orthogonal complement of M^\perp is M (i.e., $M^{\perp\perp} = M$), and H is the **direct sum** of M and M^\perp (i.e., every $x \in H$ can be uniquely represented as $x = y + z$, $y \in M$, $z \in M^\perp$, and $\|x\|^2 = \|y\|^2 + \|z\|^2$). Thus the quotient space H/M is isomorphic to M^\perp and is also a Hilbert space. The operator P_M that maps x to y is called the **projection** (or **orthogonal projection** or **projection operator**) to M . A bounded linear operator P is a projection if and only if it is idempotent ($P^2 = P$) and self-adjoint ($((Px, y) = (x, Py)$ for any $x, y \in H$) (\rightarrow 251 Linear Operators).

F. Conjugate Spaces

A linear operator from H to K is called a **linear functional**. The set H' of all continuous linear functionals f on H forms a Hilbert space with norm $\|f\| = \sup\{|f(x)| : \|x\| = 1\}$. For every $f \in H'$ there exists a unique $y \in H$ such that $f(x) = (x, y)$ for all $x \in H$ (**Riesz's theorem**), and the correspondence $f \rightarrow y$ gives an †antilinear isometric operator from H' onto H (for †linear operators on Hilbert spaces \rightarrow 68 Compact and Nuclear Operators; 251 Linear Operators; 390 Spectral Analysis of Operators).

198 (XI.1) Holomorphic Functions

A. Differentiation of Complex Functions

Let $f(z)$ be a * complex-valued function defined in an open set D in the * complex plane \mathbb{C} . We say that $f(z)$ is **differentiable** at z if the limit

$$\lim_{h \rightarrow 0} (f(z+h) - f(z))/h = f'(z) \quad (1)$$

exists and is finite as the complex number h tends to zero. We call $f'(z)$ the **derivative** of $f(z)$ at z . This definition is a formal extension of the definition of differentiability of a function of a real variable to that of a complex variable (\rightarrow 106 Differential Calculus), but it is a much stronger condition than the differentiability of a real function, since $z+h$ in (1) may be an arbitrary point in a 2-dimensional neighborhood of z . Hence many results essentially different from those for functions of a real variable follow from it.

If a function $f(z)$ is differentiable at each point of an open set D , it is said to be **holomorphic** (or **regular**) in D , or $f(z)$ is a **holomorphic function** on D . (For the definition of holomorphy of a complex-valued function of several complex variables \rightarrow 21 Analytic Functions of Several Complex Variables C.)

Let E be an arbitrary nonempty subset of \mathbb{C} . We say that $f(z)$ is holomorphic on E if it is defined in an open set D containing E and is holomorphic on D . Some results valid for differentiable real functions also hold for holomorphic functions. For instance, the derivative of a sum, product, or quotient is given by the usual rules. The derivative of a composite function is determined by the chain rule.

The set of all functions holomorphic in a * domain D forms a * ring.

Suppose $f(z)$ is holomorphic on D and $f'(z_0) \neq 0$, $z_0 \in D$. Then two curves that form an angle at z_0 are mapped by f to two curves forming the same angle at $f(z_0)$. Because of this property, the mapping f is said to be **conformal** at all points z with $f'(z) \neq 0$.

The following four conditions are equivalent for a function $f = u + iv$ defined on an open set D . (1) f is holomorphic in D . (2) $u = u(x, y)$ and $v = v(x, y)$ are * totally differentiable at each point $z = x + iy$ and satisfy the **Cauchy-Riemann differential equations**

$$\partial u / \partial x = \partial v / \partial y, \quad \partial u / \partial y = -\partial v / \partial x.$$

(3) f is represented by a * power series $\sum_{n=0}^{\infty} c_n(z - a)^n$ in a neighborhood of each point a of D ; that is, $f(z)$ is **analytic** in D . (4) f is continuous and $\int_C f(z) dz = 0$ for every rectifiable Jordan closed curve C whose interior is contained, together with C , in D . The proposition that (1) implies (4) is called **Cauchy's integral theorem**, and the proposition that (4) implies (1) is called **Morera's theorem**.

The hypothesis of Morera's theorem can be weakened as follows: Let $f(z)$ be continuous in a domain D . If $\int_C f(z) dz = 0$ for every rectangle C in D with sides parallel to the axes and whose interior consists of only points of D , then $f(z)$ is holomorphic in D . In the statement of this theorem, if we let C be an arbitrary circle, we get the same conclusion.

The following complex differential operators are often useful:

$$\frac{\partial}{\partial z} = \frac{1}{2} \left(\frac{\partial}{\partial x} - i \frac{\partial}{\partial y} \right), \quad \frac{\partial}{\partial \bar{z}} = \frac{1}{2} \left(\frac{\partial}{\partial x} + i \frac{\partial}{\partial y} \right).$$

Generally, $(\partial \bar{\phi} / \partial \bar{z}) = \partial \bar{\phi} / \partial \bar{z}$. The Cauchy-Riemann equations above can be expressed in a single equation: $\partial f / \partial \bar{z} = 0$. If f is holomorphic, $\partial f / \partial \bar{z} = f'(z)$.

In order to show that $f = u + iv$ is holomorphic in D , assumption (2) can be weakened. Actually, we have the **Looman-Men'shov theorem**: Suppose that u and v are continuous in D , $\partial u / \partial x$, $\partial u / \partial y$, $\partial v / \partial x$, and $\partial v / \partial y$ exist at every point of D except for at most a countable number of points, and the Cauchy-Riemann equations hold in D except for a set of 2-dimensional * measure zero; then $f = u + iv$ is holomorphic in D . D. E. Men'shov extended this theorem and obtained various conditions for holomorphy. For example, he proved the following theorem: If f is a topological mapping of D and f is conformal in D (i.e.,

$$\lim_{h \rightarrow 0} \arg(f(z+h) - f(z))/h$$

exists) except for at most a countable number of points, then f is holomorphic in D .

As another type of sufficient condition for holomorphy, we have the proposition: If f is locally † Lebesgue integrable in D and satisfies the Cauchy-Riemann equation $f_{\bar{z}} = 0$ in the sense of † distribution, then there exists a holomorphic function g in D such that $g = f$ † almost everywhere.

B. Cauchy's Integral Theorem

Cauchy's integral theorem can be stated as follows: If $f(z)$ is a holomorphic function in a † simply connected domain D in the complex plane, the equality $\int_C f(z) dz = 0$ holds for every (rectifiable) closed curve C in D . In particular, the integral $\int_{\alpha}^{\beta} f(z) dz$ ($\alpha, \beta \in D$) is uniquely determined by α and β provided that its path of integration lies in D . The function $F(z) = \int_{\alpha}^z f(\zeta) d\zeta$ ($z \in D$) is called the **indefinite integral** of f . $F(z)$ is holomorphic in D and $F'(z) = f(z)$.

In the proof of his integral theorem, Cauchy assumed the existence and continuity of the derivative $f'(z)$ in D . However, E. Goursat proved the theorem utilizing only the existence of $f'(z)$. Actually, by virtue of the integral formula (2) in this section, the existence of $f'(z)$ in D implies the continuity of $f'(z)$. This is sometimes called **Goursat's theorem**.

Let C, C_1, C_2, \dots, C_n be rectifiable Jordan curves. Suppose that C_1, C_2, \dots, C_n are in the interior of C and that each one lies in the exterior of the others. If $f(z)$ is holomorphic in the region D bounded by these $n+1$ curves and continuous on $D \cup C \cup C_1 \cup \dots \cup C_n = \bar{D}$, then we have

$$\int_C f(z) dz = \sum_{k=1}^n \int_{C_k} f(z) dz.$$

Here the curvilinear integrals are taken in the **positive direction** (i.e., we take the direction such that $\int_C (z-a)^{-1} dz = \int_{C_k} (z-a)^{-1} dz = 2\pi i$ for a point a in the interior of C or C_k , respectively). Henceforth, an integral along a closed curve is taken in the positive direction unless otherwise noted. Cauchy's integral theorem under the assumption that f is holomorphic in D and is continuous on \bar{D} is sometimes called the **stronger form of Cauchy's integral theorem**.

Under the same assumptions as in the stronger form, we have **Cauchy's integral formula** for $z \in D$:

$$f(z) = \frac{1}{2\pi i} \int_C \frac{f(\zeta)}{\zeta - z} d\zeta - \frac{1}{2\pi i} \int_{C_1} \frac{f(\zeta)}{\zeta - z} d\zeta \dots - \frac{1}{2\pi i} \int_{C_n} \frac{f(\zeta)}{\zeta - z} d\zeta. \quad (2)$$

This integral formula expresses the value of

$f(z)$ at a point z in the domain D in terms of the values of f on the boundary of D . In particular, when $n=0$, the integral formula reads as

$$f(z) = \frac{1}{2\pi i} \int_C \frac{f(\zeta)}{\zeta - z} d\zeta. \quad (3)$$

Furthermore, if C is a circle $|z| = R$ (i.e., D is the disk $|z| < R$), we obtain **Poisson's integral formula**:

$$\begin{aligned} f(z) &= \\ \frac{1}{2\pi} \int_0^{2\pi} f(Re^{i\varphi}) \frac{R^2 - r^2}{R^2 + r^2 - 2Rr \cos(\theta - \varphi)} d\varphi, \\ f(z) &= \\ \frac{1}{2\pi} \int_0^{2\pi} \operatorname{Re} f(Re^{i\varphi}) \frac{Re^{i\varphi} + z}{Re^{i\varphi} - z} d\varphi + i \operatorname{Im} f(0), \\ z &= re^{i\theta}, \quad 0 \leq r < R. \end{aligned} \quad (3')$$

Formula (3)' is valid for a † harmonic function.

Let C be a rectifiable curve and $f(\zeta)$ be a continuous function defined on C ; then the **integral of Cauchy type**

$$F(z) = \frac{1}{2\pi i} \int_C \frac{f(\zeta)}{\zeta - z} d\zeta$$

is holomorphic outside C . The n th derivative $F^{(n)}$ of F is given by $(n!/2\pi i) \int_C f(\zeta)/(\zeta - z)^{n+1} d\zeta$; moreover, F can be expanded in a Taylor series about every point a outside C :

$$F(z) = \sum_{n=0}^{\infty} a_n (z-a)^n, \quad a_n = \frac{F^{(n)}(a)}{n!},$$

which converges in $|z-a| < \rho$, ρ being the distance from a to C . In particular, formula (3) implies that a holomorphic function f is infinitely differentiable and is expanded in a Taylor series about every point of D as above.

Let C be a closed curve not passing through a point a . Then the integral $(1/2\pi i) \int_C dz/(z-a)$ is an integer. It is called the **winding number** of C about a and is denoted by $n(C; a)$. A cycle γ (a finite sum of oriented closed curves) in an open set D is said to be **homologous to zero** in D if $n(\gamma; a) = 0$ for all points a in the complement of \bar{D} . The general form of Cauchy's integral theorem is stated as follows. If f is holomorphic in D , then $\int_{\gamma} f(z) dz = 0$ for every cycle γ which is homologous to zero in D (E. Artin). From this we have the general form of Cauchy's integral formula: if f is holomorphic in a domain D , then

$$n(\gamma; z) \cdot f(z) = \frac{1}{2\pi i} \int_{\gamma} \frac{f(\zeta)}{\zeta - z} dz, \quad z \in D - \gamma,$$

for every cycle γ which is homologous to zero in D .

C. Zero Points

Let $f(z)$ be a holomorphic function not identically equal to zero. If $f(a) = 0$, we call a a **zero point** of f . Every zero point of f is an isolated point, and there exists a unique positive integer k and a function h holomorphic at a such that

$$f(z) = (z-a)^k g(z), \quad g(a) \neq 0. \quad (4)$$

We call k the **order of the zero point** a and a a **zero point of the k th order**. The equality (4) implies that the † Taylor series of $f(z)$ at a begins with the term $c_k(z-a)^k$. Suppose that a is a zero point of $f(z) - \gamma$ of the k th order; then we call a a **γ -point of the k th order**.

For a function $f(z)$ defined in a neighborhood of the † point at infinity, we set $f(1/w) = g(w)$ ($f(\infty) = g(0)$) and call f holomorphic at ∞ if g is holomorphic at 0; f is said to have a zero of **order k** at ∞ if g has a zero of order k at 0. If two functions f and g are holomorphic in D and $f(z) = g(z)$ on a subset E that has an † accumulation point in D , then f is identically equal to g in D (**theorem of identity** or **uniqueness theorem**) since the zeros of holomorphic functions must be isolated.

D. Isolated Singularities

Let $f(z)$ be holomorphic in an annulus $D = \{z \mid R_1 < |z-a| < R_2, 0 \leq R_1 < R_2 \leq +\infty\}$. Then $f(z)$ is expanded in the † Laurent series

$$f(z) = \sum_{n=-\infty}^{+\infty} c_n(z-a)^n. \quad (5)$$

This is called the **Laurent expansion** of f about a . The coefficients c_n are given by $c_n = (1/2\pi i) \int_C f(\zeta) d\zeta / (\zeta-a)^{n+1}$ with $C = \{z \mid |z-a| = r\}$, $R_1 < r < R_2$. In particular, if $f(z)$ is holomorphic in $D = \{z \mid 0 < |z-a| < R\}$ (or, if $a = \infty$, in $D = \{z \mid R < |z| < +\infty\}$) but not holomorphic in $D \cup \{a\}$, we call a an **isolated singular point** (or **isolated singularity**) of f . By utilizing the † local canonical parameter $t = z-a$ (or $t = 1/z$ for $a = \infty$), the Laurent expansion (5) of f is then written as $f(z) = \sum_{n=-\infty}^{-1} c_n t^n + \sum_{n=0}^{+\infty} c_n t^n$. The second sum is an ordinary power series, called the **holomorphic part** of $f(z)$. The first sum is a power series of $1/t$ with no constant term, called the **singular part** of $f(z)$ at a or the **principal part** of the singularity (or of the Laurent expansion at a).

If we have $\lim_{t \rightarrow 0} t f(z) = 0$, the Laurent expansion (5) of $f(z)$ lacks its singular part, and the limit of $f(z)$ exists as $t \rightarrow 0$ ($z \rightarrow a$) and is equal to c_0 . If we set $f(a) = c_0$, then the function $f(z)$ is holomorphic in $D \cup \{a\}$. In this case, the point a is called a **removable singular-**

ity. If $f(z)$ is bounded in a neighborhood of a singularity a , then a is removable (**Riemann's theorem**). Usually, we assume that the removable singularities of a function have already been removed in this way.

When the singular part of $f(z)$ at a exists and consists of a finite number of terms, the point a is called a **pole**; when it consists of an infinite number of terms, the point is called an **essential singularity**. If a is a pole, $f(z)$ is represented by the Laurent series $\sum_{n=-k}^{\infty} c_n t^n$ ($c_{-k} \neq 0$) and $f'(z) \rightarrow \infty$ as $z \rightarrow a$. In this case, the index k is called the **order of the pole** a . Then a relation such as (4) holds, where the index k is replaced by $-k$. Hence the point a is sometimes called a **zero point of the $-k$ th order**. If a is an essential singularity, then for an arbitrary number c there exists a sequence z_n converging to a such that $\lim_{n \rightarrow \infty} f(z_n) = c$ (the **Casorati-Weierstrass theorem** or simply **Weierstrass's theorem**). Related to Weierstrass's theorem, we have † Picard's theorem, which gives a detailed description of the behavior of a function around its singularities.

E. Residues

Let $a (\neq \infty)$ be an isolated singularity of $f(z)$. Then the coefficient c_{-1} of $(z-a)^{-1}$ in the Laurent expansion (5) of $f(z)$ is called the **residue** of $f(z)$ at a and is denoted by $\text{Res}[f]_a$, $R(a; f)$, or $R(a)$ if we need not indicate f . We have

$$R(a) = c_{-1} = \frac{1}{2\pi i} \int_{|\zeta-a|=r} f(\zeta) d\zeta,$$

where the integral is taken in the positive direction along a path for $0 < r < R$. If $f(z)$ is holomorphic at $z = a$, then $R(a) = 0$. If $f(z)$ has a pole of the first order at a ,

$$R(a) = \lim_{z \rightarrow a} (z-a)f(z).$$

The residue at the point at infinity is defined to be $-a_{-1}$, where a_{-1} is the coefficient of $1/z$ of the Laurent expansion of $f(z)$ at ∞ : $f(z) = \sum_{n=-\infty}^{\infty} a_n z^n$, and we have

$$-a_{-1} = \frac{-1}{2\pi i} \int_{|\zeta|=r} f(\zeta) d\zeta, \quad R^{-1} < r < +\infty.$$

Thus the notion of the residue of $f(z)$ is actually related to the differential form $f(z)dz$ and not to $f(z)$ itself.

From the first formula in this section and the formula for $-a_{-1}$, the **residue theorem** follows (Cauchy, 1825): Let C be a rectifiable Jordan curve in the complex plane. Let a_1, \dots, a_m be a finite number of points inside C , and let D be a domain containing C and its

interior. If $f(z)$ is a function holomorphic in $D - \{a_1, \dots, a_m\}$, we have

$$\frac{1}{2\pi i} \int_C f(z) dz = \sum_{n=1}^m R(a_n).$$

Furthermore, if $f(z)$ is holomorphic in the extended complex plane (including the point at infinity) except for a finite number of poles, the sum of all residues is equal to zero.

F. Calculus of Residues

The **calculus of residues** is a field of calculus based on application of the notion of residues. For example, we have methods for the calculation of definite integrals. Actually, one of the reasons why Cauchy studied the theory of complex functions was that he believed that the theory would provide a unified method of computing definite integrals. For example, if $\varphi(z)$ is a rational function without poles on the real axis and with a zero point at infinity whose order is at least 2, then we have

$$\int_{-\infty}^{\infty} \varphi(x) dx = 2\pi i \sum_{\text{Im } \alpha > 0} R(\alpha; \varphi(z)), \quad (6)$$

$$\int_{-\infty}^{\infty} e^{ix} \varphi(x) dx = 2\pi i \sum_{\text{Im } \alpha > 0} R(\alpha; e^{iz} \varphi(z)). \quad (7)$$

Here the sums are taken over all the poles in the upper half-plane. Formula (7) is valid also for a rational function $\varphi(z)$ with a simple zero at infinity. If $\varphi(z)$ has simple poles at a_k ($k = 1, \dots, n$) on the real axis, then we take the principal values of the integrals at those poles and add $\pi i R(a_k)$ ($k = 1, \dots, n$) to the terms on the right-hand side of (6) and (7). Sometimes we use the residue theorem to obtain the value of the sum of a series (e.g., the †Gaussian sum) by expressing it as an integral.

Let $f(z)$ be a single-valued function that is †meromorphic and not identically equal to zero in a domain D , and let $\varphi(z)$ be a function holomorphic in D . Draw a rectifiable Jordan curve C in D such that the interior of C is contained in D and $f(z)$ has neither zeros nor poles on C . Let $\alpha_1, \dots, \alpha_N$ and β_1, \dots, β_P be the zeros and poles inside C , respectively (where each of them is repeated as often as its order). Then we have

$$\sum_{n=1}^N \varphi(\alpha_n) - \sum_{p=1}^P \varphi(\beta_p) = \frac{1}{2\pi i} \int_C \varphi(z) \frac{f'(z)}{f(z)} dz.$$

If $\varphi(z) = 1$, we get

$$\frac{1}{2\pi} \int_C d \arg f(z) = N - P.$$

This is called the **argument principle**. Next, let $f(z)$ be a function meromorphic for $|z| <$

$R \leq +\infty$, $f(0) \neq 0, \neq \infty$, and set $\varphi(z) = \log z$. Take C as a closed curve consisting of the boundary of an annulus $0 < \rho < |z| < r < R$ (where ρ is sufficiently small) and two sides of a suitable †crosscut joining a point of $|z| = \rho$ and $|z| = r$. Then we obtain **Jensen's formula**:

$$\log \left| \frac{\alpha_1, \alpha_2, \dots, \alpha_N}{\beta_1, \beta_2, \dots, \beta_P} \right| = \log |f(0)| + (N - P) \log r - \frac{1}{2\pi} \int_0^{2\pi} \log |f(re^{i\psi})| d\psi.$$

The argument principle can be utilized to prove **Rouché's theorem**: Let $f(z)$ and $g(z)$ be functions holomorphic in a domain D that contains a rectifiable Jordan curve C and its interior. Suppose that $f(z) + \lambda g(z)$ never vanishes on C for any λ with $0 \leq \lambda \leq 1$. Then the number of zeros of $f(z)$ in the interior of C is equal to that of $f(z) + g(z)$. If $|f(z)| > |g(z)|$ on C or $\arg f(z) - \arg g(z) \neq (2n + 1)\pi$ (n is an integer), the hypothesis of Rouché's theorem is satisfied. This theorem is useful in proving the existence of a zero of a complex function (for example, a polynomial) and in finding its position.

G. Analytic Continuations

Let $f(z)$ be a holomorphic function in a domain D of the complex plane \mathbb{C} and D^* be a domain containing D as a proper subset. If there exists a function $F(z)$ holomorphic in D^* that coincides with $f(z)$ in D , then $F(z)$ is called an **analytic continuation** (or **analytic prolongation**) of $f(z)$ from D to D^* . By the theorem of identity an analytic continuation of $F(z)$ is uniquely determined if it exists.

The function $f_1(z)$ defined by the power series $P(z; a) = \sum_{n=0}^{\infty} a_n(z - a)^n$ with the radius of convergence $r_1 > 0$ is holomorphic in the domain $D_1: |z - a| < r_1$, and at a point b of D_1 it can be expanded into a power series $P(z; b) = \sum_{n=0}^{\infty} b_n(z - b)^n$ with the radius of convergence $r_2 (\geq r_1 - |b - a|)$. If $r_2 > r_1 - |b - a|$, the domain $D_2: |z - b| < r_2$ is not entirely contained in D_1 . Let $f_2(z)$ be the function defined in D_2 by $P(z; b)$. Then the function $F(z)$ that is equal to $f_1(z)$ in D_1 and to $f_2(z)$ in D_2 is an analytic continuation of $f_1(z)$ from D_1 to $D_1 \cup D_2$ (a **direct analytic continuation** by power series).

We have the following classical theorems about analytic continuations:

Let D_1 and D_2 be two disjoint domains, and suppose that their respective boundaries C_1 and C_2 are †rectifiable simple closed curves and that the intersection of C_1 and C_2 contains an open arc Γ . If two holomorphic functions $f_1(z)$, $f_2(z)$ defined in D_1 and D_2 , respectively, have finite common †boundary values at every

point of Γ , then there exists an analytic continuation $F(z)$ of $f_1(z)$ and $f_2(z)$ to $D_1 \cup \Gamma \cup D_2$ (**Painlevé's theorem**). We sometimes call $f_2(z)$ a continuation of $f_1(z)$ beyond Γ . If Γ is not rectifiable, the continuation beyond Γ does not exist, in general.

Let $f(z)$ be holomorphic in a \dagger Jordan domain D lying in the half-plane on one side of the real axis and containing an open interval I of the real axis in its boundary. If $f(z)$ has finite real boundary values at every point of I , then it can be continued analytically beyond I to the other side of the real axis; there the continued function is given by $\overline{f(\overline{z})}$ (**Schwarz's principle of reflection**). This theorem can be generalized to the case where the real interval is replaced by an \dagger analytic curve.

A **harmonic continuation** of \dagger harmonic functions is defined analogously to analytic continuation. Let D be a Jordan domain lying in the half-plane on one side of the real axis and having an open interval I on the real axis as a part of its boundary. If $u(z)$ is harmonic in D and has the boundary value 0 at every point of I , then $u(z)$ has a harmonic continuation beyond I .

For other properties of holomorphic functions \rightarrow 43 Bounded Functions; 429 Transcendental Entire Functions.

H. Analytic Functions

A real-valued function $f(t)$ of a real variable t is said to be **analytic** at $t = t_0$ if it can be represented by a \dagger power series in $t - t_0$ in a neighborhood of t_0 in \mathbf{R} . If $f(t)$ is defined on an open set of \mathbf{R} at every point of which it is analytic, then $f(t)$ is called an **analytic function**, or, more precisely, a **real analytic function**.

Analogously, a complex-valued function $f(z)$ of a complex variable z defined on a \dagger domain D of the complex plane \mathbf{C} is said to be **analytic** at $z = z_0 (\in D)$ if it can be represented by a power series in $z - z_0$ in a neighborhood of z_0 in \mathbf{C} , and $f(z)$ is an **analytic function** in D if it is analytic at every point of D . In the remainder of this article, we are concerned with analytic functions in this sense. To distinguish them from the real case, they are also called **complex analytic functions**. A complex analytic function $f(z)$ defined on D is \dagger differentiable in D ; therefore it is \dagger holomorphic in D . The converse is also true. Thus the term "analytic function" is synonymous with "holomorphic function" insofar as it concerns a complex function (i.e., a complex-valued function of a complex variable) on a domain, but in the theory of functions it takes on an additional meaning that is explained in the following section.

I. Analytic Functions in the Sense of Weierstrass

Let a be a point of the \dagger z -sphere and t the \dagger local canonical parameter at a ; i.e., $t = z - a$ if $a \neq \infty$ and $t = z^{-1}$ if $a = \infty$. If a power series $P(z; a) = \sum_{n=0}^{\infty} c_n t^n$ has a positive radius r_a of convergence, we call $P(z; a)$ a **function element** with center a on the z -sphere, after K. Weierstrass. $P(z; a) = \sum_{n=0}^{\infty} c_n (z - a)^n$ if $a \neq \infty$, and $P(z; a) = \sum_{n=0}^{\infty} c_n z^{-n}$ if $a = \infty$. These represent a holomorphic function in $|z - a| < r_a$ or in $r_a^{-1} < |z| \leq \infty$, respectively. If b is a point inside the circle of convergence of the function element $P(z; a)$, by the \dagger Taylor expansion of $P(z; a)$ at $z = b$, we obtain the power series $P(z; b)$ in $z - b$, which is a direct analytic continuation of $P(z; a)$. Let a and b be two points on the z -sphere, and let $C: z = z(s)$ ($0 \leq s \leq 1$, $z(0) = a$, $z(1) = b$) be a curve joining a and b . We say that $P(z; a)$ is **analytically continuable** along C and that we obtain $P(z; b)$ at the end point b by the **analytic continuation** of $P(z; a)$ along C if the following two conditions are satisfied: (i) To every $s \in [0, 1]$ there corresponds a function element $P(z; z(s))$ with center $z(s)$; (ii) for every $s_0 \in [0, 1]$, we can take a suitable subarc $z = z(s)$ ($|s - s_0| \leq \varepsilon$, $\varepsilon > 0$) of C contained inside the circle of convergence of $P(z; z(s_0))$ such that every function element $P(z; z(s))$ with $|s - s_0| \leq \varepsilon$ is a direct analytic continuation of $P(z; z(s_0))$. When $P(z; a)$ and the curve C are given, the analytic continuation along C is uniquely determined (**uniqueness theorem of the analytic continuation**).

Given a function element $P(z; a)$ with center a , the set of all function elements obtained by every possible analytic continuation along every curve starting from a is called an **analytic function in the sense of Weierstrass** determined by $P(z; a)$. In this definition, we can restrict the curves to polygonal lines. An analytic function in this sense is completely determined by a single arbitrary function element belonging to it, so two analytic functions are identically equal if they have a common function element.

A \dagger germ of a holomorphic function is identical to a function element, and the set of all germs has the natural structure of a \dagger sheaf \mathcal{O} . In the terminology of sheaves, an analytic function is a connected component of \mathcal{O} , and an **analytic continuation along a curve C** is a continuous curve Γ in \mathcal{O} whose projection is C .

J. Values and Branches of Analytic Functions

The value of an analytic function at a point b is, by definition, the value at b of its function elements with center b (whose existence is

assumed; there may be several such elements). An analytic function is, in general, a multiple-valued function because analytic continuations along different curves with the same end points may lead to different function elements. For a given analytic function $f(z)$, if the maximal number of its function elements with the same center is n , we say it is n -valued, and if $n \geq 2$ we say it is **multiple-valued** (or **many-valued**). The number of function elements of $f(z)$ with the same center is at most †countably infinite, so the value of $f(z)$ at a point is a countable set (**Poincaré-Volterra theorem**). By introducing a †Riemann surface instead of the complex plane as the domain of definition of an analytic function, we can regard multiple-valued analytic functions as single-valued functions defined on a suitable Riemann surface (\rightarrow 367 Riemann Surfaces).

Let $f(z)$ be an analytic function and $P(z; a)$ be a function element belonging to $f(z)$, where a is a point of a domain D . The set of all function elements obtained from $P(z; a)$ by every possible analytic continuation along all curves in D is called a **branch** of $f(z)$ in D determined by $P(z; a)$. When D coincides with the whole complex plane, the branch of $f(z)$ in D is the function $f(z)$ itself. A function holomorphic in a domain D can be expanded in a power series with any point of D as its center, and the set of these power series (function elements) constitutes a branch of an analytic function.

If analytic continuations of a function element are possible along all curves in D , then the analytic continuations along two †homotopic curves in D lead to the same result (**monodromy theorem**). In particular, if D is †simply connected and if analytic continuations of $P(z; a)$ are possible along all curves in D starting from a , then the branch of $f(z)$ in D determined by $P(z; a)$ is single-valued.

K. Invariance Theorem of Analytic Relations

Suppose the following four conditions hold: (1) $F(z, w)$ is a holomorphic function of two variables for $z \in \Delta_1$ and $w \in \Delta_2$, where Δ_1, Δ_2 are domains in the complex plane. (2) A curve $C: z = z(s)$ ($0 \leq s \leq 1, z(0) = a, z(1) = b$) and two sets of function elements $P(z; z(s))$ and $Q(z; z(s))$ defined for every s ($0 \leq s \leq 1$) are given. (3) $P(z; a)$ and $Q(z; a)$ can be continued analytically along C using $P(z; z(s))$ and $Q(z; z(s))$, respectively. (4) There exists a positive number $R(s)$ for every s ($0 \leq s \leq 1$) such that, if $|z - z(s)| < R(s)$, the values of $P(z; z(s))$ and $Q(z; z(s))$ belong to Δ_1 and Δ_2 , respectively. Under these conditions, if $F(P(z; a), Q(z; a)) = 0$ holds for $|z - a| < R(0)$, then $F(P(z; b), Q(z; b)) = 0$ holds for $|z - b| < R(1)$. In other words, an analytic

relation between function elements belonging to two analytic functions that holds in a neighborhood of the starting point of a curve C is conserved for function elements with center at the terminal point b of C . This is called the **invariance theorem of analytic relations**. The same statement is valid for relations among more than two analytic functions and their derivatives (differential equations).

L. Inverse Functions

Suppose that $P(z; a)$ ($a \neq \infty$) belongs to an analytic function $f(z)$ and $P'(a; a) \neq 0$. We consider the inverse function of $P(z; a)$ in a neighborhood of a and let $\mathfrak{B}(w; \alpha)$ ($\alpha = P(a; a)$) be its expansion as the power series in $w - \alpha$. We call $\mathfrak{B}(w; \alpha)$ the **inverse function element** (or simply **inverse element**) of $P(z; a)$ and the analytic function determined by $\mathfrak{B}(w; \alpha)$ the **inverse analytic function** (or simply **inverse function**) of $f(z)$. The inverse function is completely determined by $f(z)$ and is independent of the choice of $P(z; a)$. For example, analytic functions represented by \sqrt{w} or $\log w$ are defined as the inverse function of z^2 or e^z , respectively.

M. Singularities of Analytic Functions

Hereafter, when we speak of a curve $C: z = z(s)$ ($0 \leq s \leq 1$), it is always supposed that C is a curve in the complex plane starting at a and ending at ω . Let K_r be the open disk $|z - \omega| < r$; we denote by C_r the connected component of $C \cap K_r$ that contains ω . If analytic continuations of $P(z; a)$ are possible along any subarc of C with a terminal point arbitrarily near ω but impossible along the whole C , we say that the analytic continuation of $P(z; a)$ along C defines a **singularity** Ω of the coordinate ω , and that Ω lies over ω . For example, if $P(z; a)$ has a finite radius of convergence, for a suitable point ω on the circle of convergence the analytic continuation of $P(z; a)$ along the radius $a\omega$ defines a singularity over ω . Now take a point z_r on C_r and denote by $F_r(z)$ the branch of an analytic function determined by $P(z; z_r)$ in K_r . Let Ω be a singularity determined by C and $P(z; a)$, and suppose that we are given another singularity Ω^* over ω determined by C^* and $P^*(z; a^*)$. If they define the same branch $F_r(z)$ for every K_r , by definition, we put $\Omega = \Omega^*$. Thus $F_r(z)$ defines an †unramified covering surface W_r of $K_r - \{\omega\}$, and it is single-valued on W_r .

Singularities are classified according to the geometric structure of W_r and the value distribution of $F_r(z)$ on it. First, if W_r has no †relative boundary over $0 < |z - \omega| < r$ for a suitable r , then Ω is called an **isolated singularity** of the

analytic function. In this case, the number k of points of W_r lying over a point z in $K_r - \{\omega\}$ is constant. If $k = \infty$, W_r has a [†]logarithmic branch point over ω , and Ω is called a **logarithmic singularity**. If $k < \infty$, $F_r(z)$ can be represented as a single-valued holomorphic function in $0 < |t| < r^{1/k}$ by putting $z = \omega + t^k$. In this case, if we introduce an additional point P_0 corresponding to $z = \omega$, then $W_r \cup \{P_0\}$ has only an [†]algebraic branch point over ω . Now, taking into account the value of $w = F_r(z)$, we call Ω an **algebraic singularity** if $\lim w$ exists. In this case, we have $F_r(z) = \sum_{n=l}^{\infty} c_n t^n$, and if we admit analytic continuations in the wider sense (→ Section O), $P(z; a)$ is analytically continuable along the whole C .

N. The Natural Boundary

Given a domain D and an analytic function $f(z)$ holomorphic in D , if all boundary points of D are singularities of $f(z)$ and $f(z)$ is not continuable to the exterior of D , the boundary of D is called the **natural boundary** of $f(z)$. This phenomenon was first discovered for [†]elliptic modular functions. Many results are known about power series for which the circle of convergence is the natural boundary (→ 339 Power Series). For any given domain D in \mathbb{C} , there exists an analytic function whose natural boundary is the boundary of D . The original proof of this fact, given by Weierstrass, contained a defect that was corrected by J. Besse.

O. Analytic Continuation in the Wider Sense

Let two [†]Laurent series (with parameter t) $z = P(t) = \sum_{n=k}^{\infty} a_n t^n$ and $w = Q(t) = \sum_{n=l}^{\infty} b_n t^n$ (k and l are integers, and $a_k b_l \neq 0$) converge in $0 < |t| < r$, and let $(P(t_1), Q(t_1)) \neq (P(t_2), Q(t_2))$ if $t_1 \neq t_2$; then we say that the pair (P, Q) defines a **function element in the wider sense**. If a change of parameter $\tau = r_1 t + r_2 t^2 + \dots$ ($r_1 \neq 0$ and the radius of convergence > 0) gives $P(t) = \Pi(\tau)$, $Q(t) = K(\tau)$, we say that (Π, K) and (P, Q) define the same function element. By a suitable choice of parameter, any function element can be given in the form $z = t^k + a$ (or $a = t^{-k}$), $w = \sum_{n=l}^{\infty} b_n t^n$, and the elimination of t gives the representation of w as a [†]Puiseux series of z . So if $k = 1$ and $l \geq 0$, it reduces to a holomorphic function element. When $k = 1$, with $l < 0$ not excluded, the above element is called a **rational element**. If $k > 1$ it is called a **ramified element**, and if $l < 0$ it is called a **polar element**.

If P', Q' are the direct analytic continuations of P and Q at t_0 ($0 < |t_0| < r$), i.e., their Taylor expansions at t_0 , the function element (P', Q') is called a direct analytic continuation of (P, Q) ,

which is also considered its own direct analytic continuation. For a fixed r , the set of all direct continuations of (P, Q) thus obtained is called an **analytic neighborhood** of (P, Q) , and these neighborhoods define a topology in the set of all function elements. A curve in this topological space is called an **analytic continuation in the wider sense**, and a [†]connected component of this space is called an **analytic function in the wider sense**. An analytic function in the wider sense is a set of function elements in the wider sense, but it can also be regarded as a function $w = f(z)$ (with an independent variable z and a dependent variable w) defined by each function element $p(z, w): z = P(t), w = Q(t)$. An analytic continuation in the wider sense,

$$p(s) = p(z, w; s);$$

$$z = z(s) + t^{k(s)}, \quad w = \sum_{n=l(s)}^{\infty} c_n(s) t^n, \quad 0 \leq s \leq 1,$$

is sometimes called an analytic continuation along the curve $C: z = z(s)$ ($0 \leq s \leq 1$) in the complex plane. If all $p(s)$ are holomorphic function elements, this coincides with the analytic continuation along C in the original sense, but if this is not the case, $p(0)$ and C do not necessarily determine $p(1)$ uniquely. Actually, an analytic function in the wider sense is just an analytic function in the original sense with at most a countable number of ramified or polar elements added.

P. Singularities of Analytic Functions in the Wider Sense

Suppose the following three conditions hold: (1) For every point on C except ω , that is, for $z(s)$ ($0 \leq s < 1$), a function element in the wider sense $p(z, w; s)$ is given. (2) For every λ (< 1), $p(z, w; s)$ ($0 \leq s \leq \lambda$) constitutes an analytic continuation in the wider sense. (3) It is impossible to find a function element $p(z, w; 1)$ such that $p(z, w; s)$ ($0 \leq s \leq 1$) is an analytic continuation in the wider sense. When these three conditions are satisfied, we say that $p(z, w; s)$ ($0 \leq s < 1$) defines a **transcendental singularity** Ω with ω as its coordinate. The method of determining a branch $w = F_r(z)$ in an open disk with center ω is completely parallel to the case of holomorphic analytic functions. Because of the appearance of function elements in the wider sense in $F_r(z)$, the covering surface W_r of K_r defined by $F_r(z)$ may have algebraic branch points. If W_r has a logarithmic branch point over ω , Ω is called a **logarithmic singularity**. If W_r has no point over ω for suitable r , Ω is called a **direct transcendental singularity**; otherwise, it is called an **indirect transcendental singularity**. The logarithmic singularities are

direct singularities. The inverse function of $z = w \sin w$ has a direct singularity over $z = \infty$ that is not logarithmic, and the inverse function of $z = (\sin w)/w$ has an indirect singularity over $z = 0$. Taking into account the value of $w = F_r(z)$, if the \dagger cluster set of F_r at $\Omega: S_\Omega = \bigcap_{r>0} \{F_r(z)\}$ consists of only one point, it is an **ordinary singularity**; if not, it is an **essential singularity**.

Q. History

A function of a complex variable is **monogenic** in the sense of A. L. Cauchy if it is differentiable at every point of its domain of definition. It was B. Riemann who succeeded in developing Cauchy's concept. Riemann considered an analytic function as a function defined on a \dagger Riemann surface, that is, a 1-dimensional complex analytic manifold. On the other hand, Weierstrass constructed the theory of analytic functions starting from power series. When we speak of single-valued functions defined in a domain of the complex plane, the monogenic functions of Cauchy and the analytic functions of Weierstrass are identical. Although the analytic functions are very special functions, the study of complex analytic functions is usually called the theory of functions of a complex variable, or simply the theory of functions.

By considering the following point set C , which is more general than a domain, E. Borel showed that a monogenic function on C is not necessarily holomorphic in the ordinary sense. Take a countable dense subset in a subdomain D' of a domain D and a double sequence of positive numbers $\{r_n^{(h)}\}$. Put $S_n^{(h)} = \{z \mid |z - z_n| < r_n^{(h)}\}$ and $C^{(h)} = D - \bigcup_{n=1}^{\infty} S_n^{(h)}$. By a suitable choice of $r_n^{(h)}$, we can suppose that the $C^{(h)}$ are connected and monotone increasing with respect to h . Put $C = \bigcup_{h=1}^{\infty} C^{(h)}$. A function defined in C is by definition **monogenic** if it is differentiable in $C^{(h)}$ for every h . For such a monogenic function, Cauchy's \dagger integral formula in a generalized form holds, and the function is infinitely differentiable. If $f(z)$ and $g(z)$ are monogenic in C and coincide on a curve in C , then they are identical in C . Let D be the set $\{z \mid 0 < \operatorname{Re} z < 1, 0 < \operatorname{Im} z < 1\}$ and $\{z_n\}$ be all rational points in D ($z_n = (p + iq)/m$). For a natural number h , we define $C^{(h)}$ to be the set D minus the union of open disks with radius $\exp(-e^{m^2})/h$ and center $(p + iq)/m$. The function

$$f(z) = \sum_{m=1}^{\infty} \sum_{p=0}^m \sum_{q=0}^m \frac{\exp(-e^{m^4})}{z - (p + iq)/m}$$

is monogenic in C in the above-mentioned sense, but not holomorphic in C . The study of

these functions developed into the theory of \dagger quasi-analytic functions.

The concept of \dagger analytic functions of several complex variables can also be defined analogously to the case of one variable. Then non-uniformizable singularities appear that lead to a generalization of the concept of \dagger manifolds (\rightarrow 23 Analytic Spaces).

Homogeneous Spaces

A. General Remarks

Let M be a \dagger differentiable manifold. If a \dagger Lie group G acts \dagger transitively on M as a \dagger Lie transformation group, the manifold M is said to be a **homogeneous space** having G as its transformation group (→ 431 Transformation Groups). The \dagger stabilizer (isotropy subgroup) H_x of G at a point x of M is a closed subgroup of G , and a one-to-one correspondence between G/H_x and M preserving the action of G is defined by associating the element sH_x ($s \in G$) of G/H_x with the point $s(x)$ of M . This correspondence is a \dagger diffeomorphism between the manifold M and the quotient manifold G/H_x if the number of connected components of G is at most countable. Under this condition we may therefore identify a homogeneous space M with the quotient manifold G/H of a Lie group G by a closed Lie subgroup H (→ 249 Lie Groups). However, H is not uniquely determined by M , and it may be replaced by $H_{s(x)} = sH_x s^{-1}$ ($s \in G$). Each element h of the stabilizer H_x at a point x induces a linear transformation \tilde{h} on the \dagger tangent space V_x of M at the point x . The set \tilde{H}_x of all \tilde{h} is called the **linear isotropy group** at the point x .

If we represent the homogeneous space M as G/H , we obtain the canonical map $\pi: s \rightarrow sH$ of G onto M , which we call the **projection** of G onto M . Let \mathfrak{g} be the \dagger Lie algebra of G , and \mathfrak{h} the Lie subalgebra corresponding to the closed subgroup H . When we identify \mathfrak{g} with the tangent space at the identity element e of G and \mathfrak{h} with its subspace, the projection π induces a linear isomorphism of $\mathfrak{g}/\mathfrak{h}$ with the tangent space V_x of M at the point $x = \pi(e)$. The \dagger adjoint representation of G gives rise to a linear representation $h \rightarrow \text{Ad}(h)$ modulo \mathfrak{h} of the group H on the linear space $\mathfrak{g}/\mathfrak{h}$. Through the linear isomorphism between $\mathfrak{g}/\mathfrak{h}$ and the tangent space V_x defined by the projection π , this representation of H is equivalent to the one which associates with h the linear transformation \tilde{h} defined by h on the tangent space V_x .

The homogeneous space G/H is said to be **reductive** if there exists a linear subspace \mathfrak{m} of \mathfrak{g} such that $\mathfrak{g} = \mathfrak{h} + \mathfrak{m}$ (direct sum as linear spaces) and $(\text{Ad } H)\mathfrak{m} \subset \mathfrak{m}$. H is said to be **reductive** in \mathfrak{g} if the representation $h \rightarrow \text{Ad}(h)$ of H in \mathfrak{g} is \dagger completely reducible.

If a \dagger tensor field P on the homogeneous space $M = G/H$ is G -invariant (namely, invariant under the transformations defined by the elements of G), then the value of P at the point $x = \pi(e)$ is a \dagger tensor over the tangent space V_x at x which is invariant under the linear isotropy group \tilde{H} . Conversely, such a tensor over V_x is uniquely extended to a G -invariant tensor field on M . If G/H is reductive, then G -invariant tensor fields over M are in one-to-one correspondence with \tilde{H} -invariant tensors over \mathfrak{m} . For instance, if H is compact, then H is reductive in \mathfrak{g} and an \tilde{H} -invariant positive definite quadratic form on \mathfrak{m} defines a G -invariant \dagger Riemannian metric on G/H .

We say that the homogeneous space $M = G/H$ is a **Riemannian (linearly connected, complex Hermitian, Kähler) homogeneous space** if there exists on M a G -invariant Riemannian metric (\dagger linear connection, \dagger Hermitian metric, \dagger Kähler metric). Concerning such homogeneous spaces, there are various results on their structures and geometric properties [1–5] (→ 412 Symmetric Riemannian Spaces and Real Forms; 427 Topology of Lie Groups and Homogeneous Spaces).

B. Examples

Stiefel Manifold. A k -frame ($1 \leq k \leq n$) in a real n -dimensional Euclidean vector space \mathbf{R}^n is an ordered system consisting of k linearly independent vectors. If we regard the real \dagger general linear group of degree n , $GL(n, \mathbf{R})$, as the regular linear transformation group of \mathbf{R}^n , $GL(n, \mathbf{R})$ acts transitively on the set $V'_{n,k}(\mathbf{R})$ of

all k -frames in \mathbf{R}^n . Therefore, if H denotes the subgroup of $GL(n, \mathbf{R})$ consisting of the elements which leave fixed a given k -frame v_0^k , we may identify the set $V'_{n,k}$ and the quotient set $GL(n, \mathbf{R})/H$. Transferring the differentiable manifold structure of $GL(n, \mathbf{R})/H$ to $V'_{n,k}$ through this identification, we see that $V'_{n,k}(\mathbf{R}) = GL(n, \mathbf{R})/H$ becomes a homogeneous space (the differentiable manifold structure of $V'_{n,k}$ is defined independently of the choice of v_0^k). The space $V'_{n,k}(\mathbf{R})$ is called the **(real) Stiefel manifold of k -frames in \mathbf{R}^n** .

A k -frame is called an **orthogonal k -frame** if the vectors belonging to the frame are of length 1 and are orthogonal to each other. The set $V_{n,k}(\mathbf{R})$ of all orthogonal k -frames is a submanifold of $V'_{n,k}(\mathbf{R})$. The t orthogonal group $O(n)$ acts transitively on $V'_{n,k}(\mathbf{R})$, which is a homogeneous space represented as $V_{n,k}(\mathbf{R}) = O(n)/I_k \times O(n-k)$. The manifold $V_{n,1}(\mathbf{R})$ is actually the $(n-1)$ -dimensional sphere. We call $V_{n,k}(\mathbf{R})$ the **(real) Stiefel manifold of orthogonal k -frames** (or simply **Stiefel manifold**). The **complex Stiefel manifold** $V_{n,k}(\mathbf{C}) = U(n)/I_k \times U(n-k)$ is defined analogously.

Grassmann Manifold. Let $M_{n,k}(\mathbf{R})$ ($1 \leq k \leq n$) be the set of all k -dimensional linear subspaces of \mathbf{R}^n . The group $O(n)$ acts transitively on $M_{n,k}(\mathbf{R})$, so that we may put $M_{n,k}(\mathbf{R}) = O(n)/O(k) \times O(n-k)$. Here $O(k)$ and $O(n-k)$ are identified with the subgroups of $O(n)$ consisting of all elements leaving fixed every point of a fixed $(n-k)$ -dimensional subspace and of its orthogonal complement, respectively. In this way, $M_{n,k}(\mathbf{R})$ is a homogeneous space, which we call the **(real) Grassmann manifold**. The t proper orthogonal group $SO(n)$ acts transitively on $M_{n,k}(\mathbf{R})$, and $M_{n,k}(\mathbf{R})$ may be represented as a homogeneous space having $SO(n)$ as its transformation group. It follows that $M_{n,k}(\mathbf{R})$ is connected. The homogeneous space $\tilde{M}_{n,k}(\mathbf{R}) = SO(n)/SO(k) \times SO(n-k)$ is called the **Grassmann manifold formed by oriented subspaces**. $M_{n,1}(\mathbf{R})$ and $\tilde{M}_{n,1}(\mathbf{R})$ may be identified with the $(n-1)$ -dimensional real projective space and the $(n-1)$ -dimensional sphere, respectively.

Applying the above process for real Grassmann manifolds to the complex Euclidean vector space \mathbf{C}^n instead of \mathbf{R}^n , we see that the set $M_{n,k}(\mathbf{C})$ of all k -dimensional linear subspaces in \mathbf{C}^n is a homogeneous space with the t unitary group $U(n)$ of degree n as its transformation group, and we represent it as $U(n)/U(k) \times U(n-k)$. This space is called the **complex Grassmann manifold**. The manifold $M_{n,k}(\mathbf{C})$ is a simply connected complex manifold and has a cellular decomposition as a t CW complex whose cells are t Schubert varieties (\rightarrow 56 Characteristic Classes E). On

the other hand, $M_{n,k}(\mathbf{C})$ may be regarded as the set of all $(k-1)$ -dimensional linear subspaces in the $(n-1)$ -dimensional complex projective space. Then, by using the t Plücker coordinates of these subspaces, $M_{n,k}(\mathbf{C})$ can be realized as an t algebraic variety without singularity in the projective space of dimension

$$\binom{n}{k} - 1 \quad (\rightarrow 90 \text{ Coordinates B}).$$
 Sometimes

$M_{n,k}(\mathbf{R})$ is denoted by $G_{n,k}(\mathbf{R})$ or $G(n, k)$. In the same way, the homogeneous space represented as $Sp(n)/Sp(k) \times Sp(n-k)$ is called the t quaternion Grassmann manifold and is denoted by $M_{n,k}(\mathbf{H})$.

Flag Manifold. Let k_1, \dots, k_r be a sequence of integers such that $n > k_1 > \dots > k_r > 0$, and let $F(k_1, \dots, k_r)$ be the set of all monotone sequences $V_1 \supset \dots \supset V_r$, where V_i ($i = 1, \dots, r$) is a k_i -dimensional linear subspace in \mathbf{R}^n . For the two sequences $V_1 \supset \dots \supset V_r$ and $V'_1 \supset \dots \supset V'_r$ belonging to $F(k_1, \dots, k_r)$, there exists an element $s \in GL(n, \mathbf{R})$ such that $s(V_i) = V'_i$ ($i = 1, \dots, r$). Therefore $F(k_1, \dots, k_r)$ is a homogeneous space with $GL(n, \mathbf{R})$ as its transformation group, and is called the **proper flag manifold**. Since the unitary group $U(n)$ of degree n acts transitively on it, $F(k_1, \dots, k_r)$ is also regarded as a homogeneous space admitting $U(n)$ as its transformation group. In this case, putting $F(k_1, \dots, k_r) = U(n)/H$, H is isomorphic to the direct product $U(k_1 - k_2) \times U(k_2 - k_3) \times \dots \times U(k_r)$. In particular, when $r = n - 1$, $k_i = n - i$, the homogeneous space is the quotient space of the compact Lie group $U(n)$ by a maximal t torus T . In general, the quotient space G/T of a compact connected Lie group G by a maximal torus of G is called a **flag manifold**. If G acts effectively on G/T , G is a t semisimple compact Lie group. The complex Lie group $G^{\mathbf{C}}$ is a Lie transformation group of t biregular transformations which acts transitively on the flag manifold G/T , a simply connected Kähler homogeneous space. Here $G^{\mathbf{C}}$ is a complex Lie group having G as a maximal compact subgroup. If B is a maximal t solvable Lie subgroup (t Borel subgroup) of $G^{\mathbf{C}}$, G/T is represented as $G^{\mathbf{C}}/B$.

200 (III.24) Homological Algebra

A. General Remarks

Homological algebra is a new branch of mathematics that developed rapidly after World War II. The introduction of the theory was motivated by the observation that some algebraic ideas and mechanisms that arose in the development of algebraic topology, in particular, homology theory, can provide powerful tools for treating from a unified viewpoint various problems in algebra that previously were treated differently. One of its characteristic features lies in emphasizing, from the standpoint of categories and functors (\rightarrow 52 Categories and Functors), the functional structure of the objects to be investigated rather than their inner structure. Thus the theory of derived functors constitutes the main theme of homological algebra. This new theory turned out to have wide applications in other areas of mathematics, and the philosophy embodied in the theory has been influential in the general progress of mathematics. For general references \rightarrow [2, 5, 6]; for sheaf cohomology \rightarrow [3, 4, 8].

B. Graded Modules and Graded Objects

Let A be a \dagger ring with unity element and X be a \dagger unitary A -module. If we are given a sequence of A -submodules X_n ($n \in \mathbb{Z}$) such that $X = \sum_{n \in \mathbb{Z}} X_n$ (\dagger direct sum), we call X a **graded A -module** and X_n the **component of degree n** of X . Each element x of a graded A -module X has a unique representation $x = \sum_{n \in \mathbb{Z}} x_n$ ($x_n \in X_n$); we call x_n the **component of degree n** of x . An A -submodule Y of a graded A -module X is called **homogeneous** if $x \in Y$ implies $x_n \in Y$ ($n \in \mathbb{Z}$). In this case, $Y = \sum_n Y_n$ and the quotient module $X/Y = \sum_n X_n/Y_n$ are graded A -modules, where $Y_n = Y \cap X_n$. Let $X = \sum_n X_n$ and $Y = \sum_n Y_n$ be graded A -modules and $f: X \rightarrow Y$ be an A -homomorphism. If there is a fixed integer p such that $f(X_n) \subset Y_{n+p}$ for any $n \in \mathbb{Z}$, f is called an **A -homomorphism of degree p** . In this case,

$\text{Ker } f = \sum_n \text{Ker } f_n$ and $\text{Im } f = \sum_n \text{Im } f_{n-p}$ are homogeneous A -submodules of X and Y , respectively, where $f_n: X_n \rightarrow Y_{n+p}$ is the restriction of f on X_n .

Sometimes, by a graded module we mean only a sequence $\{X_n\}$ of A -modules X_n , without considering the direct sum $\sum_n X_n$. Similarly, we have the notion of a **graded object** $\{C_n\}$ in any category \mathcal{C} .

C. Chain Complexes and Homology Modules

By a **chain complex** (X, ∂) over A we mean a graded A -module $X = \sum_n X_n$ together with an A -homomorphism $\partial: X \rightarrow X$ of degree -1 such that $\partial \circ \partial = 0$. Hence a chain complex over A is completely determined by a sequence

$$\dots \rightarrow X_{n+1} \xrightarrow{\partial_{n+1}} X_n \xrightarrow{\partial_n} X_{n-1} \rightarrow \dots$$

of A -modules and A -homomorphisms such that $\partial_n \circ \partial_{n+1} = 0$ for all n . We call ∂ the **boundary operator**. For a chain complex (X, ∂) , we write $\text{Ker } \partial = Z(X)$, $\text{Ker } \partial_n = Z_n(X)$, $\text{Im } \partial = B(X)$, $\text{Im } \partial_{n+1} = B_n(X)$. Then $Z(X) = \sum_n Z_n(X)$, $B(X) = \sum_n B_n(X)$ are homogeneous submodules of X , called the **module of cycles** and the **module of boundaries**, respectively. $B(X)$ is a homogeneous submodule of $Z(X)$, and the quotient modules $Z(X)/B(X)$, $Z_n(X)/B_n(X)$ are denoted by $H(X)$, $H_n(X)$, respectively. We call $H(X) = \sum_n H_n(X)$ the **homology module** of the chain complex (X, ∂) .

If (X, ∂) , (Y, ∂') are chain complexes over A , an A -homomorphism $f: X \rightarrow Y$ of degree 0 satisfying $\partial' \circ f = f \circ \partial$ (i.e., $\partial'_n f_n = f_{n-1} \partial_n$) is called a **chain mapping** of X to Y . For a chain mapping f , we have $f(Z_n(X)) \subset Z_n(Y)$, $f(B_n(X)) \subset B_n(Y)$, and hence f induces an A -homomorphism $f_*: H(X) \rightarrow H(Y)$ of degree 0, which is called the **homological mapping** induced by f . We have $(1_X)_* = 1_{H(X)}$, and $(g \circ f)_* = g_* \circ f_*$ for chain mappings $f: X \rightarrow Y$ and $g: Y \rightarrow Z$.

Let $f, g: X \rightarrow Y$ be two chain mappings. If there is an A -homomorphism $D: X \rightarrow Y$ of degree $+1$ such that $f - g = D \circ \partial + \partial' \circ D$, we say that f is **chain homotopic** to g and write $f \simeq g$; D is called a **chain homotopy** of f to g . If f is chain homotopic to g , we have $f_* = g_*: H(X) \rightarrow H(Y)$. For chain complexes X and Y , if there are chain mappings $f: X \rightarrow Y$ and $g: Y \rightarrow X$ such that $f \circ g \simeq 1_Y$ and $g \circ f \simeq 1_X$, we say that X is **chain equivalent** to Y . In this case $f_*: H(X) \rightarrow H(Y)$ is an isomorphism and $g_*: H(Y) \rightarrow H(X)$ is its inverse.

Let (X, ∂) be a chain complex over A and $Y = \sum_n Y_n$ be a homogeneous A -submodule of X such that $\partial Y \subset Y$. Then Y and X/Y are chain complexes over A with the boundary operators induced by ∂ . Y is called a **chain**

subcomplex of X , and X/Y is called the **quotient chain complex** of X by Y or the **relative chain complex** of $X \bmod Y$. For a chain complex X and its subcomplex Y we have an exact sequence $0 \rightarrow Y \xrightarrow{i} X \xrightarrow{j} X/Y \rightarrow 0$, where i is the \dagger canonical injection and j the \dagger canonical surjection.

Let (W, ∂') , (X, ∂) , (Y, ∂'') be chain complexes over A , and $f: W \rightarrow X$, $g: X \rightarrow Y$ be chain mappings such that $0 \rightarrow W \xrightarrow{f} X \xrightarrow{g} Y \rightarrow 0$ is exact. Then an A -homomorphism $\partial_*: H(Y) \rightarrow H(W)$ of degree -1 , called the **connecting homomorphism**, is defined by $\partial_*(y + B(Y)) = f^{-1} \circ \partial \circ g^{-1}(y) + B(W)$ ($y \in Z(Y)$), and we have the **exact sequence of homology**:

$$\begin{aligned} \dots \xrightarrow{\partial_*} H_n(W) \xrightarrow{f_*} H_n(X) \xrightarrow{g_*} H_n(Y) \\ \xrightarrow{\partial_*} H_{n-1}(W) \xrightarrow{f_*} H_{n-1}(X) \xrightarrow{g_*} H_{n-1}(Y) \xrightarrow{\partial_*} \dots \end{aligned}$$

For a \dagger commutative diagram

$$\begin{array}{ccccc} 0 \rightarrow W & \rightarrow & X & \rightarrow & Y \rightarrow 0 \\ & \downarrow \varphi & \downarrow & \downarrow \psi & \\ 0 \rightarrow W' & \rightarrow & X' & \rightarrow & Y' \rightarrow 0 \end{array} \quad (1)$$

consisting of chain complexes and chain mappings in which each row is exact, we have $\partial_* \circ \psi_* = \varphi_* \circ \partial_*: H(Y) \rightarrow H(W')$.

For the \dagger inductive limit $\varinjlim X_\lambda$ of chain complexes X_λ over A , we have

$$H(\varinjlim X_\lambda) = \varinjlim H(X_\lambda).$$

A chain complex X is said to be **positive** if $X_n = 0$ for all $n < 0$. If X is a positive chain complex over A and M is an A -module, then we mean by an **augmentation of X over M** an A -homomorphism $\varepsilon: X_0 \rightarrow M$ such that the composition $X_1 \xrightarrow{\partial_1} X_0 \xrightarrow{\varepsilon} M$ is trivial: $\varepsilon \circ \partial_1 = 0$. A positive chain complex X together with an augmentation ε of X over M is called an **augmented chain complex** over M . It is said to be **acyclic** if the sequence

$$\dots \rightarrow X_n \xrightarrow{\partial_n} X_{n-1} \rightarrow \dots \rightarrow X_1 \xrightarrow{\partial_1} X_0 \xrightarrow{\varepsilon} M \rightarrow 0$$

is exact, namely, if $H_n(X) = 0$ ($n \neq 0$) and ε induces an A -isomorphism $H_0(X) \cong M$. In this case X is also called a **left resolution** of M .

Moreover, if each X_n is a \dagger projective A -module, X is called a **left projective resolution**. For any A -module M , there exists a left projective resolution of M .

Let $\alpha: M \rightarrow M'$ be an A -homomorphism of A -modules, and X, X' be augmented chain complexes over M, M' having augmentations $\varepsilon, \varepsilon'$, respectively. Then a chain mapping $f: X \rightarrow X'$ satisfying $\varepsilon' \circ f_0 = \alpha \circ \varepsilon$ is called a **chain mapping over α** . If X, X' are left projective resolutions of M, M' , respectively, then there exist chain mappings of X to X' over α , and any two such mappings are chain homotopic. In particular, a left projective resolution of an A -

module M is uniquely determined up to chain homotopy.

D. Tor

Given a right A -module M and a left A -module N , \mathbf{Z} -modules $\mathbf{Tor}_n^A(M, N)$ ($n = 0, 1, 2, \dots$), called the **torsion products** (or **Tor groups**), are defined as follows: Let

$$Y: \dots \rightarrow Y_n \xrightarrow{\partial_n} Y_{n-1} \rightarrow \dots \xrightarrow{\partial_1} Y_0 \xrightarrow{\varepsilon} N \rightarrow 0$$

be a projective resolution of N , and consider the chain complex

$$\begin{aligned} (M \otimes_A Y, 1 \otimes \partial): \dots \\ \rightarrow M \otimes_A Y_n \xrightarrow{1 \otimes \partial_n} M \otimes_A Y_{n-1} \rightarrow \dots \\ \xrightarrow{1 \otimes \partial_1} M \otimes_A Y_0 \rightarrow 0 \end{aligned}$$

obtained by forming the \dagger tensor product of M and Y . Then we see that the homology module $H_n(M \otimes_A Y)$ is uniquely determined for any choice of left projective resolution of N . We define $\mathbf{Tor}_n^A(M, N) = H_n(M \otimes_A Y)$. In particular, we have $\mathbf{Tor}_0^A(M, N) \cong M \otimes_A N$.

Properties of Tor. (1) If M is a \dagger flat A -module, we have $\mathbf{Tor}_n^A(M, N) = 0$ ($n = 1, 2, \dots$).

(2) An A -homomorphism $f: M_1 \rightarrow M_2$ induces a homomorphism $f_*: \mathbf{Tor}_n^A(M_1, N) \rightarrow \mathbf{Tor}_n^A(M_2, N)$. We have $(1_M)_* = 1$, and $(g \circ f)_* = g_* \circ f_*$ for $f: M_1 \rightarrow M_2, g: M_2 \rightarrow M_3$.

(3) For an exact sequence $0 \rightarrow M_1 \xrightarrow{f} M_2 \xrightarrow{g} M_3 \rightarrow 0$, we have the following **exact sequence of Tor**:

$$\begin{aligned} \dots \xrightarrow{\partial_*} \mathbf{Tor}_n^A(M_1, N) \xrightarrow{f_*} \mathbf{Tor}_n^A(M_2, N) \\ \xrightarrow{g_*} \mathbf{Tor}_n^A(M_3, N) \xrightarrow{\partial_*} \mathbf{Tor}_{n-1}^A(M_1, N) \rightarrow \dots \\ \rightarrow \mathbf{Tor}_1^A(M_3, N) \xrightarrow{\partial_*} M_1 \otimes_A N \rightarrow M_2 \otimes_A N \\ \rightarrow M_3 \otimes_A N \rightarrow 0, \end{aligned}$$

where ∂_* are the connecting homomorphisms.

(4) For a commutative diagram

$$\begin{array}{ccccc} 0 \rightarrow M_1 & \rightarrow & M_2 & \rightarrow & M_3 \rightarrow 0 \\ & \downarrow \varphi & \downarrow & \downarrow \psi & \\ 0 \rightarrow M'_1 & \rightarrow & M'_2 & \rightarrow & M'_3 \rightarrow 0 \end{array}$$

of A -modules and A -homomorphisms with exact rows, we have $\partial_* \circ \psi_* = \varphi_* \circ \partial_*$.

$$(5) \mathbf{Tor}_n^A(\sum_\lambda M_\lambda, N) \cong \sum_\lambda \mathbf{Tor}_n^A(M_\lambda, N)$$

$$(6) \mathbf{Tor}_n^A(\varinjlim M_\lambda, N) \cong \varinjlim \mathbf{Tor}_n^A(M_\lambda, N).$$

On the other hand, take a left projective resolution X of M and consider the chain complex $X \otimes_A N$. Then we have $H_n(X \otimes_A N) \cong \mathbf{Tor}_n^A(M, N)$ for $n = 0, 1, \dots$. Therefore properties similar to (1)–(6) hold with respect to the second variable N of $\mathbf{Tor}_n^A(M, N)$.

(7) If A° is a ring \dagger anti-isomorphic to A , then $\mathbf{Tor}_n^A(M, N) \cong \mathbf{Tor}_n^{A^\circ}(N, M)$. In particular,

if A is commutative, then $\text{Tor}_n^A(M, N)$ is an A -module and we have $\text{Tor}_n^A(M, N) \cong \text{Tor}_n^A(N, M)$.

(8) Let A be a \dagger principal ideal ring. Then $\text{Tor}_n^A(M, N) = 0$ ($n = 2, 3, \dots$) and $\text{Tor}_1^A(M, N)$ is also denoted by $M * {}_AN$. For an exact sequence $0 \rightarrow M_1 \rightarrow M_2 \rightarrow M_3 \rightarrow 0$, we have the exact sequence $0 \rightarrow M_1 * {}_AN \rightarrow M_2 * {}_AN \rightarrow M_3 * {}_AN \rightarrow 0$. In particular, $\mathbf{Z} * {}_Z N = 0$ and $(\mathbf{Z}/n\mathbf{Z}) * {}_Z N \cong {}_nN$ ($= \{x \in N \mid nx = 0\}$).

Universal Coefficient Theorem for Homology. If (X, ∂) is a chain complex over A and N is a left A -module, then $(X \otimes {}_AN, \partial \otimes 1)$ is a chain complex. If A is a principal ideal ring and each X_n is a \dagger torsion-free A -module, then we have a formula

$$H_n(X \otimes {}_AN) \\ \cong H_n(X) \otimes {}_AN + H_{n-1}(X) * {}_AN,$$

called the **universal coefficient theorem**.

E. Double Chain Complexes

By a **double chain complex** $(X_{p,q}, \partial', \partial'')$ over A we mean a family of left A -modules $X_{p,q}$ ($p, q \in \mathbf{Z}$) together with A -homomorphisms $\partial'_{p,q}: X_{p,q} \rightarrow X_{p-1,q}$ and $\partial''_{p,q}: X_{p,q} \rightarrow X_{p,q-1}$ such that $\partial'_{p-1,q} \circ \partial'_{p,q} = \partial''_{p,q-1} \circ \partial'_{p,q} = \partial'_{p,q-1} \circ \partial''_{p,q} + \partial''_{p-1,q} \circ \partial'_{p,q} = 0$. We define the associated chain complex (X_n, ∂) by setting $X_n = \sum_{p+q=n} X_{p,q}$, $\partial_n = \sum_{p+q=n} \partial'_{p,q} + \partial''_{p,q}$. We call ∂ the **total boundary operator**, and ∂', ∂'' the **partial boundary operators**.

Given a chain complex X consisting of right A -modules and a chain complex Y consisting of left A -modules, a double chain complex $(Z_{p,q}, \partial', \partial'')$ is defined by setting $Z_{p,q} = X_p \otimes {}_AY_q$, $\partial'_{p,q} = \partial_p \otimes 1$, $\partial''_{p,q} = (-1)^p 1 \otimes \partial_q$, where ∂_p, ∂_q are the boundary operators of X, Y , respectively. It is called the **product double chain complex** of X and Y , and the homology module of its associated chain complex is denoted by $H(X \otimes {}_AY)$. With respect to this homology module, the following facts hold. If X is a left projective resolution of a right A -module M and Y is that of a left A -module N , then $H_n(X \otimes {}_AY) = \text{Tor}_n^A(M, N)$. If A is a principal ideal ring and each X_n is a torsion-free A -module, then we have the formula

$$H_n(X \otimes {}_AY) \cong \sum_{p+q=n} H_p(X) \otimes {}_AH_q(Y) \\ + \sum_{p+q=n-1} H_p(X) * {}_AH_q(Y),$$

the **Künneth theorem**.

F. Cochain Complexes

By a **cochain complex** (X, d) over A we mean a graded A -module X together with an A -

homomorphism $d: X \rightarrow X$ of degree $+1$ such that $d \circ d = 0$; d is called the **coboundary operator** or **differential**. For a cochain complex (X, d) , we denote by X^n the component of degree n of X , and by $d^n, X^n \rightarrow X^{n+1}$ the restriction of d on X^n . Then a chain complex (Y, ∂) is defined by $Y_n = X^{-n}$ and $\partial_n: Y_n \rightarrow Y_{n-1}$ is equal to $d^{-n}: X^{-n} \rightarrow X^{-n+1}$.

For a cochain complex (X, d) , we write $\text{Ker } d^n = Z^n(X)$, $\text{Ker } d = Z(X)$ ($Z(X) = \sum Z^n(X)$), $\text{Im } d^{n-1} = B^n(X)$, $\text{Im } d = B(X)$ ($B(X) = \sum B^n(X)$), and $Z^n(X)/B^n(X) = H^n(X)$, $Z(X)/B(X) = H(X)$ ($H(X) = \sum H^n(X)$). These modules $Z(X)$ ($Z^n(X)$), $B(X)$ ($B^n(X)$), and $H(X)$ ($H^n(X)$) are called the **module of cocycles**, the **module of coboundaries**, and the **cohomology module** of X , respectively. If we consider the associated chain complex (Y, ∂) of (X, d) , then $H_{-n}(Y)$ corresponds to $H^n(X)$. In this way, results on chain complexes give results on cochain complexes. Thus the concepts of **cochain mapping**, **cochain homotopy**, **cochain equivalence**, **cochain subcomplex**, and **relative cochain complex** can be defined as in the case of chain complexes in B , and we have corresponding results. In particular, given an exact sequence $0 \rightarrow W \xrightarrow{f} X \xrightarrow{g} Y \rightarrow 0$ of cochain complexes and cochain mappings, the **connecting homomorphism** $d_*: H^n(Y) \rightarrow H^{n+1}(W)$ is defined, and the **exact sequence of cohomology**

$$\dots \xrightarrow{d_*} H^n(W) \xrightarrow{f_*} H^n(X) \xrightarrow{g_*} H^n(Y) \\ \xrightarrow{d_*} H^{n+1}(W) \xrightarrow{f_*} H^{n+1}(X) \xrightarrow{g_*} H^{n+1}(Y) \xrightarrow{d_*} \dots$$

exists. For a commutative diagram

$$0 \rightarrow W \rightarrow X \rightarrow Y \rightarrow 0 \\ \downarrow \varphi \quad \downarrow \quad \downarrow \psi \\ 0 \rightarrow W' \rightarrow X' \rightarrow Y' \rightarrow 0$$

of cochain complexes and cochain mappings with exact rows, we have $d_* \circ \psi_* = \varphi_* \circ d_*$.

A cochain complex X is said to be **positive** if $X^n = 0$ for $n < 0$. If X is a positive cochain complex over A and M is an A -module, we mean by an **augmentation** of X over M an A -homomorphism $\varepsilon: M \rightarrow X^0$ such that the composition $M \xrightarrow{\varepsilon} X^0 \xrightarrow{d^0} X^1$ is trivial. If the sequence $0 \rightarrow M \xrightarrow{\varepsilon} X^0 \xrightarrow{d^0} \dots \rightarrow X^n \xrightarrow{d^n} X^{n+1} \rightarrow \dots$

is exact, X is called a **right resolution** of M . Moreover, if each X^n is an \dagger injective A -module, X is called a **right injective resolution** of M . For any A -module M , there exists a right injective resolution of M , and any two such resolutions are cochain homotopic.

G. Ext

Given left A -modules M and N , \mathbf{Z} -modules $\text{Ext}_A^n(M, N)$ ($n = 0, 1, 2, \dots$), called the **Ext**

groups, are defined as follows: Let $X: \dots \rightarrow X_n \rightarrow X_{n-1} \rightarrow \dots \rightarrow X_0 \rightarrow M \rightarrow 0$ be a projective resolution of M , and consider the cochain complex $\text{Hom}_A(X, N)$:

$$0 \rightarrow \text{Hom}_A(X_0, N) \rightarrow \dots \rightarrow \text{Hom}_A(X_{n-1}, N) \rightarrow \dots \rightarrow \text{Hom}_A(X_n, N) \rightarrow \dots$$

obtained by forming the \dagger module of A -homomorphisms. Then we can show that the cohomology module $H^n(\text{Hom}_A(X, N))$ is uniquely determined for any choice of projective resolution of M . We define $\text{Ext}_A^n(M, N) = H^n(\text{Hom}_A(X, N))$. This can also be defined as the cohomology module $H^n(\text{Hom}_A(M, Y))$ of the cochain complex $\text{Hom}_A(M, Y): 0 \rightarrow \text{Hom}_A(M, Y^0) \rightarrow \dots \rightarrow \text{Hom}_A(M, Y^{n-1}) \rightarrow \text{Hom}_A(M, Y^n) \rightarrow \dots$, where $Y: 0 \rightarrow N \rightarrow Y^0 \rightarrow \dots \rightarrow Y^{n-1} \rightarrow Y^n \rightarrow \dots$ is a right injective resolution of N . Furthermore, for a left projective resolution X of M and a right injective resolution Y of N , we see that $\text{Ext}_A^n(M, N)$ is isomorphic to the cohomology module $H^n(\text{Hom}_A(X, Y))$ of the associated cochain complex of the double cochain complex $\text{Hom}_A(X, Y) = (\text{Hom}_A(X_p, Y^q), d', d'')$, where $d'_{p,q}: \text{Hom}_A(X_p, Y^q) \rightarrow \text{Hom}_A(X_{p+1}, Y^q)$ and $d''_{p,q}: \text{Hom}_A(X_p, Y^q) \rightarrow \text{Hom}_A(X_p, Y^{q+1})$ are given by $d'_{p,q}(u) = u \circ \partial_{p+1}$, $d''_{p,q}(u) = (-1)^{p+q+1} d^q \circ u$ ($u \in \text{Hom}_A(X_p, Y^q)$) by using the boundary operator ∂ of X and the co-boundary operator d of Y .

Properties of Ext. (1) We have $\text{Ext}_A^0(M, N) \cong \text{Hom}_A(M, N)$.

(2) If M is a projective A -module or N is an injective A -module, then $\text{Ext}_A^n(M, N) = 0$ ($n = 1, 2, \dots$).

(3) An A -homomorphism $f: M_1 \rightarrow M_2$ (resp. $f: N_1 \rightarrow N_2$) induces a homomorphism $f_*: \text{Ext}_A^n(M_2, N) \rightarrow \text{Ext}_A^n(M_1, N)$ (resp. $f_*: \text{Ext}_A^n(M, N_1) \rightarrow \text{Ext}_A^n(M, N_2)$). We have $1_M^* = 1$ and $(g \circ f)^* = f^* \circ g^*$ for $f: M_1 \rightarrow M_2$, $g: M_2 \rightarrow M_3$ (resp. $1_N^* = 1$ and $(g \circ f)_* = g_* \circ f_*$ for $f: N_1 \rightarrow N_2$, $g: N_2 \rightarrow N_3$).

(4) For an exact sequence $0 \rightarrow M_1 \rightarrow M_2 \rightarrow M_3 \rightarrow 0$ (resp. $0 \rightarrow N_1 \rightarrow N_2 \rightarrow N_3 \rightarrow 0$), we have the **exact sequence of Ext**:

$$\begin{aligned} 0 \rightarrow \text{Hom}_A(M_3, N) \rightarrow \text{Hom}_A(M_2, N) \\ \rightarrow \text{Hom}_A(M_1, N) \rightarrow \text{Ext}_A^1(M_3, N) \\ \rightarrow \text{Ext}_A^1(M_2, N) \rightarrow \dots \\ (\text{resp. } 0 \rightarrow \text{Hom}_A(M, N_1) \rightarrow \text{Hom}(M, N_2) \\ \rightarrow \text{Hom}(M, N_3) \rightarrow \text{Ext}_A^1(M, N_1) \\ \rightarrow \text{Ext}_A^1(M, N_2) \rightarrow \dots) \end{aligned}$$

(5)

$$\text{Ext}_A^n\left(\sum_{\alpha} M_{\alpha}, \prod_{\beta} N_{\beta}\right) = \prod_{\alpha, \beta} \text{Ext}_A^n(M_{\alpha}, N_{\beta}).$$

(6) If A is a principal ideal ring, then $\text{Ext}_A^n(M, N) = 0$ ($n = 2, 3, \dots$), and $\text{Ext}_A^1(M, N)$ is also denoted by $\text{Ext}_A(M, N)$. In particular, $\text{Ext}_{\mathbb{Z}}(\mathbb{Z}, N) = 0$, $\text{Ext}_{\mathbb{Z}}(\mathbb{Z}/n\mathbb{Z}, N) \cong N/nN$, $\text{Ext}_{\mathbb{Z}}(M, \mathbb{Q}/\mathbb{Z}) = 0$, $\text{Ext}_{\mathbb{Z}}(M, \mathbb{Z}/n\mathbb{Z}) = \hat{M}/n\hat{M}$, where $\hat{M} = \text{Hom}_{\mathbb{Z}}(M, \mathbb{Q}/\mathbb{Z})$.

Universal Coefficient Theorem for Cohomology

If X is a chain complex over a principal ideal ring A such that each X_n is a free A -module, then for any A -module N we have the formula

$$\begin{aligned} H^n(\text{Hom}_A(X, N)) \\ \cong \text{Hom}_A(H_n(X), N) + \text{Ext}_A(H_{n-1}(X), N), \end{aligned}$$

the **universal coefficient theorem**. This is generalized as follows: Let X be a chain complex and Y a cochain complex, both over a principal ideal ring A . Assume that each X_n is a free A -module or that each Y^n is an injective A -module. Then we have the formula

$$\begin{aligned} H^n(\text{Hom}_A(X, Y)) \\ \cong \sum_{p+q=n} \text{Hom}_A(H_p(X), H^q(Y)) \\ + \sum_{p+q=n-1} \text{Ext}_A(H_p(X), H^q(Y)) \end{aligned}$$

(\rightarrow 201 Homology Theory).

H. Complexes in Abelian Categories

We mainly consider general \dagger Abelian categories \mathcal{C} . Consideration may, however, be restricted to the \dagger category (Ab) of Abelian groups (whose \dagger objects are Abelian groups and whose \dagger morphisms are homomorphisms) or the \dagger category ${}_R\mathcal{M}$ of R -modules.

A **(cochain) complex** C in an Abelian category \mathcal{C} is a graded object $\{C^n\}$ in \mathcal{C} with **differentials** $d^n: C^n \rightarrow C^{n+1}$ subject to the condition that $d^{n+1} \circ d^n = 0$ ($n \in \mathbb{Z}$). The n th **cohomology** $H^n(C)$ of C is defined by the \dagger exact sequence $0 \rightarrow B^n(C) \rightarrow Z^n(C) \rightarrow H^n(C) \rightarrow 0$, where $B^n(C)$ and $Z^n(C)$ are objects representing $\text{Im } d^{n-1}$ and $\text{Ker } d^n$, respectively. The complex C is called **positive (negative)** if $C^n = 0$ for $n < 0$ ($n > 0$). We sometimes interchange positive superscripts and negative subscripts and write C_{-n} instead of C^n . Then the differentials become $d_n: C_n \rightarrow C_{n-1}$, and C is then called a **chain complex**. The quotient of $\text{Ker } d_n = Z_n$ by $\text{Im } d_{n+1} = B_n$ is called the n th **homology** $H_n(C)$. Negative complexes are usually described in this manner. When C^n , Z^n , B^n , and H^n are sets, as in the category ${}_R\mathcal{M}$ of R -modules, their elements are called **cochains**, **cocycles**, **coboundaries**, and **cohomology classes**, respectively. Similarly, in the group C_n of **chains**, residue classes of **cycles** ($\in Z_n$) modulo **boundaries** ($\in B_n$) are called **homology classes** ($\in H_n$).

A **morphism** (or **chain transformation**) $f: C \rightarrow C'$ is a \dagger natural transformation of the complexes considered as \dagger functors $\mathbf{Z} \rightarrow \mathcal{C}$; i.e., f is a family of morphisms $f^n: C^n \rightarrow C'^n$ ($n \in \mathbf{Z}$) satisfying $f^{n+1} \circ d^n = d'^n \circ f^n$. It induces a morphism of cohomology $H^n(C) \rightarrow H^n(C')$. A **subcomplex** of C is an equivalence class of \dagger monomorphisms $D \rightarrow C$, usually denoted by any representative D of the class. A **(chain) homotopy** between two chain transformations $f, g: C \rightarrow C'$ is a family of morphisms $h^n: C^n \rightarrow C'^{n-1}$ ($n \in \mathbf{Z}$) satisfying $f^n - g^n = h^{n+1} \circ d^n + d'^{n-1} \circ h^n$. If there exists a homotopy between f and g , then f and g induce the same morphism of cohomology. A morphism $f: C \rightarrow C'$ is called a **(chain) equivalence** if there exists a morphism $f': C' \rightarrow C$ such that $f' \circ f$ and $f \circ f'$ are homotopic to the identities of C and C' , respectively. In this case we have $H^n(C) \cong H^n(C')$. An exact sequence of complexes $0 \rightarrow C' \rightarrow C \rightarrow C'' \rightarrow 0$ gives rise to the **connecting morphisms** $H^n(C'') \rightarrow H^{n+1}(C')$ ($n \in \mathbf{Z}$), and the resulting sequence $\dots \rightarrow H^{n-1}(C'') \rightarrow H^n(C') \rightarrow H^n(C) \rightarrow H^n(C'') \rightarrow H^{n+1}(C') \rightarrow \dots$ is exact (the **exact cohomology sequence**), and similarly for homology instead of cohomology. An object $A \in \mathcal{C}$ defines a complex (also denoted by A) such that $A^0 = A$, $d^0 = 0$. A positive complex C together with a morphism $\varepsilon: A \rightarrow C$ is called a **complex over A** , and ε is the **augmentation**. A complex C over A is **acyclic** if $0 \rightarrow A \xrightarrow{\varepsilon} C^0 \rightarrow C^1 \rightarrow \dots$ is exact. An acyclic positive complex over A is called a **right resolution** of A . Let $\{C, \varepsilon\}, \{C', \varepsilon'\}$ be complexes over A and A' , respectively, and α a morphism $A \rightarrow A'$. Then a morphism $f: C \rightarrow C'$ satisfying $f \circ \varepsilon = \varepsilon' \circ \alpha$ is called a morphism over α . For a negative complex C , we define similarly augmentations $\varepsilon: C \rightarrow A$, acyclicity, left resolutions, etc.
